PREFACE

The INTERNATIONAL DICTIONARY OF APPLIED MATHEMATICS defines the terms and describes the methods in the applications of mathematics to thirty-one fields of physical science and engineering. These definitions and descriptions have been chosen to comprise those terms in general use and those methods which have proved most fruitful in practical calculations and analysis. Moreover, they are discussed in sufficient detail to permit the adaptation of methods from related fields. For example, electric circuits are treated not only from the standpoint of stability and topology, but also from that of dynamical analogies, because of the usefulness of this method in solving problems in acoustics and mechanics that are related to those in electric networks.

Furthermore, to broaden the usefulness of this book, the important terms which are used here in defining or describing a concept or method of applied mathematics are also defined in these pages, even though they belong in the fields of pure mathematics, science or engineering. Thus the definitions and methods of differential geometry, vector analysis, tensor analysis, mathematical statistics and other general mathematical fields are covered at considerable length. Moreover, since the primary objective of this book is to enable the reader to obtain the necessary mathematical results by the best available methods, the subject of numerical analysis is treated in some detail, and in certain cases where no analytical method is available, empirical relationships are cited.

To render available the fund of information which this book contains, a most comprehensive system of referencing has been developed. The key words occurring in a definition which are defined elsewhere in the book are printed

in boldface type. These references make available the necessary related information whether from applied mathematics, pure mathematics, science or engineering.

An important feature of this book is the group of four foreign language indices which list alphabetically the French, German, Russian and Spanish equivalents of the terms defined in this book, accompanied by their English equivalents. Thus the reader seeking a definition of a term in one of those languages need merely to find it with its English equivalent in the index for that language and then look up the English equivalent in the main part of this Dictionary. In cases where a foreign language has two or more equivalents of an English term, first consideration has been given to those which are essentially different from the corresponding English expression.

The editorial policy followed in the organization of this book has been directed to facilitate speedy and convenient reference. To that end, the methods and relationships which bear proper names such, for example, as those of Abel, Dyson, Euler, Maxwell, etc., have been stated as far as possible in uninflected form (e.g., without the use of the possessive). Furthermore, the entries beginning with adjectives have been listed generally under the shortest form of the adjective (that is, acoustic rather than acoustical, electric rather than electrical, etc.).

Necessarily, those questions of organization and arrangement have involved many compromises. All those who have worked on this book will welcome the views of the readers on the effectiveness of the arrangement, as well as the selection of entries or any other respect in which the plan and scope of this Dictionary can be improved.

A

ABAMPERE. The cgs electromagnetic unit of current. It is that current which, when flowing in straight parallel wires 1 cm apart in free space, will produce a force of 2 dynes per cm length on each wire. One abampere is ten absolute amperes. (See **electromagnetic units**.)

ABBE-MAXWELL THEOREM. An axially symmetrical optical system is perfect if and only if it is plane-perfect for two different object planes perpendicular to the axis.

ABBE NUMBER. In correcting an optical system for first order chromatic aberration the Abbe number or reciprocal mean dispersion of a medium $\nu = (n_D - 1)/(n_F - n_C)$ is used as a discrete substitute for $dn/d\lambda$. The indices of refraction n_D, n_F, n_C are for light of the wavelength of the mean of two yellow sodium lines, D (5892.9Å), the blue hydrogen line, F (4861.327Å), and the mean of two red hydrogen lines, C (6562.8Å), respectively. For ordinary crown glass ν is approximately 60.

ABBE SINE CONDITION. An identity involving the second partial derivatives of the characteristic function of an optical system leads to an important relation that must be satisfied if a surface element containing a point source is to be imaged accurately into a corresponding surface element at the image point. This is Abbe's sine condition

$$ny \sin \theta = -n'y' \sin \theta'$$

where n, n' are indices of refraction, y, y' are distances from the optical axis, and θ, θ' are the angles light rays make with the optical axis in object, image space, respectively. If a system is corrected for spherical aberration and has an infinite exit pupil, then fulfillment of the sine condition is equivalent to freedom from coma.

The Abbe sine condition is equivalent to the extended sine relationship

$$ny \sin \theta + n'y' \sin \theta' = yy'\phi,$$

where ϕ is the power of the system, when the approximation $yy'\phi \cong 0$ is valid.

ABCOULOMB. The electromagnetic unit (emu) of charge. One abcoulomb is the amount of charge that passes when a steady current of one abampere flows for one second.

ABEL EQUATION. A mass point moves along a smooth curve in a vertical plane and under the influence of gravity alone. Given the time, t , required for the particle to fall from a point, x , to the lowest point on the curve as a function of x , what is the equation of the curve? The problem leads to a **Volterra integral equation** of the first kind

$$f(x) = \int_0^x \frac{\phi(t)dt}{\sqrt{2g(x-t)}},$$

which is a particular case of an Abel equation, where g is the acceleration of gravity.

A more general case of the Abel equation is

$$f(x) = \int_0^x (x-y)^{-\alpha} \phi(y)dy$$

where $f(x)$ is continuously differentiable for $x \geq 0$ and $0 < \alpha < 1$.

A first-order **differential equation**

$$y' = f_0(x) + f_1(x)y + f_2(x)y^2 + f_3(x)y^3$$

is also known as an Abel equation. When the $f_i(x)$ are given explicitly, the equation can often be converted into one of simpler type and solved in terms of elementary functions. In the general case the solution involves **elliptic functions**.

ABELIAN GROUP. A commutative group, namely such that $AB = BA$ where A, B are any two elements contained in it. A simple example is the **cyclic group** of order n .

ABEL IDENTITY. The sum of n terms of a sequence a_1, a_2, a_3, \dots , where $a_1 = b_1c_1, a_2 = b_2c_2$, etc., can obviously be written in the form

$$a_1 + a_2 + \dots + a_n = b_1s_1 + b_2(s_2 - s_1) + \dots + b_n(s_n - s_{n-1})$$

where $s_i = c_1 + c_2 + \dots + c_i$. Then this sum can be at once rearranged as

$$a_1 + a_2 + \cdots + a_n = s_1(b_1 - b_2) + s_2(b_2 - b_3) + \cdots + s_{n-1}(b_{n-1} - b_n) + s_n b_n,$$

which is the Abel identity. (Cf. **Abel inequality**.)

ABEL INEQUALITY. Let k_1, k_2, \cdots be a non-increasing sequence of positive numbers. Denote by A the greatest of the sums $|a_1|, |a_1 + a_2|, |a_1 + a_2 + a_3|, \cdots$, then the Abel inequality, which is easily deduced from the **Abel identity**, states that

$$|a_1 k_1 + a_2 k_2 + \cdots + a_n k_n| \leq A k_1.$$

This inequality is useful for proving certain tests of convergence.

ABEL TEST FOR CONVERGENCE. If $a_1 + a_2 + \cdots$ is convergent and u_1, u_2, \cdots is a bounded monotonic sequence, then $a_1 u_1 + a_2 u_2 + \cdots$ converges.

ABEL THEOREM ON POWER SERIES. If $a_0 + a_1 z + a_2 z^2 + \cdots$ is a power series with unity for its radius of convergence and with convergent sum of coefficients $a_0 + a_1 + a_2 + \cdots$, then the Abel theorem states that $\lim_{z \rightarrow 1} (a_0 + a_1 z + a_2 z^2 + \cdots)$ is equal to the sum $a_0 + a_1 + a_2 + \cdots$; that is, the power series is continuous up to and including the end point.

ABERRATIONAL CONSTANT. The aberrational constant is given by

$$k = \frac{2\pi a \operatorname{cosec} 1''}{cT\sqrt{1-e^2}}$$

in which a is the semi-major axis of the earth's orbit, c is the velocity of light, T is the sidereal year expressed in mean solar seconds, and e is the eccentricity of the earth's orbit. The value of the aberrational constant is about $20''.47$.

ABERRATION OF LIGHT, ASTRONOMICAL (CORRECTIONS FOR). The apparent change in the direction of a celestial object due to the component of the earth's motion perpendicular to the line of sight and the finite speed of light is known as the *aberrational correction*.

Calling θ the true direction and θ' the displaced direction (displacement due to aberration) there results

$$\sin(\theta - \theta') = \frac{v}{c} \sin \theta'$$

in which v is the velocity of the earth and c is the speed of light. Since v/c is a very small quantity one can write the above equation as

$$\theta - \theta' = \frac{v}{c} \sin \theta' \operatorname{cosec} 1'' \text{ which may be further simplified to } \theta - \theta' = k \sin \theta' \text{ in which } k = \frac{v}{c}$$

$\operatorname{cosec} 1''$ and k is known in astronomy as the **aberrational constant**. Since k does not exceed $20''.5$, then $\theta - \theta' = k \sin \theta$.

Since the aberrational displacements are in the plane of the ecliptic the aberrational corrections to celestial latitude B and celestial longitude λ are given by

$$\Delta\lambda = -k \sec B \cos(\lambda_0 - \lambda)$$

$$\Delta B = -k \sin B \sin(\lambda_0 - \lambda)$$

in which λ_0 is the longitude of the sun.

The aberrational corrections to the equatorial coordinates of right ascension and declination are much more complicated since the plane of the equator is inclined to the plane of the ecliptic in which the aberrational displacement takes place. Let

$$C = -k \cos \epsilon \cos \lambda_0$$

$$c = \frac{1}{15} \cos \alpha \sec \delta$$

$$d = \frac{1}{15} \sin \alpha \sec \delta$$

$$D = -k \sin \lambda_0$$

$$c' = \tan \epsilon \cos \delta - \sin \alpha \sin \delta$$

$$d' = \cos \alpha \sin \delta$$

in which ϵ is the obliquity of the ecliptic, α and δ are the true right ascension and declination, α' and δ' are the displaced right ascension and declination.

The values of $\log C$ and $\log D$ vary throughout the year due to the position of the sun. They are tabulated as the Besselian star numbers in almanacs for each day of the year.

Finally there results

$$\alpha' = \alpha + Cc + Dd$$

$$\delta' = \delta + Cc' + Dd'$$

ABERRATIONS OF AN OPTICAL SYSTEM. Let a point (x, y) in the object plane of an optical system be imaged by the point (x', y') in the image plane. In the approximation of Gaussian optics,

$$x' = mx, \quad y' = my$$

where m is the magnification. The aberrations of the system are the deviations,

$$x = x' - mx, \quad y = y' - my;$$

which are decomposed in several ways into constituent aberration functions (see **Seidel aberrations** and **Nijboer-Zernike aberration functions**) and various methods have been developed for the calculation of the constituent aberrations (see the **Schwarzschild-Kohlschütter formulas**).

ABERRATIONS OF LENSES, SEIDEL THEORY OF. See **Seidel aberrations**.

ABSCISSA. The horizontal coordinate of a point in a two-dimensional system, commonly rectangular Cartesian, and usually designated by x . Together with the **ordinate** it locates the position of the point in a plane.

ABSOLUTE ACCELERATION. The time rate of change of **velocity** with respect to axes fixed in space or to an **inertial frame** is a vector called absolute acceleration.

ABSOLUTE ACTIVITY. A quantity defined by the equation

$$\lambda = \exp\left(\frac{\mu}{kT}\right)$$

where k is the Boltzmann constant, T , the absolute temperature and μ , the **thermal potential**. In systems undergoing chemical reactions, this formula takes the following form:

$$\lambda_i = \exp\left(\frac{\mu_i}{kT}\right),$$

where λ_i is the absolute activity of component i , and μ_i is the chemical potential of component i .

ABSOLUTE ANGULAR MOMENTUM. The angular momentum as measured in an **absolute coordinate system**, hence the vector product of the position vector of a particle by the **absolute momentum** of the particle.

In the atmosphere the absolute angular momentum M per unit mass of air is equal to the sum of the angular momentum relative to the earth and the angular momentum due to the rotation of the earth:

$$M = ua \cos \phi + \Omega a^2 \cos^2 \phi,$$

where a is the radius of the earth, u the relative eastward speed, ϕ the latitude, and Ω the

angular speed of the earth. (See **angular momentum balance**, **conservation of angular momentum**.)

ABSOLUTE CONTINUITY. Let the function $f(x)$ be defined on the closed interval $[a,b]$ and let l denote the total length of a finite or countable number of nonoverlapping intervals (a_i, b_i) in $[a,b]$. If the limit, as l approaches zero, of the sum $\sum |f(b_i) - f(a_i)|$ is zero, then $f(x)$ is said to be absolutely continuous. An absolutely continuous function is *a fortiori* continuous.

ABSOLUTE CONVERGENCE. See **convergence**.

ABSOLUTE COORDINATE SYSTEM. (Or absolute reference frame.) In meteorology, that **inertial coordinate system** which has its origin on the axis of the earth and is fixed with respect to the stars. Thus, any mechanical quantities in meteorology defined with respect to this frame take into account the movement of the earth. (See **Coriolis force**, **absolute vorticity**.)

ABSOLUTE DERIVATIVE OF TENSOR. See **intrinsic derivative of tensor field**.

ABSOLUTE DIFFERENTIAL CALCULUS. Theory of the differentiation of **tensor fields**. Also called *tensor calculus*, *Ricci calculus*.

ABSOLUTE DISPLACEMENT. The change in **position** measured with respect to coordinate axes fixed in space or to an **inertial frame** is a vector called the absolute displacement.

ABSOLUTE HUMIDITY. (1) (Also called vapor concentration, vapor density.) In a system of moist air, the ratio of the mass of **water vapor** present to the volume occupied by the mixture; that is, the density of the water vapor component.

Absolute humidity is usually expressed in grams of water vapor per cubic meter or, in engineering practice, in grains per cubic foot. (Cf. **mixing ratio**, **specific humidity**, **relative humidity**, **dew point**.)

(2) As occasionally used in air conditioning practice, the number of grains of water vapor per pound of moist air, which is dimensionally identical with the **specific humidity**.

ABSOLUTE INVARIANT. See **invariant**.

ABSOLUTE ISOHYPSE. A line that has the properties of both constant pressure and con-

stant height above mean sea level. Therefore, it can be any **contour line** on a constant-pressure chart, or any **isobar** on a constant-height chart.

ABSOLUTE MAGNITUDE (STELLAR). The apparent stellar magnitude of a celestial object depends both upon the intrinsic brightness of the object and also upon the distance of the object from the earth. The absolute magnitude, either visual or photographic, is the brightness, expressed on the stellar magnitude scale, that it would have if the object were at a distance of 10 parsecs (stellar parallax $0''.1$). If we call M the absolute magnitude, m_g the apparent magnitude and ϕ'' the parallax in seconds of the object

$$M = m_g + 5 + 5 \log \phi''.$$

The sun has an apparent magnitude of -26.72 and a parallax of $206265''$. The absolute magnitude of the sun is 4.85 . Antares has an apparent magnitude of 1.22 and a parallax of $0''.009$. The absolute magnitude of Antares is found to be -4.0 . Hence it follows that actually Antares is nearly 4000 times as bright as the sun.

ABSOLUTE MOMENTUM. (Often called absolute linear momentum.) The (linear) **momentum** of a particle as measured in an **absolute coordinate system**; hence in meteorology, the sum of the (vector) momentum of the particle relative to the earth and the (vector) momentum of the particle due to the earth's rotation.

ABSOLUTE REACTION RATE THEORY. A reformulation of the **collision theory of chemical kinetics** due to Wigner, Eyring and others makes possible the expression of the rate constant in a more general form. Similar considerations may be applied to a great many of other rate processes (see **Eyring theory of transport processes**). Because the purpose of this theory is to calculate the rate in terms of molecular quantities alone, it is often called the absolute reaction rate theory.

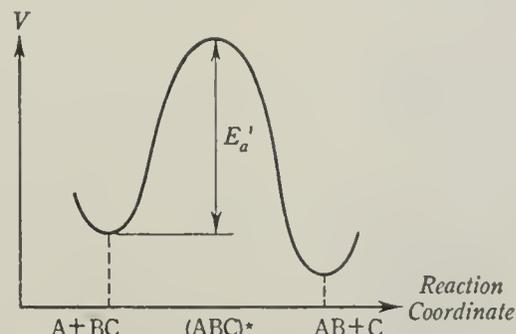

Consider the reaction

To simplify the discussion, assume that A, B and C always remain in a straight line. The course of the reaction may then be followed by noting the values of the two interatomic distances r_{AB} and r_{BC} . At the beginning of the

reaction r_{AB} is large and r_{BC} is small while at the end of the reaction r_{AB} is small and r_{BC} is large.

Let us introduce the potential energy surface. The representative point of the system moves on this surface along the so-called *reaction coordinate*. The potential energy along the reaction coordinate is represented schematically in the figure. The maximum of the

Potential energy along the *reaction coordinate*.

curve corresponds to a situation where three atoms are very close to one another. Moreover this point is a *maximum* along the reaction coordinate but a *minimum* for the direction normal to the reaction coordinate. Indeed the most probable path is the path involving the minimum potential energy in going from the initial to the final state.

Therefore the point considered corresponds to a *saddle point* of the energy surface. It is called the **activated complex**.

One may now assume that the reaction rate is the product of the following three factors: (1) the average number of activated complexes; (2) the characteristic frequency of the activated complex (that is, the inverse of its lifetime); (3) the *transmission coefficient*, K , which is the probability that a chemical reaction takes place after the system has reached the activated state.

Moreover the number of activated complexes is calculated by the equilibrium assumption. (See **equilibrium theory of chemical reactions**.)

Using this description of the reaction process one derives the following expression for the reaction constant

$$k = K \frac{\phi_r(T)}{\phi_A(T)\phi_{BC}(T)} \frac{kT}{h} \exp\left(-\frac{E^x}{kT}\right). \quad (2)$$

Here the ϕ terms are the **partition functions** $f(T, V)$, the volume factor being removed

$$f = V\phi. \quad (3)$$

ϕ_r corresponds to the activated complex, the degree of freedom associated with the reaction coordinate being removed; k is **Boltzmann's constant**, h is **Planck's constant**, E^x is the energy associated with the activated complex, or **activation energy** of the reaction.

This expression may also be written in the thermodynamic form

$$\begin{aligned} k &= K \frac{kT}{h} \exp\left(-\frac{\Delta G^\ddagger}{kT}\right) \\ &= K \frac{kT}{h} \exp[-(\Delta H^\ddagger - T\Delta S^\ddagger)/kT] \quad (4) \end{aligned}$$

where ΔG^\ddagger is a suitable **free energy** of activation and ΔH^\ddagger , ΔS^\ddagger the corresponding **enthalpy** and **entropy** of activation.

ABSOLUTE SCALAR. See **scalar, absolute**.

ABSOLUTE TEMPERATURE. See **temperature**.

ABSOLUTE TENSOR (TENSOR FIELD). Tensor (tensor field) of weight zero. Often called tensor (tensor field) when context admits no confusion.

ABSOLUTE VALUE. See **complex number**.

ABSOLUTE VELOCITY. The time rate of change of **position** measured with respect to **absolute coordinate system** (i.e., a system with coordinate axes fixed in space or to an **inertial frame**) is a vector called the absolute velocity. For example, (1) in a turbine, the average flow velocity measured with respect to the turbine casing. (See **velocity diagram**.) (2) In meteorology, the (vector) sum of the velocity of a fluid parcel relative to the earth and the velocity of the parcel due to the earth's rotation. The east-west component is the only one affected:

$$u_a = u + \Omega a \cos \phi;$$

where u and u_a are the relative and absolute eastward speeds, Ω the angular speed of the earth's rotation, a the radius of the earth, and ϕ the latitude of the parcel.

ABSOLUTE VISCOSITY. (Also called dynamic viscosity.) The property of a fluid which determines the shearing stresses which arise in it during motion. In pure shear flow, the shearing stress τ is proportional to the transverse velocity gradient du/dy ,

$$\tau = \mu \frac{du}{dy} \text{ (Newton's law of fluid friction)}$$

where μ is the absolute viscosity. In a general field of flow, u_1, u_2, u_3 , of a homogeneous, Newtonian, incompressible fluid, the shearing stresses are proportional to the respective rates of change of strain (Stokes' law). The symmetric stress tensor t_{ij} is assumed to be a linear function of the rate of strain tensor e_{ij} . Taking into account that in a fluid at rest the stress is an isotropic tensor, we put

$$t_{ij} = -p\delta_{ij} + \lambda\delta_{ij}e_{kk} + 2\mu e_{ij}$$

where δ_{ij} is the Kronecker delta. Since $t_{ij} = 0$ for $e_{ij} = 0$, we have $t_{ii} = -3p$ and $3\lambda + 2\mu = 0$. Consequently

$$t_{ij} = -p\delta_{ij} - \frac{2}{3}\mu\delta_{ij}e_{kk} + 2\mu e_{ij}$$

when p is now the hydrostatic pressure. The scalar μ is defined as the absolute viscosity. It is a function of the thermodynamic state of the fluid and is independent of the velocity field.

The ratio

$$\nu = \frac{\mu}{\rho}$$

of absolute viscosity to density is called *kinematic viscosity*.

ABSOLUTE VORTICITY. (1) The **vorticity** of a fluid particle determined with respect to an **absolute coordinate system**.

(2) The vertical component η of the absolute vorticity (as defined above) given by the sum of the vertical component of the vorticity with respect to the earth (the **relative vorticity**) ζ and the vorticity of the earth (equal to the **Coriolis parameter**) f :

$$\eta = \zeta + f.$$

ABSOLUTE ZERO. See **temperature**.

ABSOLUTE ZERO UNATTAINABILITY. See **thermodynamics, third law of**.

ABSORBANCE. The common logarithm of the **absorptance**. It may be applied to the total radiation, the visible radiation or to a particular part of the spectrum (spectral absorbance).

ABSORPTANCE. The ratio of the luminous flux absorbed by the body to the flux it receives. (See **spectral absorptance**; **internal**

absorptance; absorptivity; extinction coefficient.)

ABSORPTION. (1) The process whereby the total number of particles emerging from a body of matter is reduced relative to the number entering, as a result of interaction of the particles with the body. (2) The process whereby the kinetic energy of a particle is reduced while traversing a body of matter. This loss of kinetic energy of corpuscular radiation is also referred to as moderation, slowing, or stopping. (3) The process whereby some or all of the energy of sound waves or electromagnetic radiations is transferred to the substance on which they are incident or which they traverse. (4) The process of "attraction into the mass" of one substance by another so that the absorbed substance disappears physically.

ABSORPTION COEFFICIENT. (1) In the most general use of the term absorption coefficient, applied to electromagnetic radiation and atomic and sub-atomic particles, it is a measure of the rate of decrease in intensity of a beam of photons or particles in its passage through a particular substance. (See **absorption coefficient for light**.) (2) In the case of sound, the absorption coefficient (which is also called the acoustical absorptivity) is defined as the fraction of the incident sound energy absorbed by a surface or medium, the surface being considered part of an infinite area. (See also **acoustic attenuation coefficient**.) (3) For the absorption of one substance or phase in another, as in the absorption of a gas in a liquid, the absorption coefficient is the volume of gas dissolved by a specified volume of solvent; thus a widely-used coefficient is the quantity α in the expression $\alpha = V_0/Vp$, where V_0 is the volume of gas reduced to standard conditions, V is the volume of liquid and p is the partial pressure of the gas.

ABSORPTION COEFFICIENT, AMPLITUDE. See **acoustic attenuation coefficient**.

ABSORPTION COEFFICIENT FOR LIGHT. The absorption coefficient κ_ν measures the loss in intensity suffered by a beam of light of intensity I_ν when passing through an absorbing layer of thickness ds . κ_ν depends on the physical properties of the absorbing substance, on the frequency ν , and, some-

times, on the direction of flow of radiation. The decrease in intensity is therefore

$$dI_\nu/ds = -\kappa_\nu I_\nu. \quad (1)$$

It is sometimes useful to introduce the *mass absorption coefficient*

$$\kappa_{\nu,M} = \kappa_\nu/\rho \quad (2)$$

or the *atomic absorption coefficient*

$$\kappa_{\nu,at} = \kappa_\nu/n, \quad (3)$$

where ρ stands for the density of the absorbing substance and n for the number of absorbing atoms per cubic centimeter. The loss of intensity is then

$$dI_\nu/ds = -\kappa_{\nu,M}\rho I_\nu \quad (4)$$

or

$$dI_\nu/ds = -\kappa_{\nu,at}nI_\nu. \quad (5)$$

Another usage in optics is to express the absorption coefficient in terms of the wavelength rather than the frequency (as above). In this notation the absorption coefficient is written simply as $\alpha_\lambda = -dI/I$. Then by integration (see **absorption coefficient, integrated**) one arrives at the common form of **Bouguer's law of absorption**, $I = I_0 \exp(-\alpha x)$. In traversing perpendicularly a thin layer of absorbing material of thickness x , the amplitude of vibration of light is damped by the factor $\exp(-2\pi m x/\lambda)$ where m is the *absorption index* or *absorption constant*. In consequence the intensity is damped by $\exp(-4\pi m x/\lambda)$ and so the absorption coefficient is $\alpha = 4m/\lambda$ in terms of the absorption index. (For solutions, see **Beer's law**.)

ABSORPTION COEFFICIENT, INTEGRATED. The total intensity of an absorption feature (line or unresolved band) is given by

$$I_{abs} = \int (I_\nu^0 - I_\nu) d\nu = I_\nu^0 \Delta s \int \kappa_\nu d\nu.$$

Here I_ν^0 and I_ν stand for the initial and final intensities, κ_ν for the **absorption coefficient** at frequency ν , and Δs for the thickness of the absorbing layer. The integral

$$\int \kappa_\nu d\nu$$

of the absorption coefficient κ_ν over the frequency range is called the **integrated absorption coefficient**.

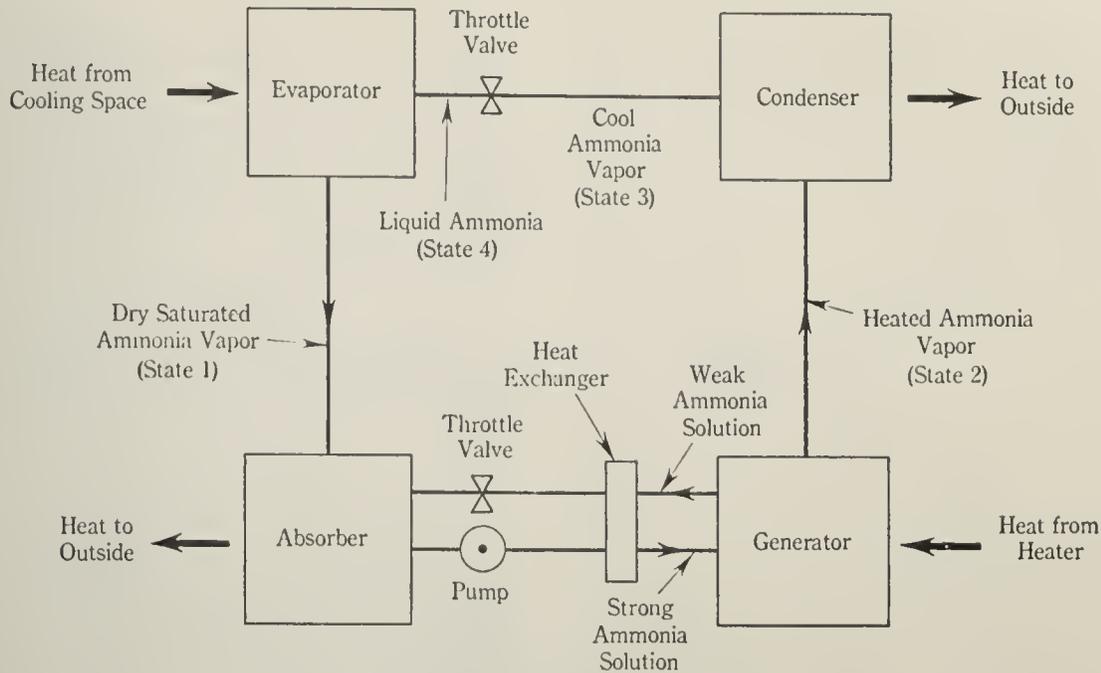

Fig. 1. Block diagram of absorption refrigerator.

ABSORPTION CONSTANT. A synonym for the optical absorption index. (See **absorption coefficient for light; index of refraction, complex.**)

ABSORPTION DISCONTINUITY. The discontinuities of the **absorption coefficient** κ_ν (in terms of frequency) or α_λ (using the wavelength notation), of a medium, correspond to spectral absorption lines and are often associated with anomalies in other frequency (wavelength) dependent properties of the medium, e.g., the refractive index.

ABSORPTION, EXPONENTIAL. The intensity of a beam of light of frequency ν passing through a homogeneous absorbing substance, decreases exponentially according to

$$I = I_0 e^{-\kappa_\nu s}$$

where I_0 and I are the initial and final intensity respectively, κ_ν the **absorption coefficient** for frequency ν , and s the thickness of the absorbing layer (see also **optical depth**).

Note that in wavelength notation, the coefficient κ_ν becomes $\alpha(\lambda)$, α_λ or simply α .

ABSORPTION FACTOR. Ratio of absorbed to unabsorbed radiation. (See also **optical depth**.)

ABSORPTION OF RADIANT ENERGY. The transformation of radiant energy to a different form of energy by the intervention of matter.

ABSORPTION REFRIGERATOR. A refrigerator in which the work of compression is considerably reduced by dissolving the refrigerant in a suitable liquid before compression. Thus the compression of a liquid is substituted for that of a gas. To compensate for it, it is necessary to introduce a source of heat at a temperature higher than that of the surroundings (i.e., of the cooling water available). (See Figures 1, 2 and 3.)

The mixture of gaseous and liquid ammonia is evaporated in the *evaporator* until it becomes dry saturated (state 1). After evaporation, the dry saturated vapor is passed into an *absorber* where it is absorbed in water, rejecting heat Q_s to the surroundings. The temperature of the water is only a little above atmospheric and the solubility of ammonia in water

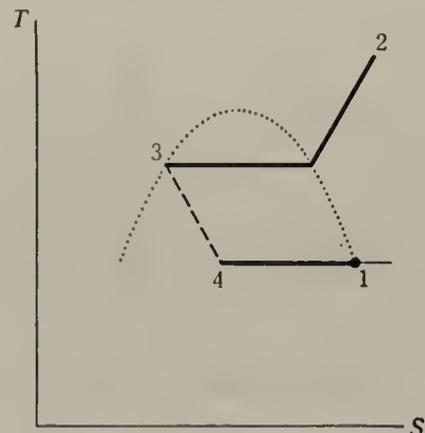

Fig. 2. Temperature-entropy diagram of absorption refrigerator.

is very high. The liquid solution is compressed in a pump, the process requiring a very small amount of work only ($W \simeq 0$). The liquid solution is then heated in the *generator*

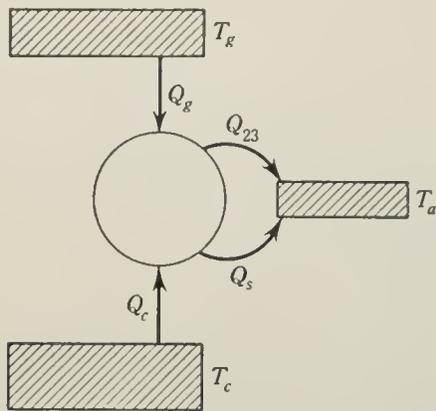

Fig. 3. Heat flow diagram of absorption refrigerator.

at a temperature T_g . This causes the ammonia to be driven off from the solution at the expense of heat Q_g absorbed. At this temperature the solubility of ammonia in water is considerably reduced. In order to maintain steady-state operation a weak solution is throttled back to the absorber, and the weak and strong solutions are made to exchange heat in a counter-flow heat exchanger (heat regeneration) for the sake of economy. Gaseous, usually superheated, ammonia at state 2 is used to complete a conventional refrigeration cycle: (a) cooling at constant pressure from state 2 to state 3 in the *condenser*, with the

possibility of undercooling below T_3 ; (b) throttling in a throttle valve to state 4, etc.

Energy is transferred at three levels: T_g in the generator, T_c in the evaporator (cold chamber), and T_a in the absorber and condenser. We have $T_g > T_a > T_c$. By the first law of thermodynamics

$$Q_g + Q_c = Q_{23} + Q_s.$$

In the ideal case there is no entropy increase due to the operation of the refrigerator and hence

$$\frac{Q}{T_g} - \frac{Q_c}{T_c} + \frac{Q_{23} + Q_s}{T_a} \geq 0.$$

The performance of the refrigerator can be judged by the ratio Q_c/Q_g of the refrigerating effect, Q_c , to the quantity of heat, Q_g , added at the highest temperature. It is seen that

$$\frac{Q_c}{Q_g} \leq \frac{T_c(T_g - T_a)}{T_g(T_c - T_a)}.$$

The so-called *Electrolux refrigerator* constitutes a special form of the absorption refrigerator in which the pump has been replaced by a syphon, and the throttling valve has been eliminated. Instead of throttling through a valve, ammonia is mixed with inert hydrogen so that its partial pressure is decreased, giving the same effect as throttling. Owing to its great simplicity, it is widely used in domestic refrigerators. (See Figure 4.)

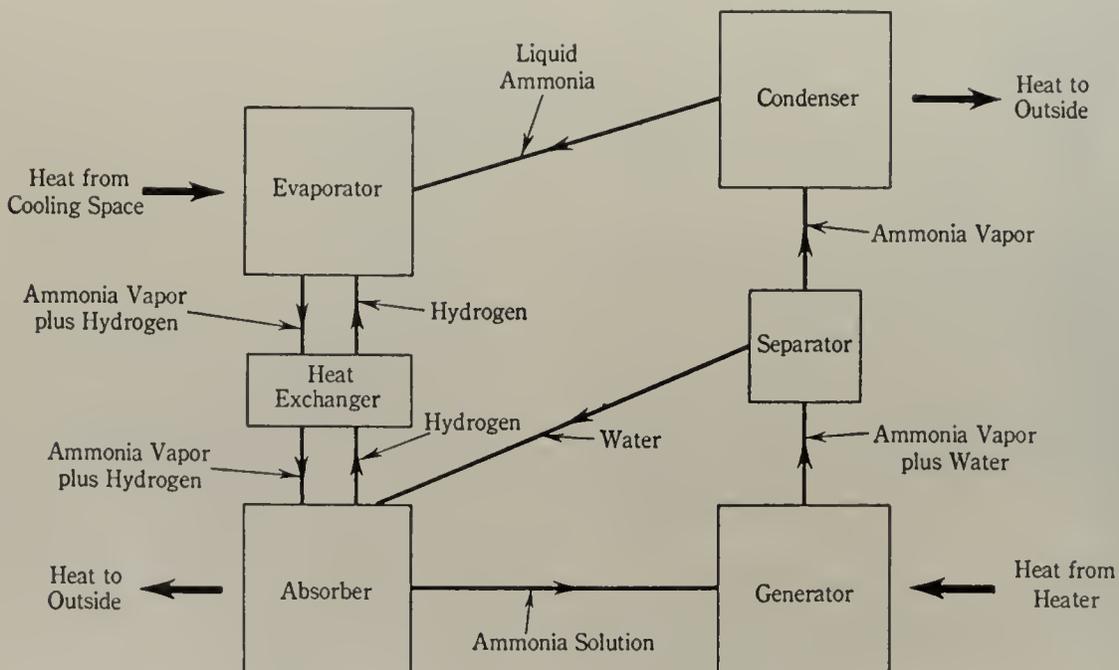

Fig. 4. Block diagram of Electrolux refrigerator.

The concentrated solution of ammonia in water is boiled in the *generator* and the syphon action through the connector tube makes it rise to the *separator*. The gaseous ammonia flows to the *condenser*, whereas the liquid water, while cooling, returns to the *absorber* through a liquid trap. The gaseous ammonia is cooled in the *condenser* shaped like a finned heat exchanger, and eventually condenses. The liquid ammonia flows through a trap to the *evaporator* filled with hydrogen so that its partial pressure decreases to that corresponding to the low temperature prevailing. In the process, the evaporator absorbs heat Q from the cooling space at that reduced temperature. The mixture of hydrogen and ammonia flows down through a heat exchanger to the absorber where the ammonia vapor enters into solution freeing the hydrogen in the process. The hydrogen rises to the evaporator, while the solution of ammonia in water flows to the generator to complete the cycle.

ABSORPTIVE POWER. That part of the radiation of a given wavelength which is absorbed by a body. When radiation falls on a surface, a portion A_λ of it is absorbed, a portion R_λ is reflected and a portion Z_λ is transmitted, so that

$$A_\lambda + R_\lambda + Z_\lambda = 1,$$

where A_λ is the absorptive power or absorptivity, R_λ is the reflecting power or reflectivity, Z_λ is the transmitting power or transmissivity at wavelength λ . Sometimes the adjective "monochromatic" is added to the above terms to emphasize that they relate to a definite wavelength.

ABSORPTIVITY. See *absorptive power*.

ABVOLT. See *electromagnetic units*.

ACCELERATING CONVERGENCE OF SERIES AND SEQUENCES. See *summation of series*.

ACCELERATION. The rate of change of the velocity with respect to the time is called acceleration. It is expressed mathematically by $\frac{d\mathbf{v}}{dt}$, the vector derivative of the velocity, \mathbf{v} with respect to the time, t . If the motion is in a straight line whose position is clearly understood, it is convenient to treat the velocity v and the acceleration $\frac{dv}{dt}$ as scalars with appro-

priate algebraic signs; otherwise they must be treated by vector methods.

Acceleration may be rectilinear or curvilinear, depending upon whether the path of motion is a straight line or a curved line. A body which moves along a curved path has acceleration components at every point. One component is in the direction of the tangent to the curve and is equal to the rate of change of the speed at the point. For uniform circular motion this component is zero. The second component is normal to the tangent and is equal to the square of the tangential speed divided by the radius of curvature at the point. This normal component which is directed toward the center of curvature also equals the square of the angular velocity multiplied by the radius of curvature. The acceleration due to gravity is equal to an increase in the velocity of about 32.2 ft per sec per sec at the earth's surface and is of prime importance since it is the ratio of the weight to the mass of a body. (For examples of acceleration in both curved and linear motion, see *kinematics*.)

ACCELERATION, ANGULAR. See *angular acceleration*.

ACCELERATION, CENTRIPETAL. See *centripetal acceleration*.

ACCELERATION, COMPATIBLE. Another name for *Coriolis acceleration*.

ACCELERATION, COMPLEMENTARY. Another name for *Coriolis acceleration*.

ACCELERATION, COMPOSITION LAW OF (RELATIVITY). Let a'_x, a'_y, a'_z be the components of the acceleration in Σ' and w'_x, w'_y, w'_z the velocity components in Σ' and a_x, a_y, a_z the components of the acceleration in Σ (v the velocity of Σ' with respect to Σ in the common x -direction) then

$$a_x = \left[\frac{c\sqrt{c^2 - v^2}}{c^2 + vw'_x} \right]^3 \cdot a'_x$$

$$a_y = \left[\frac{c\sqrt{c^2 - v^2}}{c^2 + vw'_x} \right]^2 \cdot \left[a'_y - \frac{vw'_y a'_x}{c^2 + vw'_x} \right]$$

$$a_z = \left[\frac{c\sqrt{c^2 - v^2}}{c^2 + vw'_x} \right]^2 \cdot \left[a'_z - \frac{vw'_z a'_x}{c^2 + vw'_x} \right].$$

ACCELERATION, CORIOLIS. See *Coriolis acceleration*.

ACCELERATION, NORMAL. See **centripetal acceleration**.

ACCELERATION OF GRAVITY. (1) The ratio of the weight of a material particle to its mass at any specific point in an approximately uniform gravitational field. This is the **acceleration** with which a body would fall in the absence of all other disturbing forces, such as those due to friction.

(2) Specifically, the acceleration with which a body falls *in vacuo* at a given point on or near a given point on the earth's surface. This acceleration, frequently denoted by g , varies by less than one percent over the entire surface of the earth. Its "average value" has been defined by the International Commission of Weights and Measures as 9.80665 M/S² or 32.174 ft/S². Its value at the poles is 9.8321 M/S² and at the equator 9.7799 M/S².

ACCELERATION POTENTIAL. The scalar function (if it exists) whose **gradient** is equal to the total acceleration of a fluid. In meteorology, this must include the **Coriolis acceleration**:

$$\frac{d\mathbf{V}}{dt} + 2\boldsymbol{\Omega} \times \mathbf{V} = -\nabla\chi$$

where \mathbf{V} is the velocity, $\boldsymbol{\Omega}$ the angular velocity of the earth, and χ the acceleration potential.

So defined, this potential exists if and only if the atmosphere is **barotropic**, in which case $\chi = \pi + gz$, where π is the **barotropic pressure function**, g , the acceleration of gravity, and z , the vertical coordinate.

However, if some thermodynamic variable σ be taken as vertical coordinate, the horizontal acceleration will have a potential

$$\frac{\partial \mathbf{V}_H}{\partial t} + \mathbf{V}_H \cdot \nabla_\sigma \mathbf{V}_H + 2\boldsymbol{\Omega} \times \mathbf{V}_H = -\nabla_\sigma \chi,$$

where \mathbf{V}_H is the horizontal velocity and ∇_σ the horizontal del operator in the σ -surface. In the case of pressure as vertical coordinate, $\sigma = p$, and $\chi = gz$. In the case of potential temperature θ as vertical coordinate, $\sigma = \theta$ and $\chi = c_p T + gz$, where c_p is the specific heat of air at constant pressure and T the absolute temperature. Note that the acceleration potential acts as the **stream function** in the case of **geostrophic equilibrium**. (See **velocity potential**; **potential**.)

ACCELERATION, TANGENTIAL. The component of acceleration along the path of motion is called the tangential acceleration. Its magnitude is dv/dt , the time rate of change of the **speed** along the path.

ACCELERATOR, PARTICLE. A device designed to give to charged particles, such as electrons or positive ions, the high energies necessary to penetrate the **Coulomb barrier** of the target nucleus.

ACCEPTOR BOND. See **donor bond**.

ACCESS TIME. (1) The time interval, characteristic of a memory or storage device, between the instant at which **information** is requested of the **memory** and the instant at which this information begins to be available in useful form. (2) The time interval between the instant at which information is available for storage and the instant at which it is effectively stored.

ACCOMMODATION COEFFICIENT. Let E_i be the average kinetic energy of the gaseous molecules which collide with a wall whose temperature corresponds to an equilibrium kinetic energy E_1 per molecule. If E_i and E_1 differ, the average kinetic energy of the reflected molecules will in general have a value E_r intermediate between E_i and E_1 . Knudsen has defined an *accommodation coefficient* α , which expresses how much of the maximum possible kinetic energy exchange does actually occur:

$$\alpha = \frac{E_i - E_r}{E_i - E_1}.$$

Similar accommodation coefficients can be introduced for the internal degrees of freedom, or even for chemical reactions.

ACCOMPANYING FLUID. The fluid in irrotational motion which travels with a moving vortex system. It surrounds the **substance of the vortex** and is itself surrounded by fluid in irrotational motion which does not travel with it but which passes by it as if it were a solid body. Hill's **spherical vortex** has no accompanying fluid.

ACCUMULATION POINT. One of a set such that any neighborhood of this point, no matter how small, contains a member of the set. All the points of a set which is everywhere dense are accumulation points.

ACCURACY. The degree of exactness actually possessed by an approximation, measurement, etc. It may be contrasted with precision, which is the degree of exactness with which the quantity is expressed. For example, as a value of π , the number 3.1428 is more precise than accurate.

ACHROMATIC. In the accepted colorimetric sense: (1) for primary light sources, the color of the **equi-energy spectrum** ($x = y = z = \frac{1}{3}$) is taken as achromatic; (2) for surface colors the light source serving as illuminant is taken as achromatic. On this basis, an ideal white surface is always defined as achromatic whatever may be the color of the light.

In optical design: (3) an optical system is achromatic if it is approximately corrected for chromatic aberration in the sense that the focal length is the same for two distinct wavelengths.

ACHROMATIC LIGHT, SPECIFIED. (1) Light of the same chromaticity as that having an **equi-energy spectrum**. (2) The colorimetric standard illuminants *A*, *B* and *C*, the spectral energy distributions of which were specified by the C.I.E. in 1931, with various scientific applications in view:

Standard A. Incandescent electric lamp of color temperature 2854°K.

Standard B. Standard A combined with a specified liquid filter, to give a light of color temperature approximately 4800°K.

Standard C. Standard A combined with a specified liquid filter to give a light of color temperature approximately 6500°K.

(3) Any other specified white light.

ACIDS AND BASES. DEFINITIONS OF BRØNSTED AND LEWIS. The two most common definitions of acids and bases are those of Brønsted and Lewis.

According to Brønsted, an acid is a proton donor; a base, a proton acceptor. For example NH_3 and H_2O are acids in the reactions:

They act as bases in the reactions:

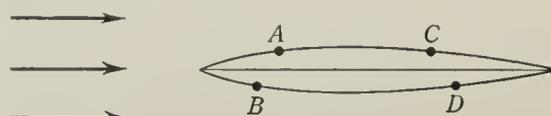

In a more general definition, Lewis calls a base any substance with a free doublet of electrons which it is capable of sharing with

an electron pair acceptor, which is called an acid. For example, in the reaction:

the ethyl ether molecule is a base, the boron trifluoride an acid. The resulting complex is a *Lewis salt*.

ACKERET THEORY. A theory of two-dimensional airfoils in supersonic flow. Since the theory is based on the linearized equation, it is valid only when the perturbation velocities are small, and for Mach numbers that are not either near 1 or large enough to make the hypersonic similarity parameter M_τ of order 1. The limitation to small perturbation velocities means that the theory can only be applied to thin airfoils, with sharp leading and trailing edges, at small angles of incidence.

Ackeret theory.

The theory gives the pressure coefficient at any point on an airfoil, where the surface is inclined at an angle θ to the stream, as

$$C_p = \frac{2\theta}{\sqrt{M^2 - 1}}, \quad (1)$$

where M is the Mach number of the stream. In Equation (1), the angle θ is considered to be positive if its sign corresponds to deflection of the stream at a concave corner. Thus, in the figure, θ and C_p are positive for the points *A* and *B*, and negative for *C* and *D*.

By integration of Equation (1) over the surface of an airfoil, a number of simple results relating to lift, drag and pitching moment may be obtained. Thus for a thin airfoil of any shape, at an incidence α ,

$$C_L = \frac{4\alpha}{\sqrt{M^2 - 1}}, \quad (2)$$

and for a symmetrical airfoil the center of pressure is at the half-chord point.

Drag coefficients calculated from Equation (1) do not include any boundary-layer effects and are, in fact, coefficients of wave drag. For a thin flat plate the wave drag coefficient is

$$C_D = \alpha C_L = \frac{4\alpha^2}{\sqrt{M^2 - 1}}. \quad (3)$$

Equation (3) expresses the simple condition that, in inviscid flow, the resultant force on a thin flat plate acts in a direction normal to the plate.

The total wave drag coefficient of an airfoil with thickness is the sum of two terms, the first given by Equation (3) and the second associated with the thickness of the airfoil. For a series of airfoils related by an **affine transformation**, the drag coefficient due to thickness at a given Mach number is proportional to the square of the thickness/chord ratio.

ACOUSTIC ABSORPTION COEFFICIENT. See **sound absorption coefficient of surfaces**.

ACOUSTIC ABSORPTIVITY. See **sound absorption coefficient of surfaces**.

ACOUSTIC AMPLITUDE EQUATIONS, FINITE. See **finite amplitude equations (acoustic)**.

ACOUSTIC ATTENUATION COEFFICIENT. When a plane harmonic sound wave is propagated through an attenuating medium, it is generally found that the amplitude of the wave decays exponentially with distance. The absolute value of the natural logarithm of the ratio of the peak sound pressures (or the peak particle velocities) at two points, unit distance apart, is called the acoustic attenuation coefficient or, more strictly, the acoustic amplitude attenuation coefficient. In the absence of scattering, this quantity can be related to other measures of internal friction (see **friction, internal**). The acoustic attenuation coefficient is generally measured in nepers per cm.

ACOUSTIC ATTENUATION CONSTANT. See **acoustic attenuation coefficient**.

ACOUSTIC CAPACITANCE. See **compliance, acoustic**.

ACOUSTIC CENTER, EFFECTIVE. The point from which spherically divergent sound waves, emitted by an acoustic generator, appear to diverge.

ACOUSTIC COMPLIANCE. See **compliance, acoustic**.

ACOUSTIC DAMPING. See **damping, acoustic**.

ACOUSTIC ENERGY EQUATION. See **Franklin equation**.

ACOUSTIC IMPEDANCE. See **impedance, acoustic**.

ACOUSTIC INERTANCE. See **inertance, acoustic**.

ACOUSTIC MASS. See **mass, acoustic**.

ACOUSTIC MEAN FREE PATH. See **mean free path, acoustic**.

ACOUSTIC OHM. See **acoustic units**.

ACOUSTIC PHASE CONSTANT. The acoustic phase constant is the imaginary part of the **acoustic propagation constant**. The commonly used unit is the radian per section or per unit distance. In the case of a symmetrical structure, the imaginary parts of both the transfer constant and the acoustic propagation constant are identical, and have been called the "wavelength constant."

ACOUSTIC POWER GENERATED. See **radiation, acoustic**.

ACOUSTIC PRINCIPLE OF SIMILARITY. For any acoustical system involving **diffraction** phenomena, it is possible to construct a new system on a different scale which will perform in similar fashion, provided that the wavelength of the sound is altered in the same ratio as the linear dimensions of the original system.

ACOUSTIC PROPAGATION CONSTANT. Of a uniform system or of a section of a system of recurrent structures, the natural logarithm of the complex ratio of the steady-state particle velocities (see **velocity, particle**), **volume velocities**, or pressures at two points separated by unit distance in the uniform system (assumed to be of infinite length), or at two successive corresponding points in the system of recurrent structures (assumed to be of infinite length). The ratio is determined by dividing the value at the point nearer the transmitting end by the corresponding value at the more remote point.

ACOUSTIC RADIATION. See **radiation, acoustic**.

ACOUSTIC REACTANCE. See **reactance, acoustic**.

ACOUSTIC RECIPROCITY THEOREM. See **reciprocity theorem, acoustical**.

ACOUSTIC REDUCTION FACTOR. The ratio of the sound energy density in a room containing a sound source to the sound energy in an adjoining receiving room:

$$R.F. = T.L. + 10 \log_{10} \frac{A}{S} \quad (1)$$

where $R.F.$ is the acoustic reduction factor, in decibels, A is the total absorption in the receiving room, in sabins, S is the area of the partition, in square feet and $T.L.$ is the transmission loss, in decibels.

Equation (1) shows that the reduction is due to both the loss introduced by the partition and the absorption in the receiving room.

The choice of a partition for insulating a room against sound involves a number of considerations. Some of the factors are the frequency distribution and intensity level of the components of the objectionable sound, the transmission frequency characteristics of the partition, the ambient noise or sound level in the receiving room which will mask the objectionable sound, and the response frequency characteristic of the ear.

ACOUSTIC RESISTANCE. See **resistance, acoustic.**

ACOUSTIC SYSTEM OF ONE DEGREE OF FREEDOM. An acoustic system of one degree of freedom is shown in Figure 1. In one degree of freedom the activity in every

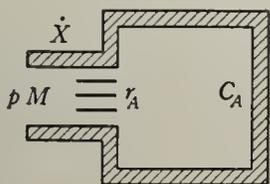

Fig. 1. Acoustic system of one degree of freedom.

element of the system may be expressed in terms of one variable. In the acoustic system an impinging sound wave of pressure p acts upon an inertance M and an acoustical resistance r_A comprising the air in the tubular opening which is connected to the volume or acoustical capacitance C_A . The acoustical resistance r_A is due to viscosity.

The principle of the conservation of energy states that the total store of energy of all forms remains constant if the system is isolated so that it neither receives nor gives out energy; in the case of transfer of energy the total gain or loss from the system is equal to the loss or

gain outside the system. The sum of the kinetic, potential, and heat energy during an interval of time is, by the principle of conservation of energy, equal to the energy delivered to the system during that interval. In the acoustical system of Figure 1 there are three forms of energy, namely, kinetic, potential, and heat energy.

Kinetic Energy. The kinetic energy T_{KA} stored in the inertance of the acoustical system is

$$T_{KA} = \frac{1}{2} M \dot{X}^2 \quad (1)$$

where M is m/S^2 , the inertance, in grams per (centimeter)⁴, m is the mass of air in the opening, in grams, S is the cross-sectional area of the opening, in square centimeters, $\dot{X} = S\dot{x}$ is the volume current, in cubic centimeters per second, \dot{x} is the velocity of the air particles in the opening, in centimeters per second.

It is assumed that all the air particles in the opening move with the same phase.

Potential Energy. The potential energy V_{PA} stored in the acoustical capacitance of the acoustical system is

$$V_{PA} = \frac{1}{2} \frac{X^2}{C_A} \quad (2)$$

where X is the volume displacement, in cubic centimeters, $C_A = V/\rho c^2$ is the acoustical capacitance, in (centimeters)⁵ per dyne, V is the volume of the cavity, in cubic centimeters, ρ is the density of air, in grams per cubic centimeter, and c is the velocity of sound, in centimeters per second.

Kinetic and Potential Energy. The total energy stored in the system is

$$W_A = T_{KA} + V_{PA} = \frac{1}{2} M \dot{X}^2 + \frac{1}{2} \frac{X^2}{C_A} \quad (3)$$

The rate of change of energy in the system is

$$\frac{dW_A}{dt} = M \dot{X} \ddot{X} + \frac{X \dot{X}}{C_A} \quad (4)$$

Dissipation of Energy. The acoustical energy is converted into heat by the dissipation due to viscosity as the fluid is forced through the narrow slits. The rate at which acoustical energy D_A is converted into heat is

$$D_A = r_A \dot{X}^2 \quad (5)$$

where r_A is the acoustical resistance, in acoustical ohms, and \dot{X} is the volume current in cubic centimeters per second.

Equation of Motion. The power delivered to the system must be equal to the rate of kinetic energy storage plus the rate of potential energy storage plus the power loss due to dissipation.

The rate at which work is done or power delivered to the acoustical system by the applied sound pressure is $\dot{X}Pe^{j\omega t} = p\dot{X}$.

The rate of increase of energy ($T_{KA} + V_{PA}$) of the system plus the rate at which work is done on the system or power delivered to the system by the external forces must be equal to the rate of dissipation of energy D_A . Writing this sentence mathematically yields the equation of motion for the acoustical system of Figure 1.

$$M\dot{X}\ddot{X} + r_A\dot{X}^2 + \frac{X\dot{X}}{C_A} = Pe^{j\omega t}\dot{X} \quad (6)$$

$$M\ddot{X} + r_A\dot{X} + \frac{X}{C_A} = Pe^{j\omega t}. \quad (7)$$

Solution of Equation of Motion. The steady-state solution of the differential Equation 7 is

$$\dot{X} = \frac{Pe^{j\omega t}}{r_A + j\omega M - \frac{j}{\omega C_A}} = \frac{p}{z_A}. \quad (8)$$

Acoustical Impedance. From Equation 8 the vector acoustical impedance z_A , in acoustical ohms, is

$$z_A = r_A + j\omega M - \frac{j}{\omega C_A}. \quad (9)$$

Acoustical Reactance. Acoustical reactance x_A is the imaginary part of the acoustical impedance z_A of Equation 10. The acoustical reactance x_A , in acoustical ohms, is

$$x_A = \omega M - \frac{1}{\omega C_A}. \quad (10)$$

Response. The response of the acoustical system of Figure 1 can be obtained from Equation 8. The response is the volume current \dot{X} , in cubic centimeters per second, for a constant

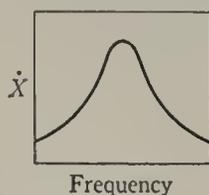

Fig. 2. Response-frequency characteristic of the acoustic system of Figure 1.

applied pressure p , in dynes per square centimeter. A typical response-frequency characteristic is shown in Figure 2.

Resonant Frequency. For a certain value of M and C_A there will be a certain frequency at which the imaginary component of the acoustical impedance is zero. This frequency is called the resonant frequency. At this frequency the ratio of the current to the applied voltage is a maximum. At the resonant frequency the current and voltage are in phase. The resonant frequency f_r , in cycles per second, is given by

$$f_r = \frac{1}{2\pi\sqrt{MC_A}}. \quad (11)$$

Power. The power P_A , in ergs per second, dissipated in the acoustical system of Figure 1 is given by

$$P_A = r_A\dot{X}^2. \quad (12)$$

ACOUSTIC UNITS. In acoustics, the centimeter-gram-second (cgs) system of units has been and is at present predominantly used; but some practical units such as English and metric system units of length are also being used; and the watt is commonly being employed for designating acoustic power. In recent years there has been a trend toward adoption of the rationalized meter-kilogram-second system of units in many fields of science and engineering. Therefore the MKS units are included in the table on page 15.

ACOUSTIC VELOCITY (SOUND VELOCITY). The velocity relative to the medium at rest at which infinitesimal disturbances are propagated through a fluid. It is given by

$$a^2 = (\partial p / \partial \rho)_s,$$

where s is entropy, in general. For **perfect gases** the expression is simplified to

$$a^2 = \gamma p / \rho = \gamma R T,$$

where γ need not be a constant and can depend on temperature. (For a perfect gas γ can be a function of temperature alone.)

The velocity of sound plays an important part in the study of the flow of compressible fluids because the character of the flow changes its nature according to whether the flow velocity is subsonic, sonic, or supersonic. (See **compressible fluid flow; nozzles; Mach number.**)

ACOUSTIC UNITS (COMPARISON OF CGS AND MKS UNITS)

Quantity	Dimensions	Cgs unit	MKS unit	Conversion Factor (Cgs units to MKS units)
Sound velocity (particle velocity)	LT^{-1}	cm per sec	meter per sec	10^{-2}
Volume velocity	L^3T^{-1}	cu cm per sec	cu meter per sec	10^{-6}
Sound energy	ML^3T^{-2}	erg	joule	10^{-7}
Force	MLT^{-2}	dyne	newton	10^{-5}
Sound pressure (sound energy density)	$ML^{-1}T^{-2}$	microbar (dyne per sq cm)	newton per sq meter	10^{-1}
Sound energy flux	ML^2T^{-3}	erg per sec	watt	10^{-7}
Sound intensity (specific sound energy flux)	MT^{-3}	erg per sec per sq cm	watt per sq meter	10^{-8}
Acoustic impedance (resistance, impedance)	$ML^{-4}T^{-1}$	acoustic ohm (dyne-sec per cm^6)	MKS acoustic ohm (newton-sec per meter)	10^5
Specific acoustic impedance (characteristic impedance)	$ML^{-2}T^{-1}$	rayl (acoustic ohm $\times cm^2$ or dyne-sec per cu cm)	MKS rayl (MKS acoustic ohm $\times sq meter$ or newton-sec per cu meter)	10

ACTION INTEGRAL. For a generalized coordinate q_i and its conjugate momentum p_i the phase integral,

$$J_i = \oint p_i dq_i,$$

is called the action integral (see **action variable**). The integral is taken over one complete cycle of a system and is therefore only defined for periodic, or multiply periodic, systems. The Bohr-Sommerfeld quantum condition states that the action integral of a system must be an integral multiple of Planck's constant ($J_i = nh$). (See **Bohr-Sommerfeld quantum theory**.)

ACTION PRINCIPLE. In classical mechanics a variational principle (sometimes also called **Hamilton's Principle**) which states that the motion of a mechanical system described by coordinates $q_i = q_i(t)$ can be characterized by the requirement that the action integral $I(t_2, t_1)$

$$I(t_2, t_1) = \int_{t_2}^{t_1} L dt \quad (1)$$

where $L = L(q_i, \dot{q}_i, t)$ is the Lagrangian of the system, is stationary for the physically possible trajectories $q_i(t)$. More precisely, the action principle states that the variation $q_i(t) \rightarrow q_i(t) + \delta q_i(t)$ produces no change in I to first order

in $\delta q_i(t)$, if $\delta q_i(t)$ is an arbitrary variation vanishing at time t_1 and t_2 . The action principle is then equivalent to the Lagrangian equations of motion

$$\frac{\partial L}{\partial q_i} - \frac{d}{dt} \left(\frac{\partial L}{\partial \dot{q}_i} \right) = 0 \quad (2)$$

(see **Lagrangian formalism**). Although the action principle states only that the action is stationary for variations vanishing at the end points t_1 and t_2 one can deduce the result of a variation which does not vanish at the end points. This is possible because each state of motion is defined by fixing as many coordinates as can be fixed independently (for the case of a single particle e.g., the three spatial coordinates at two different times, or three coordinates and three velocities at one time) and then the whole past and future is determined by the field equations. In the **quantum theory** the coordinates $q_i(t)$ of a particle are operators. In the **Heisenberg picture** they satisfy the same equations of motion (2) as in classical mechanics. This will be guaranteed if one assumes that the same action principle holds, namely $\delta I = 0$

$$I = \int_{t_2}^{t_1} L(q_i, \dot{q}_i) dt$$

for all variations of the q_i vanishing at t_1 and t_2 . In the quantum theoretic case by a variation is meant a change of q_i to $q_i + \delta q_i$ where

the δq_i are c-numbers and not operators. Because of the uncertainty principle (or equivalently due to lack of commutativity of $q(t)$ and $q(t')$ for $t \neq t'$) it is not possible in the quantum theory to assign values to the $q_i(t)$ throughout a physical motion. The motion is specified by giving values to the $q^i(t)$, or to the $\dot{q}_i(t)$, at a single time t . The future of the state cannot then be determined from the equations which are of second order in the time. The action principle, $\delta I = 0$, is therefore no longer sufficient to compute δI for variations which do not vanish at t_1 and t_2 . Additional statements must be made about the behavior of δI for variations δq which do not vanish at the end point. This additional information is contained in the Schwinger action principle which is the quantum mechanical generalization of the classical action principle. It can be stated as follows:

$$\delta \langle q_1 t_1 | q_2 t_2 \rangle = \frac{i}{\hbar} \langle q_1 t_1 | \delta I | q_2 t_2 \rangle$$

which action principle gives the changes in the transformation function $\langle q_1 t_1 | q_2 t_2 \rangle$ due to particular variations (including variations at the boundary), δI being the variation induced in I by such variations, where I , the action integral, is now an operator function.

The dynamical principle of the quantum theory of fields which governs the development of field systems between two space-like surfaces σ_1 and σ_2 , is called the Schwinger action principle. It states that

$$\delta \langle \sigma_1 | \sigma_2 \rangle = \left\langle \sigma_1 \left| \delta \left\{ i \int_{\sigma_2}^{\sigma_1} d^4x \mathcal{L}(\chi) \right\} \right| \sigma_2 \right\rangle$$

where the Lagrangian, which is a Hermitian operator function of the multicomponent Hermitian field $\chi(x)$, can in general be written in the form

$$\mathcal{L}(\chi) = \frac{1}{4} (\chi A^\mu \partial_\mu \chi - \partial_\mu \chi A^\mu \chi) - \mathcal{H}(\chi).$$

The A^μ are finite dimensional and skew Hermitian matrices. They can be reduced into two classes, one consisting of real antisymmetrical matrices and the other of imaginary symmetrical matrices. This expresses the separation of the total field χ into two fundamental classes of Bose-Einstein fields ϕ (integer spin fields) and Fermi-Dirac fields ψ (odd half integer spin field). Corresponding to the symmetry of the relevant parts of the matrices A^μ , the Bose-Einstein fields must essentially be commutative at space-like points) and the Fermi-Dirac fields

anticommutative in order that the first term in the Lagrangian be a non-trivial operator. Similarly the structure of \mathcal{H} must involve the ϕ and ψ in a symmetrical and antisymmetrical fashion respectively. It can be shown that \mathcal{H} , and hence \mathcal{L} , are even functions of the Fermi-Dirac field.

The finite multiplicity of the Hermitian field χ pertains in part to space time properties (spin) and in part to internal properties (charge, isotopic spin etc.).

ACTION, QUANTUM OF. Synonym for Planck constant, h . (See also action integral.)

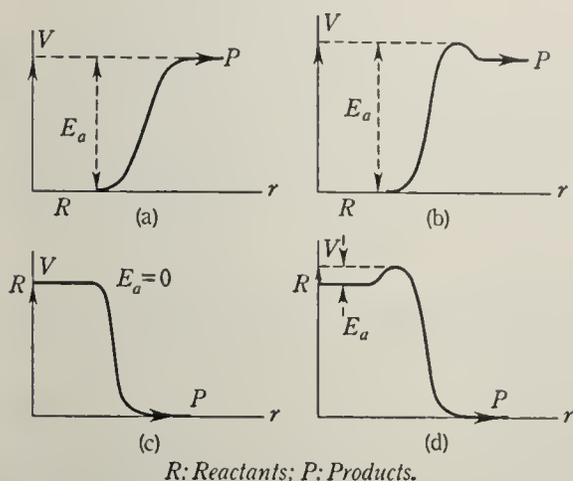

ACTION VARIABLE. If one of the momenta of a classical dynamical system yields a closed curve when graphed against the conjugate coordinate, the area contained within this curve is the action variable corresponding to this degree of freedom. Usually denoted by J .

ACTIVATED COMPLEX. A short-lived transition state which appears during chemical reactions, when the molecules can no longer be considered as reactants, and not yet as products. The activated complex is the point of maximum energy along the *reaction path* (see absolute reaction rate theory). The difference between the energy of the activated complex and that of the reactants is the **activation energy** of the reaction. The *activation entropy* is defined similarly as the difference between the **entropy** of the activated complex and that of the reactants.

ACTIVATION ENERGY. The excess energy over the ground state which must be acquired by an atomic system in order that a particular process may occur. Examples are the energy needed by a molecule to take part in a chemical reaction, by an electron to reach the conduction band in a semiconductor, and by a lattice defect to move to a neighboring site.

In the first example cited, the rate of an elementary chemical reaction can usually be expressed as a product of a function of the concentrations of the participants and of a rate constant. This latter can be written as $A \exp(-E_a/kT)$, where k is the Boltzmann constant, T , the absolute temperature, A , a frequency factor which varies slowly with the activation energy E_a which appears in the exponential. It is the minimum height of the potential barrier which must be crossed when one follows the reaction coordinate from the

reactants to the products. The figure illustrates four typical situations. It is to be noted that it is only a case (a) that E_a is equal to the energy of the reaction. (See **absolute reaction rate theory**; **equilibrium theory of reaction kinetics**; and **activated complex**.)

Activation energy. Variation of the energy along the reaction coordinate for two endothermic (a) and (b) and two exothermic (c) and (d) reactions. E_a is the activation energy.

ACTIVATION ENTROPY. See **absolute reaction rate theory**; and **activated complex**.

ACTIVATION RATE (NEUTRON REACTIONS). The activation rate for unit volume of a substance containing neutron flux is based upon the number of neutron-capture reactions taking place per unit time in a small energy range about a particular energy, E . Thus,

$$\text{overall activation rate} = \int_0^{\infty} dE \Sigma_{act}(E) \Phi(r, E)$$

where Σ_{act} is the macroscopic activation cross section and $\Phi(r, E)$ is the total neutron flux at energy E at point r .

ACTIVE FORCE. See **force**, **external** or **active**.

ACTIVE MOLECULES. See **unimolecular reactions**.

ACTIVE NETWORK. See **network**, **active**.

ACTIVITY. See **reference systems**.

ACTIVITY, ABSOLUTE. See **absolute activity**.

ACTIVITY COEFFICIENT. See **reference systems**.

ADAMS-BASHFORD METHOD. A method for solving an **ordinary differential equation**, $y' = f(x, y)$, expressed in terms of **difference operators**, which uses the **predictor**

$$y_{\nu+1} = y_{\nu} + h[f_{\nu} + \frac{1}{2}\nabla f_{\nu} + \frac{5}{12}\nabla^2 f_{\nu} + \frac{3}{8}\nabla^3 f_{\nu} + \dots],$$

and the **corrector**

$$y_{\nu+1} = y_{\nu} + h[f_{\nu+1} - \frac{1}{2}\nabla f_{\nu+1} - \frac{1}{12}\nabla^2 f_{\nu+1} - \frac{1}{24}\nabla^3 f_{\nu+1} - \dots].$$

The first amounts to approximating

$$\int_{x_{\nu}}^{x_{\nu+1}} f(x, y) dx$$

by means of a quadrature formula which utilizes values of f at x_{ν} and to the left only, the second utilizes also the value of f at $x_{\nu+1}$. The corrector is to be used with the best current approximation of $y_{\nu+1}$, and reapplied until the next approximation does not differ significantly from the previous. The formulas have significance when y and f are vectors. (See F. B. Hildebrand, *Introduction to Numerical Analysis*, McGraw-Hill Book Company, 1956; Lothar Collatz, *Numerische Behandlung von Differentialgleichungen*, 2nd edition, Springer, 1955).

ADAMS-STÖRMER METHOD. See **Störmer method**.

ADAPTATION. (1) The process taking place as the eye becomes accustomed to the luminance or the color of the field of view. (2) The final state of the process. In particular, the terms light adaptation and dark adaptation are used, according as the luminance is of the order of at least several **candela** per square meter, or less than some hundredths of a candela per square meter.

ADDITION OF TENSORS. The operation of forming the **sum** of (two) **tensors**.

ADDITIVE COMPLEMENTARY COLORS. Two lights are of complementary colors when it is possible to reproduce the color of a specified achromatic light by a suitable mixture of these two lights.

ADDITIVE MIXTURE OF COLORS. The mixture of light stimuli in such manner that they enter the eye simultaneously or in rapid succession and are incident on the same area

of the retina, or enter in the form of a mosaic which the eye cannot resolve.

ADDITIVE PROCESS. A **stochastic process** in which the increments over non-overlapping time intervals are independent; i.e., a process $\{x(t)\}$ is additive if, for $t_1 < t_2 < t_3 < \dots$, the increments $x(t_2) - x(t_1)$, $x(t_3) - x(t_2)$ \dots , are independent. The process is also known as a *random walk process*. An additive process may be defined in more than one dimension. It may also be defined for continuous t and is then sometimes known as a *differential process*.

ADDRESS. The symbol designating a particular cell in the **storage unit** of a **stored-program computer**.

ADDRESS PART. In an instruction, any part that is usually an address. (See also **code, instruction**.)

ADHESION, WORK OF. The work of adhesion W_{AB} between two liquids A and B is the increase in free surface energy (see **surface energy, free**) on separating 1 cm² of interface AB

$$W_{AB} = \gamma_A + \gamma_B - \gamma_{AB}$$

where γ_A and γ_B are the **surface tensions** of A and B respectively against their vapors, and γ_{AB} is the **interfacial tension**. For a solid-liquid interface the work of adhesion W_{SL} is defined as the work required to separate 1 cm² of interface in a vacuum to give a naked solid surface

$$W_{SL} = \gamma_S + \gamma_L - \gamma_{SL}$$

where γ_S and γ_L are the surface free energies measured in a vacuum. It may be shown that

$$W_{SL} = \gamma_S - \gamma_{SV_0} + \gamma_L(1 + \cos \theta_E)$$

where γ_{SV_0} is the surface tension of the solid covered by an absorbed film of liquid in equilibrium with the vapor, and θ_E the equilibrium **contact angle**.

ADIABATIC. (1) Occurring without gain or loss of heat by the system involved, for example adiabatic expansion. A completely adiabatic process is unrealizable, but it can be closely approximated in practice by providing good thermal insulation and by carrying out the process rapidly so that little time is allowed for heat flow in or out of the system. (2) If a thermally-isolated system moves through a series of equilibrium states, i.e., undergoes an

adiabatic and reversible process, the locus of the points representing these states on a graph is called an **adiabatic**. The present tendency is to avoid this usage and to replace adiabatic by the designations *isentrop*e or *isentrop*ic line. (See **adiabatic process**.)

ADIABATIC APPROXIMATION. The assumption that the electronic wave functions in a molecule or solid are distorted by the motion of the nuclei, but in such a way that their energy is a function only of the nuclear configuration at a given moment, and does not depend on the rate at which the nuclei are moving.

ADIABATIC BULK MODULUS. See **bulk modulus**.

ADIABATIC CHANGE. See **adiabatic process**.

ADIABATIC CHANGES OF RADIATION PRESSURE. Suppose radiation is confined in a container whose volume is altered. If this change is performed in such a way that the **entropy** remains constant, it is a reversible adiabatic change. For such a change the radiation pressure and the volume are related by the equation

$$pV^{4/3} = \text{const. (adiabatic).}$$

(See also **adiabatic equation of state**.)

ADIABATIC COOLING LIMIT. See **adiabatic saturation**.

ADIABATIC DEMAGNETIZATION. In a system whose state can be completely defined by the temperature and an external magnetic field **B**, the equation for a reversible adiabatic process is

$$S(T, \mathbf{B}) = \text{const. (adiabatic).}$$

For a paramagnetic substance at temperatures which are not too low (for example $T \geq 10^{-2} \text{°K}$) the entropy depends only on the ratio **B/T**. Therefore

$$\frac{\mathbf{B}}{T} = \text{const. (adiabatic).}$$

Thus when the field is reduced the temperature drops. This is the principle of cooling by adiabatic demagnetization.

ADIABATIC ENTHALPY DROP. See **enthalpy drop**.

ADIABATIC EQUATION OF STATE. The adiabatic equation of state expresses the relation between pressure and volume at constant **entropy** (instead of constant temperature). For a **perfect gas** of monoatomic molecules the adiabatic equation of state is of the form

$$pV^{\gamma} = \text{const.} \quad (1)$$

More generally, if γ is the ratio of the specific heats (see **thermal coefficients**) at constant pressure and at constant volume respectively, the adiabatic equation of state of a perfect gas is:

$$pV^{\gamma} = \text{const.}$$

ADIABATIC FLAME TEMPERATURE. See **combustion**.

ADIABATIC FLOW, ENERGY EQUATION FOR STEADY. See **energy equation for steady adiabatic flow**.

ADIABATIC HEAT DROP. See **enthalpy drop**.

ADIABATIC INVARIANT. A quantizable physical quantity which remains unchanged to some order of approximation under the action of a slowly varying spatial or temporal disturbance.

ADIABATIC IONIZATION POTENTIAL. See **ionization potential**.

ADIABATIC LAPSE RATE. The rate of decrease of temperature with height in an atmosphere in which a parcel of air displaced vertically assumes the same temperature as its surroundings if the changes are adiabatic. The potential temperature is then independent of height. For air of constant composition with gas constant R and ratio of specific heats γ , the adiabatic lapse rate Γ is given by

$$\Gamma = \frac{(\gamma - 1)g}{\gamma R} = \frac{g}{C_p}$$

which in the earth's atmosphere is 10°C per km with sufficient accuracy for practical purposes. The air is statically unstable or stable according to whether the lapse rate is greater or less than adiabatic, i.e., according to whether the lapse rate of **potential temperature** is positive or negative.

ADIABATIC LAW FOR QUANTIZED STATES (EHRENFEST). For a virtual, infinitely slow alteration of the **coupling** condi-

tions, the quantum numbers of the system do not change, and, in particular, the number of **terms** does not vary.

ADIABATIC PROCESS. Any thermodynamic process, reversible or irreversible, which takes place in a system without the exchange of heat with the surroundings. When the process is also reversible, it is called *isentropic*, because then the entropy of the system remains constant at every step of the process. (In older text-books isentropic processes were called simply adiabatic, or quasi-static adiabatic; the distinction between adiabatic and isentropic processes was not always sharply drawn.)

When a closed system undergoes an adiabatic process without performing work (*unresisted expansion*), its internal energy remains constant whenever the system is allowed to reach thermal equilibrium. Such a process is necessarily irreversible. At each successive state of equilibrium, the entropy of the system S_i , has a higher value than the initial entropy, S_0 . Example (see also **Joule's experiment**): When a gas at pressure p_0 , temperature T_0 , occupying a volume V_0 (see Figure 1) is allowed to expand

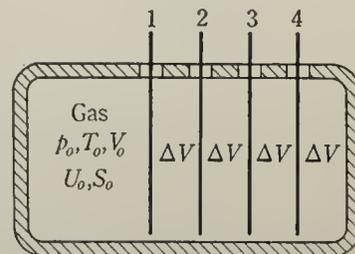

Fig. 1. Successive adiabatic expansions of gas by withdrawing slides.

progressively into volumes $V_1 = V_0 + \Delta V$, etc., by withdrawing slides 1, 2, etc., one after another, it undergoes such a process if it is enclosed in an adiabatic container. After each withdrawal of a slide, the irreversibility of the process causes the system to depart from equilibrium; equilibrium sets in after a sufficiently long waiting period. At each successive state of equilibrium $U_1 = U_2 = \dots = U_0$, but $S_0 < S_1 < S_2$, etc.

When an open system in steady flow undergoes an adiabatic process without performing external work, the enthalpy of the system regains its initial value at each equilibrium state, and the entropy increases as before. Example (see **Joule-Thomson experiment** and **throttling**): Successive, *slow* expansions through

porous plugs $P_1, P_2 \dots$ (Figure 2), when we have

$$H_1 = H_2 = \dots = H_0,$$

but

$$S_0 < S_1 < S_2, \text{ etc.}$$

This process is also necessarily irreversible (see **stagnation enthalpy, stagnation temperature**).

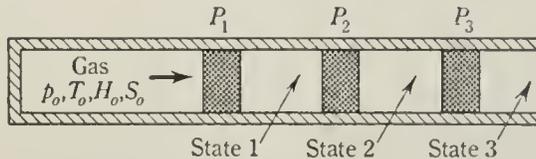

Fig. 2. Successive, slow adiabatic expansions of gas through porous plugs.

A closed system cannot perform an isentropic process without performing work. Example: (Figure 3). A quantity of gas enclosed by an ideal, frictionless, adiabatic piston in an adiabatic cylinder is maintained at a pressure p by

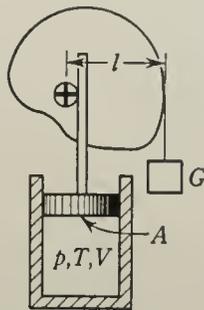

Fig. 3. Isentropic compression (or expansion) in cylinder.

a suitable ideal mechanism, so that $Gl = pA$ (A being the area of piston). When the weight G is increased (or decreased) by an infinitesimal amount dG , the gas will undergo an isentropic compression (or expansion). In this case

$$S = \text{const.}, \quad dS = 0, \quad (a)$$

at any stage of the process, but

$$U \neq \text{const.}, \quad H \neq \text{const.}$$

During an isentropic process of a closed system between states 1 and 2, the change in internal energy equals *minus* the work done between the two states, or

$$U_2 - U_1 = -W_{12}$$

work is done "at the expense" of the internal energy.

Equation (a) is the general equation of the process. In the case of a perfect gas, the differential Equation (a) can be written in three alternative forms:

$$\frac{dp}{p} + \gamma \frac{dv}{v} = 0$$

$$\frac{dT}{T} + (\gamma - 1) \frac{dv}{v} = 0 \quad (b)$$

$$\frac{dT}{T} - \frac{\gamma - 1}{\gamma} \frac{dp}{p} = 0$$

where γ can be a function of temperature. Since γ (or c_p or c_v) of a perfect gas is a tabulated function of temperature (temperature alone), it is necessary to evaluate certain integrals, in order to facilitate practical calculations. These are usually tabulated in the forms:

$$\left. \begin{aligned} \phi(T) &= \int_{T_0}^T c_p(T) \frac{dT}{T} \\ \phi_v(T) &= \int_{T_0}^T c_v(T) \frac{dT}{T} \\ p_r(T) &= p_0 \exp\left(\frac{\phi(T)}{R}\right) \\ v_r(T) &= v_0 \exp\left(-\frac{\phi_v(T)}{R}\right) \end{aligned} \right\} (c)$$

where T_0, p_0, v_0 denote an arbitrary *reference* state. (See Keenan and Kaye, *Gas Tables*, Wiley, 1958.) The integral equation of the isentropic process can then be written

$$\left. \begin{aligned} \phi(T) - \phi(T_1) &= R \ln\left(\frac{p}{p_1}\right) \\ \phi_v(T) - \phi_v(T_1) &= -R \ln\left(\frac{v}{v_1}\right) \\ \frac{p}{p_1} &= \frac{p_r(T)}{p_r(T_1)} \\ \frac{v}{v_1} &= \frac{v_r(T)}{v_r(T_1)} \end{aligned} \right\} (d)$$

where subscript 1 refers to the initial state of the system, and the symbols without subscripts refer to any other state. When the specific heats are constant, the above equations can be simplified to

$$\left. \begin{aligned} pv^\gamma &= \text{const.} \\ Tv^{\gamma-1} &= \text{const.} \\ \frac{T}{p^{\frac{\gamma-1}{\gamma}}} &= \text{const.} \end{aligned} \right\} (e)$$

The picture of an isentropic process in a **thermodynamic diagram** is called an isentrope or an isentropic. It is the locus of all states of constant entropy passing through the initial state 1. In a T, S diagram the isentrope is always a straight line as shown in Figure 4.

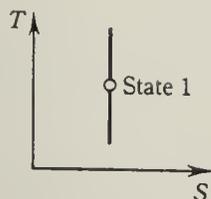

Fig. 4. Temperature-entropy diagram of isentropic process.

In any other system of coordinates, the shape of the curve depends on the thermodynamic properties of the system. The curve for a perfect gas with constant specific heats in p, V coordinates ($pV^\gamma = \text{const.}$) is shown in Figure 5.

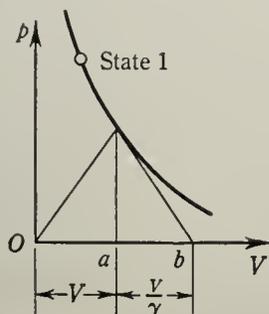

Fig. 5. Pressure-volume diagram for perfect gas at constant specific heat.

It is best obtained by cross-plotting from a log-log diagram. The subtangent ab at any state is equal to V/γ . For steam at moderate pressures and temperatures it is found empirically that it can be represented by the equation

$$Pv^n = \text{const.}$$

with $n = 1.3$, for superheated steam

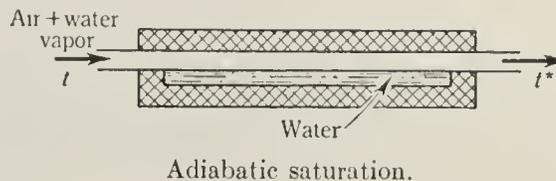

$n = 1.035 + 0.1x$, for wet steam of dry-ness fraction x

$n = 1.135$, for dry saturated steam.

(See also **Wilson line**.)

ADIABATIC SATURATION. When a mixture of air and water vapor is passed through an adiabatically insulated pipe over a large surface of water, the water will evaporate into the air until it becomes saturated. Owing to the extraction of the latent heat of vaporization, the temperature of the air will decrease, reaching a limit t^* at adiabatic saturation (*adiabatic cooling limit*). This temperature

is very close to that measured by a wet-bulb thermometer (thermodynamic wet-bulb temperature). By contrast, the actual temperature t is called the dry-bulb temperature.

The temperature t^* of adiabatic saturation is given approximately by Carrier's equation

$$p_w = p_s^* - \frac{p - p_s^*}{2,830 - 1.44t^*} (t - t^*)$$

where p_w is the partial pressure of water vapor in entering air, p_s^* is the saturation pressure at temperature t^* , p is the total pressure of entering moist air. (See figure.)

This formula is used to determine the relative humidity $\phi = p_w/p_s$ of the entering air from a measurement of t and t^* .

ADIABATIC WALL. (Perfect heat insulator.) Since in a rigorous development of the principles of thermodynamics it is necessary to introduce the concept of an adiabatic wall before the concept of heat, it is convenient to adopt the following alternative definition. If two closed systems are placed in contact through an adiabatic wall, their states can be varied independently of one another. Any state of one system can co-exist with any state of the other system through such a wall; the systems are not coupled in any way. (See **diathermal wall**.) The number of independent properties of the combined system is equal to the sum of the number of independent properties of the component systems.

ADIATHERMAL WALL. See **diathermal wall**.

ADJACENCY MATRIX. See **matrix, adjacency**.

ADJACENT VERTICES. See **vertices, adjacent**.

ADJOINT EQUATION. Consider the differential equation

$$L(u) = u'' + p(x)u' + q(x)u = 0.$$

The **operator adjoint** to $L(u)$ is

$$\bar{L}(v) = v'' - p(x)v' + [q(x) - p'(x)]v.$$

Then

$$vL(u) - u\bar{L}(v) = (d/dx)[P(u,v)]$$

is the **Lagrange identity**, and

$$P = uv[u'/u - v'/v + p(x)]$$

is the **bilinear concomitant**. If the adjoint equation $\bar{L}(v) = 0$ can be solved, the original equation $L(u) = 0$ is equivalent to the first order equation $P(u,v) = C$, where C is an arbitrary constant.

An equation identical with its adjoint is said to be **self-adjoint**. Any second-order differential equation may be put into self-adjoint form if the appropriate factor is introduced.

These procedures are not limited to equations of second order but may be generalized for those of any order. (See **Sturm-Liouville problem**.)

ADJOINT FLUX. See **flux, adjoint**.

ADJOINT OF A MATRIX. The adjoint of a square matrix **A** is the **transpose** of the matrix obtained from **A** by replacing each element of **A** by its **cofactor**.

ADJOINT OF AN OPERATOR. The adjoint A^* of an operator A is an operator such that, for all f and g in the domain of A , we have $(Af, g) = (f, A^*g)$. If $A^* = A$, then A is said to be self-adjoint. (Compare, e.g., **Sturm-Liouville problem**.)

ADJOINT SPINOR. See **Dirac equation**.

ADJOINT WAVE FUNCTION. In **Dirac electron theory** the row-vector $\bar{\psi} = \psi^* \gamma_4$ where ψ is the wave function, the asterisk denotes **Hermitean conjugate** and γ_4 is a **Dirac operator**.

ADMISSION. In a reciprocating steam engine, the point at which the inlet (admission) valve opens to feed steam into the cylinder.

ADMISSION, PARTIAL. In an impulse turbine, the device of admitting the working fluid (steam, combustion gases) over a portion of the inlet annulus only, in order to avoid the necessity of using inconveniently short blades.

ADMITTANCE. The ratio of current to voltage in an alternating current circuit. Therefore, admittance is the reciprocal of **impedance**. Thus if the impedance of a circuit element is

$$Z = R + jX, \quad |Z|^2 = R^2 + X^2,$$

its admittance is

$$Y = \frac{1}{R + jX} = \frac{R - jX}{R^2 + X^2} = \frac{R}{|Z|^2} - j \frac{X}{|Z|^2} \\ \equiv G + jB.$$

The real part of admittance is called **conductance** (G); the imaginary part, **susceptance** (B). Note that positive reactance implies negative susceptance.

ADMITTANCE, DRIVING-POINT (between the j th Terminal and the Reference Terminal of an n -Terminal Network). The quotient of the complex alternating component I_j of the current flowing to the j th terminal from its external termination by the complex alternating component V_j of the voltage applied to the j th terminal with respect to the reference point when all other terminals have arbitrary external terminations. In specifying the driving-point admittance of a given pair of terminals of a network or transducer having two or more pairs of terminals, no two pairs of which contain a common terminal, all other pairs of terminals are connected to arbitrary admittances.

ADSORPTION. See **Gibbs division surface; adsorption isotherm**.

ADSORPTION, HEAT OF. When a gas or vapor is adsorbed on a solid, heat is liberated. There are two ways of expressing these heat effects: (1) Integral heat of adsorption, which is the total amount of heat, Q cal, given out when 1 g of the outgassed solid takes up m g of the gas or vapor. It is expressed as calories per g of adsorbent, for an adsorption of m g of adsorbate. (2) Differential heat of adsorption,

$$-\Delta H = M \frac{\partial \phi}{\partial m}$$

where M is the molecular weight of adsorbate. Heats of adsorption may be measured by means of a calorimeter. They may also be calculated from heats of immersion and condensation.

In the case of a liquid, the heat of adsorption of solute from solution may be determined from the thermodynamic relation:

$$\Delta H^\circ = \Delta G^\circ - T \frac{d(\Delta G^\circ)}{dT}$$

where ΔH° and ΔG° are the heat of and free energy (see **free energy** (1)) of adsorption. For dilute solutions:

$$\Delta G^\circ = -RT \ln \frac{C_{\text{solid}}}{C_{\text{solution}}} = -RT \ln \frac{\Gamma}{\gamma C_{\text{solution}}}$$

where C_{solution} is the concentration of the solute in solution, C_{solid} is the concentration of the adsorbed solute, Γ is the amount of adsorbed solute per unit area of surface, and γ is the thickness of the adsorbed film. Older values of the heat of adsorption are subject to sizable errors.

ADSORPTION ISOTHERM. The adsorption isotherm expresses the equilibrium condition between an adsorbed film, which is often a monolayer (see **localized monolayers**) and the vapor pressure.

If one considers a localized monolayer with negligible interactions between the adsorbed molecules and assumes, moreover, that all sites are equivalent, the adsorption isotherm is

$$\frac{\theta}{1 - \theta} = \frac{p}{p_o} \quad \text{or} \quad \theta = \frac{p}{p_o + p}$$

where θ is the fraction of sites occupied by molecules, p the vapor pressure and p_o a characteristic constant depending on temperature, the nature of the molecule and the energy of adsorption.

This formula was first derived by Langmuir and is known as the **Langmuir adsorption isotherm**.

Many other forms of the adsorption isotherm have been suggested or derived in the literature.

ADSORPTION ISOTHERM, LANGMUIR TREATMENT. See **Langmuir adsorption isotherm**.

ADVANCED POTENTIALS. The electromagnetic potentials at a point \mathbf{r} at time t due to sources at points $\mathbf{r} - \mathbf{R}$ and times $t + |\mathbf{R}|/c$. These sources lie on the future light cone through the point \mathbf{r} , t in space-time. Although these potentials arise in the mathematical formulation of classical field theory, they appear to have no physical significance. (See **retarded potentials**.)

ADVECTION. Transfer by the bulk motion of a fluid, e.g., horizontal transport by the wind. It is included in the more general term

convection which, however, more usually denotes transfer by turbulent or penetrative motions of a fluid.

Advection may be expressed in vector notation by

$$\mathbf{V} \cdot \nabla \phi$$

where \mathbf{V} is the wind vector, ϕ the atmospheric property, and ∇ the del operator. In three-dimensional **Cartesian coordinates**, it is

$$u \frac{\partial \phi}{\partial x} + v \frac{\partial \phi}{\partial y} + w \frac{\partial \phi}{\partial z}$$

If (u, v) is taken as the horizontal wind, and w , the vertical air velocity, the first two terms comprise the *horizontal advection* and the last term is the *vertical advection*. The property ϕ may itself be a vector field.

Often, particularly in synoptic meteorology, advection refers only to the horizontal or isobaric components of motion, that is, the wind field as shown on a synoptic chart.

AELOTROPIC MATERIAL. A material which is not isotropic. In elasticity theory, a material which is not isotropic with respect to its elastic properties. Also called *anisotropic material*.

AERODYNAMIC CENTER. If C_m is the pitching-moment coefficient on an airfoil at incidence α , the position of the pitching-moment axis on the chord line for which

$$\frac{dC_m}{d\alpha} = 0$$

is known as the aerodynamic center. For an unstalled airfoil, C_m varies almost linearly with α , so that the aerodynamic center is very nearly a fixed point, independent of α . For a symmetrical airfoil the aerodynamic center coincides with the center of pressure, since $C_m = C_L = 0$ when $\alpha = 0$.

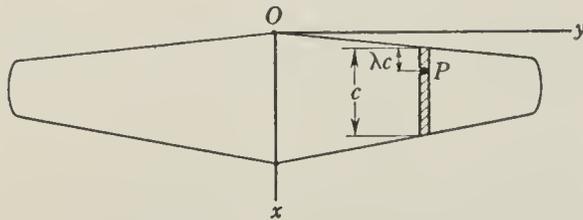

According to thin-airfoil theory, the aerodynamic center of a two-dimensional airfoil in subsonic flow is at the quarter-chord point. The linear theory of supersonic flow shows that the aerodynamic center of a two-dimensional airfoil is at the half-chord point.

AERODYNAMIC MEAN CHORD (OF WING). Referring to the figure on page 24 if c is the local chord of a wing at a distance y from the center line, the aerodynamic mean chord is defined as

$$\bar{c} = \frac{1}{S} \int_{-b/2}^{+b/2} c^2 dy \quad (1)$$

where S is the area and b is the span of the wing.

If a point $P(x,y)$ is at a distance λc from the leading edge, the point at a distance $\lambda \bar{c}$ from

Aerodynamic mean chord.

the leading edge of the aerodynamic mean chord is at a distance from the y -axis

$$\bar{x} = \frac{1}{S} \int_{-b/2}^{+b/2} x c dy. \quad (2)$$

Thus Equation (1) defines the length of the aerodynamic mean chord and Equation (2) defines its position along the x -axis.

The position of the mean quarter-chord point is found from Equation (2) by putting $\lambda = 1/4$.

AERODYNAMIC TIME UNIT. See **airplane stability**.

AEROFOIL. See **airfoil**.

AEROGRAM. (1) A thermodynamic diagram designed by Refsdal with logarithm of temperature as abscissa and the product of temperature and logarithm of pressure ($T \log p$) as ordinate, increasing downward. Isotherms are the only straight lines, but convenient spacing between dry adiabats, saturation adiabats, and vapor lines is obtained. The energy of a cyclic process is *not* proportional to the area enclosed by the curve representing the process. (2) The record traced by an aerograph.

AFFINE CONNECTION, FUNDAMENTAL. See **fundamental affine connection**.

AFFINE TENSORS AND FREE VECTORS. A quantity which behaves like a tensor under a linear (affine) coordinate transformation, but not under a general coordinate transformation is called an affine tensor. From an affine tensor it is possible to construct a *free vector*,

i.e., a vector not related to a given point (non-localized vector): Consider an affine tensor U_i^k and vector \mathbf{p}^k which is constant inside a "world-canal" (i.e., a region in the four dimensional world of tube shape, such that its lateral surface is space-like and the other two boundaries are time-like). If

$$\frac{\partial \sqrt{g} U_i^k \mathbf{p}^i}{\partial x^i} \equiv 0,$$

then the

$$J_k \equiv \iiint \sqrt{g} g_{ki} U_m^i \mathbf{p}^m dx^1 dx^2 dx^3$$

form the components of a free vector. The integral is extended over the lateral surface of the world canal.

AFFINE TRANSFORMATION. Using the **indicial notation** and **summation convention**, the transformation

$$\bar{x}^i = a_j^i x^j + b^i,$$

with a_j^i and b^i real constants, which transforms the point at x^i to \bar{x}^i . The transformation called non-singular or singular according as its determinant $|a_j^i|$ is non-zero or zero. If the constant terms b^i are zero, the transformation is *homogeneous affine*.

AFFINITY. See **chemical affinity**.

AFOCAL SYSTEM. An optical system with foci at infinity.

AFTER EFFECT, ELASTIC. Recovery of **strain** on unloading associated with delayed elasticity. (See **elasticity, delayed**.)

AGE APPROXIMATION. In the analysis of the energy-dependent transport equation in neutron transport theory, an approximation in which the collision density, appearing in the integrand of the collision integral, is replaced by the first two terms of its **Taylor expansion** about **lethargy** value u . The approximation, used in conjunction with a P_1 approximation for the angular dependence, leads directly to the Fermi Age Equation. (See **P_N Approximation**.)

AGE EQUATION (FERMI). In the theory of neutron slowing-down in matter, the age equation

$$\nabla^2 q(r, \tau') = \frac{\partial q}{\partial \tau'}(r, \tau')$$

describes the slowing-down density of neutrons as a function of space and generalized age, τ' . It is generally solved under particular boundary conditions and the initial condition $q(r, 0) = S(r)$, where $S(r)$ gives the space distribution of neutron sources. The generalized age,

$$\tau' = \int_E^{E_0} \frac{dE'}{E' \xi \Sigma_s + \gamma \Sigma_a} D(E')$$

reduces to the usual age, τ , when Σ_a , the macroscopic absorption cross section is zero. For definition of γ , see **Goertzel-Greuling approximation**.

AGE, NEUTRON. In the theory of neutron slowing-down in matter, the neutron age, $\tau(E, E_0)$ is defined by

$$\tau(E, E_0) = \int_E^{E_0} \frac{dE'}{E' \xi \Sigma_s(E')} D(E')$$

where E is the neutron energy, E_0 a reference energy, $D(E)$ is the diffusion coefficient appropriate to neutrons having energy E , ξ is the average logarithmic energy loss for a neutron in collision with an atom of the moderating material, and Σ_s is the microscopic cross-section for scattering. In the case of slowing-down in a mixture, average values of D and $\xi \Sigma_s$ are used. Note that the age has dimensions of length squared.

AGEOSTROPHIC WIND. The actual wind less the **geostrophic wind** (measured vectorially). If there is no frictional drag or eddy stress the ageostrophic wind \mathbf{v}_A is related to the acceleration in the same way as the geostrophic wind is related to the pressure gradient; thus

$$\mathbf{v}_A \times \mathbf{f} = \frac{D\mathbf{v}}{Dt}$$

where \mathbf{v} is the air velocity relative to the earth, assumed horizontal, and \mathbf{f} is twice the vertical component of the earth's rotation.

AIR, ATMOSPHERIC. Atmospheric air is a mixture of gases of remarkably constant composition, except for its *moisture content* (H_2O vapor). The composition of dry atmospheric air is as follows:

	Parts by Volume	Parts by Mass
N_2	0.7803	0.7547
O_2	0.2099	0.2320
A	0.00933	0.0128
CO_2	0.00030	0.00046
H_2	0.0001	0.00001
Ne	0.000018	0.000012
He	0.000005	0.0000007
Kr	0.000001	0.000003
Xe	0.0000009	0.0000004

For rapid calculation a simpler composition is often assumed:

	Parts by Volume	Parts by Mass
N_2	0.79	0.77
O_2	0.21	0.23

The gas constant for air is

$$R = 53.35 \text{ ft lbf/lbm } ^\circ\text{F} = 29.27 \text{ kp m/kg } ^\circ\text{C} \\ = 287.0 \text{ J/kg } ^\circ\text{C},$$

the molecular weight is

$$M = 28.964 \text{ lbm/lbmol} = 28.964 \text{ kg/kmol},$$

the density at 0°C and 760 mm Hg is

$$\rho_0 = 1.2928 \text{ kg/m}^3 = 0.08071 \text{ lbm/ft}^3.$$

When air is treated as a perfect gas with constant specific heats, it can be assumed that

$$c_p = 0.240 \text{ Btu/lbm } ^\circ\text{F} = 0.240 \text{ kcal/kg } ^\circ\text{C} \\ c_v = 0.171 \text{ Btu/lbm } ^\circ\text{F} = 0.171 \text{ kcal/kg } ^\circ\text{C} \\ \gamma = 1.40.$$

See also **atmosphere, standard**.

AIR COMPRESSOR. See **compressor**.

AIR EXCESS RATIO. Ratio of volume of excess air supplied for combustion to theoretical (stoichiometric) volume required for complete combustion. If λ denotes the **air ratio**, then the air excess ratio $\delta = \lambda - 1$.

AIRFOIL, ALSO AEROFOIL. A surface whose cross section is so shaped as to provide nearly **potential flow** around it; when placed in an air stream, an airfoil produces a large lift and a relatively small drag. Airfoils are used for airplane wings, turbine and turbo-compressor blades, etc.

AIRFOIL, LIFT AND MOMENT ON. See **lift and moment on an airfoil, general formulae**.

AIRFOIL STARTED FROM REST. It is supposed that an airfoil is started impulsively

from rest with velocity V , the angle of incidence α being kept constant. Immediately after starting, the circulation round the airfoil is zero and the streamlines in the vicinity of the trailing edge are as sketched in Figure 1. There is a rapidly rising pressure in the

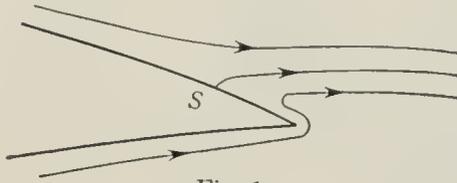

Fig. 1.

flow along the upper surface from the trailing edge towards the stagnation point S , and after a very short time a boundary layer develops in this region and separates, leading to the formation of a vortex as shown in Figure 2. This vortex, known as the *starting vortex*, does

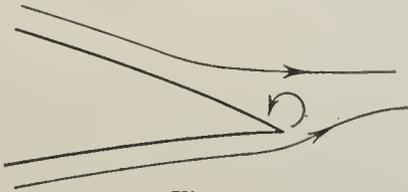

Fig. 2.

not remain in this position; it separates from the trailing edge and is left behind in the fluid as the airfoil moves on. The circulation round a path enclosing the airfoil and its wake remains zero, so that as the starting vortex is left behind in the wake the circulation round the airfoil alone becomes equal to the strength of the starting vortex, but of opposite sign.

The general problem of an airfoil in accelerated motion will now be considered in greater detail. Vorticity of the sign shown in Figure 2 is shed from the lower surface, and from the part of the upper surface between the stagnation point S and the trailing edge (Figure 1), while vorticity of opposite sign is shed from the part of the upper surface upstream of S . The former predominates, so that the net vorticity in the wake is of the sign shown in Figure 2. The shedding of net vorticity into the wake, and the associated growth of circulation around the airfoil, continue until

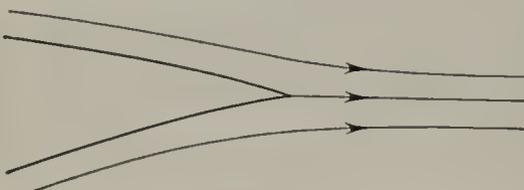

Fig. 3.

the fluid is flowing smoothly from the trailing edge as in Figure 3. This state is only approached asymptotically; the circulation and the lift then have their steady-flow values.

This discussion shows that, immediately after starting an airfoil from rest, the circulation is less than the final steady-flow value corresponding to the **Joukowski condition**. There is also a deficiency of lift, although the **Kutta-Joukowski law** relating the lift to the circulation for steady flow is not applicable in unsteady flow. The phenomenon of lift deficiency just after the start was studied theoretically by Wagner and is known as the *Wagner effect*. This term is also used with reference to the corresponding deficiency of lift immediately after an abrupt increase of incidence.

In the theoretical study of the problem by Wagner and others, it is assumed that the airfoil is thin, uncambered, and at a small angle of incidence. It is also assumed that the circulation at any instant is such that the fluid leaves the trailing edge smoothly, so that the velocity there is finite. It is found that the circulation and lift reach values within about 5% of the steady-flow values after the airfoil has travelled a distance of the order of 10 times the chord.

It is also found that immediately after an impulsive start, for an airfoil at constant incidence, or immediately after an abrupt increase of incidence from zero, for an airfoil at constant speed, the lift coefficient is exactly half the value in steady flow. (See A. Robinson and J. A. Laurmann, *Wing Theory*, Cambridge, 1956.)

AIRFOIL THEORY (TWO-DIMENSIONAL).

For calculating the properties of thin airfoils of small camber, at small angles of incidence, the methods of **thin-airfoil theory** are most useful. For thick airfoils, or for large angles of incidence, thin-airfoil theory becomes inaccurate and other methods must be used.

The family of airfoils known as **Joukowski airfoils** is obtained by conformal mapping of the flow past a circular cylinder, using the simple mapping function

$$\zeta = z + \frac{c^2}{z} \quad (1)$$

In the *Theodorsen method* Equation (1) is used to transform a given airfoil in the ζ -plane

into a contour in the z -plane which is not exactly a circle but does not differ greatly from a circle. This "pseudo-circle" in the z -plane is then related to a true circle in the z' -plane by a further transformation. The calculation involves a process of successive approximations, and although this converges rapidly the numerical work required is extensive. The method is exact and free from any restriction on thickness, camber or incidence, but it can only be used to calculate the pressure distribution on a given airfoil, and not for the inverse problem of designing an airfoil to have a given pressure distribution.

For this inverse problem, the *Lighthill method* may be used, if the thickness is so large that an exact theory is required. With this method it is unfortunate that the calculation has to be started with the velocity distribution prescribed, not on the airfoil itself, but on the circle into which the airfoil may be transformed. It is found in practice, however, that this does not restrict the usefulness of the method very seriously. The region outside the airfoil in the ζ -plane is transformed into the region outside the circle $|z| = a$ in the z -plane by means of a transformation function $\zeta(z)$ such that $\frac{d\zeta}{dz} \rightarrow 1$ as $z \rightarrow \infty$. The coordinates of the airfoil surface are obtained in terms of two integrals, involving the fluid speed and the direction of flow as functions of position on the circle in the z -plane. The fluid speed is prescribed at the start, and the direction of flow θ is found as the conjugate **Fourier series** of $\log q_0$, where q_0 is the fluid speed at zero incidence.

Lighthill's method has also been applied in designing cascades of airfoils, and contractions and bends in two-dimensional channels. For airfoils of small or moderate thickness, the approximate methods of Goldstein are more useful; these are considered briefly below. For very thick airfoils, especially those incorporating suction slots, the approximate methods cannot be used and Lighthill's method is unrivalled.

Goldstein has developed a series of systematic approximations to exact airfoil theory which lead to useful results with a comparatively small effort in computing. His first approximation corresponds to the linearized "thin-airfoil theory," while the second and third are higher order approximations allowing for greater thickness and camber. The

approximations are based on Theodorsen's method, and it is assumed that the differences between the pseudo-circle in the z -plane and the true circle in the z' -plane are small; this implies fairly small thickness and camber of the airfoil, but does not restrict the incidence. With this assumption, simplifications can be made in Theodorsen's method which reduce considerably the labor involved in computing the velocity distribution on a given airfoil. Moreover, Goldstein has been able to develop his approximate methods so that they can be used fairly easily for designing airfoils to have prescribed velocity distributions. (See A. Robinson and J. A. Laurmann, *Wing Theory*, Cambridge, 1956.)

AIR-FUEL RATIO. The ratio of the mass of air to the mass of fuel supplied in a combustion device.

AIR INJECTION. The process of injecting the fuel into a diesel engine with the aid of a blast of air from a compressor. In modern engines air injection has been replaced by *solid injection* when the fuel is compressed to several hundred atmospheres in an injection pump and injected into the cylinder through an *atomizer*. The object in either case is to inject the liquid fuel in the form of a fine spray.

AIR PARCEL. An imaginary body of air to which may be assigned any or all of the basic dynamic and thermodynamic properties of atmospheric air. A parcel is large enough to contain a very great number of molecules, but small enough so that the properties assigned to it are approximately uniform within it and so that its motions with respect to the surrounding atmosphere do not induce marked compensatory movements. It cannot be given precise numerical definition, but a cubic foot of air might fit well into most contexts where air parcels are discussed, particularly those related to **static stability**. Any fluid parcel may be defined similarly.

AIRPLANE ENERGY EQUATION. For an airplane of weight W , flying at height h with velocity V , the sum of the potential and kinetic energies is

$$E = W \left(h + \frac{V^2}{2g} \right).$$

Also, if D is the drag of the airplane and T is the propulsive thrust,

$$V(T - D) = \frac{dE}{dt} = W \left(\frac{dh}{dt} + \frac{V}{g} \frac{dV}{dt} \right).$$

Thus the rate of climb is

$$\frac{dh}{dt} = \frac{V}{W} (T - D) - \frac{V}{g} \frac{dV}{dt}.$$

AIRPLANE PERFORMANCE. For an airplane of weight W , flying at constant velocity and climbing at an angle θ , the required propulsive thrust T is given by

$$\frac{T}{W} = \gamma \cos \theta + \sin \theta, \quad (1)$$

where γ is the ratio of drag to lift. Thus the rate of climb, or vertical component of velocity, is equal to $V(T/W - \gamma)$, where V is the velocity of flight.

For horizontal flight at constant speed and incidence, the distance flown while using fuel of weight f is

$$\frac{V}{C\gamma} \log_e \frac{W}{W - f},$$

where W is the total weight of the airplane and fuel at the start and C is the ratio of the weight of fuel used per unit time to the propulsive thrust.

AIRPLANE STABILITY. In the theory of airplane stability it is usual to consider separately the *symmetric* disturbances, in which all the forces lie in the plane of symmetry, and the *asymmetric* disturbances in which there are rolling, yawing and side-slipping motions and associated forces.

The equations are expressed in terms of body axes, with origin at the center of gravity, chosen so that in undisturbed horizontal flight Ox is in the direction of flight and Oz is vertical and downward. The velocity components in undisturbed flight are $(U, 0, 0)$ and the components of the disturbance velocity are (u, v, w) . The angular velocities about the x, y and z -axes are p, q and r , while the moments of inertia about these axes are A, B and C . The components of the resultant aerodynamic force acting on the aircraft are (X, Y, Z) and the aerodynamic couples about the three axes are L, M and N . Then, if θ is the angular displacement about the y -axis from the undisturbed state and terms involving products of inertia are neglected, the equations for the

motion of the airplane when disturbed *symmetrically* are

$$\left. \begin{aligned} m\dot{u} &= X_u \cdot U + X_w \cdot W + X_q \cdot q \\ &\quad - mg\theta \\ m(\dot{w} - Uq) &= Z_u \cdot U + Z_w \cdot W + Z_q \cdot q \\ B\dot{q} &= M_u \cdot U + M_w \cdot W \\ &\quad + M_q \cdot q + M_{\dot{w}} \cdot \dot{w} + M_o, \end{aligned} \right\} (1)$$

where m is the mass of the aircraft.

In Equation (1), \dot{u} denotes $\frac{du}{dt}$ and X_u denotes $\frac{\partial X}{\partial u}$. M_o is the pitching moment due to displacement (if any) of the elevator control. With the exception of the term $M_{\dot{w}} \cdot \dot{w}$ in the third equation, terms involving aerodynamic forces or couples due to acceleration are negligible. In practice the terms $X_q \cdot q, Z_q \cdot q$ and $M_u \cdot U$, which are included here in the equations, are also negligible.

If ϕ and ψ are the angles of roll and yaw, respectively, the equations of motion for asymmetric disturbances are

$$\left. \begin{aligned} m(\dot{v} + Ur) &= Y_v \cdot v + Y_p \cdot p + Y_r \cdot r \\ &\quad + mg\phi \\ Ap &= L_v \cdot v + L_p \cdot p + L_r \cdot r \\ &\quad + L_o \\ C\dot{r} &= N_v \cdot v + N_p \cdot p + N_r \cdot r \\ &\quad + N_o \end{aligned} \right\} (2)$$

In Equation (2), L_o and N_o are the rolling and yawing moments due to displacement (if any) of the ailerons and rudder.

It is usual to convert Equations (1) and (2) into a dimensionless form. In principle, this is done by expressing all masses in terms of m , the mass of the airplane, all lengths in terms of a representative length l defining the scale of the airplane, and all times in terms of a quantity

$$\frac{m}{\rho US},$$

where ρ is the air density and S is the wing area.

The quantity $\frac{m}{\rho US}$ is known as the *unit of aerodynamic time*. The equations in this dimensionless form apply to any airplane of the specified shape, whatever its size, weight, or altitude of flight.

In solving Equations (1) and (2) it is often

assumed that the dimensionless forms of the derivatives X_u , Y_v , etc., are not affected by changes of airplane velocity. Then, expressing the solution for the disturbance velocities in the form $u = u_1 e^{\lambda t}$, $p = p_1 e^{\lambda t}$ and so on, a pair of quartic equations in λ is obtained, one for Equation (1) and another for Equation (2). The form of the solution of these quartic equations determines the stability or instability of the motion. (See W. J. Duncan, *Control and Stability of Aircraft*, Cambridge, 1952.)

AIR PREHEATING. In order to increase the overall efficiency of a steam plant, the combustion gases from the boiler can be used to preheat the air supplied for combustion. The air preheater is also known as an *economizer*.

AIR RATIO. Ratio of volume of air supplied for combustion to theoretical (stoichiometric) volume required for complete combustion.

AIRSCREW. An airscrew may be used either as a propeller, for converting shaft power into thrust, or as a windmill, for extracting energy from an air stream and converting this into shaft power. The lifting rotor of a helicopter in upward vertical flight may be regarded as a special form of propeller.

The usual theory of airscrews has been developed primarily for use in the design of propellers, but it is also applicable to windmills. Each element of a blade is regarded as an element of a two-dimensional airfoil, operating in a stream whose velocity is determined in magnitude and direction not only by the forward and rotational speeds, but also by the induced velocity due to the system of helical trailing vortices from the blades. It can be shown that the induced velocity at a given radius depends only on the thrust and torque loading at that radius.

In the usual method of calculating the induced velocities, the airscrew is replaced by an equivalent airscrew having an infinite number of blades and the same radial distribution of thrust and torque. This approximation gives very good results in many cases. For other cases, more refined theories are available in which allowance is made for the finite number of blades in calculating the induced velocities. (See H. Glauert, *The Elements of Aerofoil and Airscrew Theory*, Cambridge, 2nd Edition, 1947.)

AIR-STANDARD CYCLE. An ideal sequence of processes forming a cycle which serves as a standard of comparison for the evaluation of the performance of internal combustion engines. The essential idealization consists in replacing the process of combustion by the addition of heat from an external source and by assuming that the working fluid has the properties of air (perfect gas with constant, or variable, specific heats) throughout the cycle. The precise details of an air-standard cycle for a particular type of engine are to a certain extent arbitrary and must be fixed by convention.

AIR-STANDARD EFFICIENCY. The efficiency of an air-standard cycle which corresponds to a given internal-combustion engine.

AIR-STEAM MIXTURES. Mixtures of air and steam play an important part in the study of atmospheric conditions, drying and air conditioning. In evaluating their properties it is usually assumed that the air (or, generally, gas) is perfect and non-condensing, and that the steam (or, generally, the vapor) is also a perfect gas, except that the fact that the steam condenses under specified conditions is taken into account. Processes involving mixtures of gases and vapor are usually studied graphically. (See **psychrometric chart** and **Mollier diagram**.)

AIRY DIFFERENTIAL EQUATION. See **Airy functions**.

AIRY DISC. The diffraction pattern in the Gaussian image plane of an axially symmetrical optical system is given by

$$F(r) = \int_0^{\rho_0} J_0 \left(\frac{2\pi}{\lambda} \rho r \right) e^{i \frac{2\pi}{\lambda} W(\rho)} \rho d\rho$$

where $\rho_0 = n \sin \theta$ is the exit aperture, n is the index of refraction in image space, θ is the angle of projection, λ is the wavelength, $W(\rho)$ is the mixed characteristic function of the system, and r is radial distance in the image plane from the focus. (J_0 and J_1 are Bessel functions of orders 0 and 1.) If the system is free from spherical aberration so $W(\rho) = W(0)$ is constant, then

$$F(r) = \frac{\lambda \rho_0}{2\pi r} J_1 \left(\frac{2\pi}{\lambda} \rho_0 r \right) e^{i \frac{2\pi}{\lambda} W(0)}$$

The intensity of the diffraction patterns is

$$I(r) = I(0) \left\{ \frac{2J_1(\beta)}{\beta} \right\}^2, \quad \beta = \frac{2\pi\rho_0}{\lambda} r.$$

The first positive zero of $I(r)$, as determined from the first positive zero of $J_1(z)$ is approximately $r_1 = 0.61\lambda/\rho_0$. The Airy disc is then the illuminated circle in the image plane with center at the focus and radius r_1 .

AIRY FUNCTIONS. In an investigation of diffraction near a **caustic** surface Airy introduced what is now called the Airy integral

$$\begin{aligned} Ai(x) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \exp i(tx + \frac{1}{3}t^3) dt \\ &= \frac{1}{\pi} \int_0^{\infty} \cos (tx + \frac{1}{3}t^3) dt \end{aligned}$$

which satisfies Airy's differential equation

$$\frac{d^2y}{dx^2} = xy.$$

$x_0 - x$	$y_x(x_0)$	$y_x(x_0, x_1)$	$y_x(x_0, x_1, x_2)$	$y_x(x_0, x_1, x_2, x_3)$
$x_1 - x$	$y_x(x_1)$	$y_x(x_1, x_2)$	$y_x(x_1, x_2, x_3)$	
$x_2 - x$	$y_x(x_2)$	$y_x(x_2, x_3)$		
$x_3 - x$	$y_x(x_3)$			

The solutions of this equation are called Airy functions. A second solution is

$$Bi(x) = \frac{1}{\pi} \int_0^{\infty} \left\{ \exp (tx - \frac{1}{3}t^3) + \sin (tx + \frac{1}{3}t^3) \right\} dt.$$

AIRY INTEGRAL. See **Airy functions**.

AIRY STRESS FUNCTION. See **plane strain**.

AITKEN δ^2 PROCESS. See **delta-square process**.

AITKEN METHOD OF INTERPOLATION. The procedure is to form a table

$x_0 - x$	$y_x(x_0)$			
$x_1 - x$	$y_x(x_1)$	$y_x(x_0, x_1)$		
$x_2 - x$	$y_x(x_2)$	$y_x(x_0, x_2)$	$y_x(x_0, x_1, x_2)$	
$x_3 - x$	$y_x(x_3)$	$y_x(x_0, x_3)$	$y_x(x_0, x_1, x_3)$	$y_x(x_0, x_1, x_2, x_3)$
			

by means of the relations $y_x(x_i) = y_i$ and

$$\begin{aligned} y_x(x_i, x_j) &= \frac{\begin{vmatrix} y_x(x_i) & x_i - x \\ y_x(x_j) & x_j - x \end{vmatrix}}{(x_j - x_i)}, \\ y_x(x_i, x_j, x_k) &= \frac{\begin{vmatrix} y_x(x_i, x_j) & x_j - x \\ y_x(x_i, x_k) & x_k - x \end{vmatrix}}{(x_k - x_i)}, \\ &\dots \end{aligned}$$

Then $y_x(x_i, x_j)$ is the result of linear interpolation based upon the abscissae x_i and x_j ; $y_x(x_i, x_j, x_k)$ that of quadratic interpolation based upon the abscissae $x_i, x_j,$ and $x_k; \dots$. The process may be terminated whenever consecutive entries in a column agree to sufficiently many figures.

It is not necessary that the abscissae be equally spaced, or even ordered, but only that they be distinct. The method of Neville is based upon the same principle but utilizes the table

AITKEN NUCLEI. The microscopic particles in the atmosphere which serve as condensation nuclei for droplet growth during the rapid adiabatic expansion produced by an Aitken dust-counter. These nuclei, often numbering many tens of thousands per cubic centimeter in city air, are both solid and liquid particles whose diameters are of the order of tenths of microns or even smaller.

ALBEDO. (1) The **reflection factor** of a diffusely reflecting surface, e.g., a planet. (2) In particle physics, the albedo is the ratio of the current of particles (neutrons, photons, . . .) reflected from a surface, to the current incident upon the surface. (3) In cosmic ray

physics, albedo refers to those energetic charged secondary cosmic rays which move generally upward. Since some of these particles go far into the upper atmosphere and return to the earth's surface (because of the effect of the earth's magnetic field), measurements of primary cosmic radiation must be corrected for the contribution of the albedo particles. (4) In determining the albedo of a planet, it is evident that observations must be taken at all phases of the object as seen from the earth and an average value obtained. The average values of the albedo for various members of the solar system are:

Mercury... 7%	Saturn.... 42%
Venus.... 59	Uranus... 45
Earth.... 29	Neptune.. 52
Ceres.... 6	Pluto.... 3(?)
Jupiter... 44	

ALFÉN WAVE. (Also called magnetohydrodynamic wave.) A transverse wave in a **magnetohydrodynamic** field in which the driving force is the tension introduced by the magnetic field along the lines of force. The dynamics of such waves are analogous to those in a vibrating string, the phase speed being given by

$$C^2 = \mu H^2 / 4\pi\rho,$$

where μ is the permeability, H the magnitude of the magnetic field, and ρ the fluid density. Dissipative effects due to fluid viscosity and electrical resistance may also be present. (For further details see T. G. Cowling, *Magneto-hydrodynamics*, Interscience, 1957.)

ALGEBRA. In general, algebra is the theory of multiplication and addition; see **field**, etc. Specifically, an algebra (the concept is important, e.g., in quantum mechanics, and in crystallography) is defined as follows:

Let K be any field (in physical practice, usually a complex field) whose elements we shall call scalars. Let γ_{ijk} , with $i, j, k = 1, 2, \dots, n$, be any n^3 elements of K . Then the set of all ordered n -tuples (x_1, x_2, \dots, x_n) of element of K is called an algebra over K if addition, multiplication and scalar multiplication are defined thus:

$$\begin{aligned} (x_1, x_2, \dots, x_n) + (y_1, y_2, \dots, y_n) \\ = (x_1 + y_1, x_2 + y_2, \dots, x_n + y_n) \end{aligned}$$

$$\begin{aligned} (x_1, x_2, \dots, x_n)(y_1, y_2, \dots, y_n) \\ = (\gamma_{ij1}x_i y_j, \gamma_{ij2}x_i y_j, \dots, \gamma_{ijn}x_i y_j), \\ \lambda(x_1, x_2, \dots, x_n) = (\lambda x_1, \lambda x_2, \dots, \lambda x_n), \end{aligned}$$

where λ is a scalar and we have used the summation convention. Setting

$$\begin{aligned} l_1 = (1, 0, \dots, 0), l_2 = (0, 1, \dots, 0), \dots, l_n \\ = (0, 0, \dots, 1) \end{aligned}$$

we have $(x_1, x_2, \dots, x_n) = x_i l_i$, and $l_i l_j = \gamma_{ijk} l_k$. The l_i form a basis of the algebra and the γ_{ijk} are its structure constants.

ALGEBRAIC EQUATIONS. An equation, or set of **simultaneous equations**, in which the unknowns occur as rational functions only. Hence the equations are expressible by equating polynomials to zero. Here the case of a single equation in one unknown is considered:

$$\begin{aligned} a_0 P(x) \equiv a_0 x^n + a_1 x^{n-1} + \dots + a_n = 0, \\ a_0 \neq 0, \end{aligned}$$

where the a_i do not depend upon x , and are called the coefficients of the equation, while n is the degree. This equation is equivalent to

$$\begin{aligned} P(x) \equiv x^n - c_1 x^{n-1} + \dots + (-1)^n c_n = 0, \\ c_i = (-1)^i a_i / a_0, \end{aligned}$$

where the c_i are the elementary **symmetric functions** of the roots x_i .

The *remainder theorem* states that if $a_0 P(x)$ is divided by $x - r$, the remainder is $a_0 P(r)$:

$$a_0 P(x) \equiv (x - r)Q(x) + a_0 P(r);$$

the *factor theorem* is a corollary and states that if r is a root of $P(x) = 0$, then $x - r$ divides $P(x)$. The "fundamental theorem of algebra" states that every algebraic equation has a root, real or complex. These theorems imply that $P(x)$ can be factored completely:

$$P(x) = (x - x_1)(x - x_2) \dots (x - x_n),$$

each x_i being a root. If $x_i = x_j$ for some $i \neq j$, then $x_i = x_j$ is a double root; if $x_i = x_j = x_k$, a triple root, \dots . Counting a root x_i of multiplicity m as being m coincident roots, one says that an algebraic equation of degree n has exactly n roots (neither more nor less). A **Taylor series** expansion gives

$$\begin{aligned} P(x - r) = P(r) + (x - r)P'(r) + \dots \\ + (x - r)^n P^{(n)}(r) / n! \end{aligned}$$

Hence r is a root of multiplicity m if and only if $0 = P(r) = P'(r) = \dots = P^{(m-1)}(r) \neq P^{(m)}(r)$, hence r satisfies the derived equations

$$P^{(i)}(x) = 0, \quad i = 0, 1, \dots, m - 1.$$

In general, setting $y = x - r$, if

$$b_i = P^{(n-i)}(r)/(n - i)!,$$

then any root of

$$y^n + b_1y^{n-1} + \dots + b_n = 0$$

is r less than a root x_i , hence the roots are said to have been reduced by r . Repeated **synthetic division** can be applied to the original equation to obtain the b_i , since $b_n = P(r)$ is the remainder after dividing $P(x)$ by $x - r$; b_{n-1} that after dividing the quotient by $x - r$; \dots .

Other useful transformations are the following:

The roots of

$$a_0y^n - a_1y^{n-1} + \dots + (-1)^na_n = 0$$

are the negatives of the roots of the original; those of

$$a_0y^n + a_1\alpha y^{n-1} + \dots + a_n\alpha^n = 0$$

are α times the roots of the original; those of

$$a_ny^n + a_{n-1}y^{n-1} + \dots + a_0 = 0$$

are the reciprocals of those of the original. These can be derived by setting $x = -y$, $x = y/\alpha$, and $x = 1/y$.

When the coefficients a_i are integers, then any rational root when expressed as a fraction p/q in lowest terms is such that p divides a_n and q divides a_0 without remainder. In particular, any integral root must be a divisor of a_n . In principle all rational roots can be found exactly, and once any root r is known, all other roots must satisfy $Q(x) = 0$ where $Q = P/(x - r)$. For irrational roots see **Budan theorem**, **Sturm theorem**, **Horner method**, **Newton method**, **Bernoulli method**, **Graeffe method**, **iterative methods**.

While these methods, except for Horner's, apply as well to complex roots as to real, it may be convenient to evaluate $P(z)$ with $z = x + iy$, and write

$$P(z) = R(x, y) + iJ(x, y),$$

after collecting real and pure imaginary terms.

Then

$$R(x, y) = J(x, y) = 0$$

are two **simultaneous equations** in x and y , and any real solution (x, y) determines a complex solution $z = x + iy$ of $P(z) = 0$. More to be recommended, however, is the **Bairstow method** for complex roots, which is, in fact, an adaptation of Newton's method to complex roots.

ALGEBRA OF A GROUP. The algebra of polynomials, with coefficients in a field K , of the elements a_1, a_2, \dots, a_n of a finite group G , where if

$$x = k_1a_1 + k_2a_2 + \dots + k_na_n$$

$$y = k'_1a_1 + k'_2a_2 + \dots + k'_na_n,$$

then

$$x + y = (k_1 + k'_1)a_1 + \dots + (k_n + k'_n)a_n$$

and $xy = l_1a_1 + l_2a_2 + \dots + l_na_n$,

where x and y have been multiplied together as polynomials, the product a_ia_j being determined by the law of multiplication of the group.

ALGORITHM. A term derived from the word algorism, which meant the art of computing with Arabic numerals. The term algorithm is now used (1) to denote any method of computation, whether algebraic or numerical, or (2) any method of computation consisting of a comparatively small number of steps; the steps to be taken in a preassigned order and usually involving iteration, which are specifically adapted to the solution of a problem of some particular type. The best known example is Euclid's algorithm for finding the highest common factor of two given numbers. Algorithms play an important role in the theory of computing machines.

ALIASING. The introduction of error in the **Fourier analysis** of a discrete sampling from continuous data, by which frequencies too high to be analyzed with the given sampling interval contribute to the amplitude of lower frequencies. (See also **Nyquist frequency**.)

ALIENATION. A term used, mainly in psychology, to denote the departure of random variables from dependence on one another. If r is the coefficient of **correlation** between two variables x and y , their *coefficient of alienation* is defined as $\sqrt{(1 - r^2)}$. Likewise, if x and y

are p -way and q -way vectors with dispersion matrices v_1 and v_2 and if v is the dispersion matrix of all $(p + q)$ variables together, the vector alienation coefficient is defined as $\sqrt{\{|v|/|v_1||v_2|\}}$.

ALLOWED TRANSITION. See transition, allowed; selection rules; transition, forbidden.

ALPHA DISINTEGRATION (ALPHA DECAY). The process whereby a nucleus disintegrates spontaneously with the emission of an alpha particle (see radioactivity). The alpha particle is assumed to be formed at the instant of emission at the surface of the nucleus.

ALPHA DISINTEGRATION ENERGY. (1) The energy of disintegration of an α -disintegration process, equal to the value $Q_\alpha = E_\alpha + E_R$ where Q_α is the α -disintegration energy, E_α is the kinetic energy of the α -particle, and E_R is the recoil kinetic energy of the product atom. If M_α and M_R are the masses of the α -particle and the recoil atom, respectively, then

$$E_\alpha = \frac{M_R}{M_R + M_\alpha} Q_\alpha$$

and

$$E_R = \frac{M_\alpha}{M_R + M_\alpha} Q_\alpha.$$

(2) Often, the ground state α -disintegration energy, which is the total energy evolved, including the energy of gamma and associated radiations, when the disintegrating and product nuclei are in their ground states: Q_α .

ALPHA-PARTICLE MODEL OF NUCLEI.

The nuclei of mass $A = 4n$ and charge $Z = 2n$, where n is an integer, are known to have binding energies somewhat in excess of their neighbors, and approximately equal to the total binding energy of n free alpha-particles, or helium nuclei. For example, the binding energy of O^{16} is 127 Mev, whereas that of 4 free α -particles is 113 Mev. Consequently a model has been proposed whereby these nuclei are supposed to consist of more or less stable α -particles as sub-units bound together by weak residual attraction forces similar to the van de Waals forces in molecules. The theory does not stand up to detailed investigation.

ALTERNATING CURRENT (A-C). Current in which the charge-flow periodically reverses, as opposed to direct current, and whose average value is zero.

ALTERNATING CURRENT CIRCUIT. Suppose that any element of a circuit, such as a straight wire, a coil, or a capacitor, carries a current that varies periodically with the time t . A simple example occurs when the current I can be expressed as

$$I = I_o \cos \omega t = I_o \cos 2\pi ft,$$

where I_o is a constant amplitude, f is the frequency, and ω is the angular frequency. The potential difference required to maintain this current is then also periodic and can be shown to be

$$V = V_o \cos (\omega t + \phi),$$

where V_o is the voltage amplitude and ϕ is the phase angle. Further,

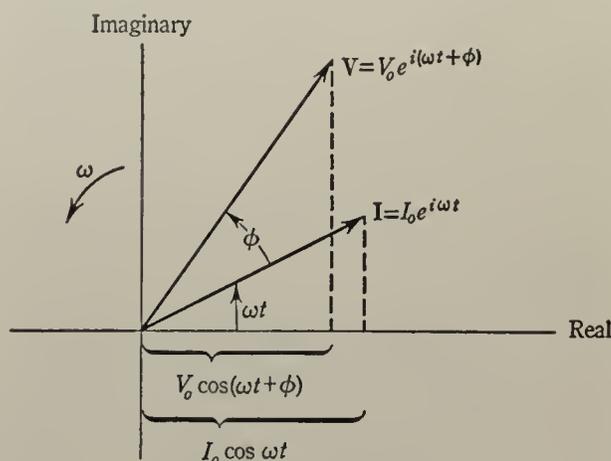

$$V_o = I_o Z,$$

where Z is the magnitude of a quantity known as the impedance, and

$$\tan \phi = X/R$$

where X is the reactance and R is the effective resistance.

It is often convenient to express the current through and voltage across the circuit element by a **complex number**, $\mathbf{I} = I_o e^{i\omega t}$ or $\mathbf{V} = V_o e^{i(\omega t + \phi)}$ and to consider the instantaneous current or voltage to the real part of the number. The situation can then be represented on an Argand diagram as shown in the figure. The

Argand diagram for an alternating current circuit.

vectors \mathbf{I} and \mathbf{V} are then each of constant length, I_o and V_o respectively, and both rotate about the origin with an angular velocity ω , so that the phase angle ϕ between them remains constant. Then one can write

$$\mathbf{V} = \mathbf{Z}\mathbf{I} = (R + iX)\mathbf{I},$$

where \mathbf{Z} is the (complex) impedance and $i = \sqrt{-1}$.

The magnitude of \mathbf{Z} is then

$$Z = (\mathbf{Z}\mathbf{Z}^*)^{1/2} = (R^2 + X^2)^{1/2},$$

\mathbf{Z}^* being the **complex conjugate** of \mathbf{Z} .

For a pure **resistance** R :

$$\mathbf{Z}_R = Z_R = R; \quad \phi_R = 0;$$

for a pure **inductance** L :

$$\mathbf{Z}_L = iZ_L = i\omega L; \quad \phi_L = 90^\circ;$$

and for a pure **capacitance** C :

$$\mathbf{Z}_C = iZ_C = -i/\omega C; \quad \phi_C = -90^\circ.$$

Any real circuit element can either be approximated (at a particular frequency) by one of the ideal elements mentioned above or can be considered to be built up of a combination of such elements. Thus a coil of wire, such as a solenoid, can often be considered to consist of a resistance R in series with an inductance L . When it carries an alternating current \mathbf{I} , the potential difference across its terminals is

$$\mathbf{V} = \mathbf{I}R + i\mathbf{I}X_L = \mathbf{I}Z,$$

so that

$$\mathbf{Z} = R + i\omega L \quad \text{and} \quad Z = (R^2 + \omega^2 L^2)^{1/2}$$

and

$$\tan \phi = L/R.$$

Similarly, a capacitor or condenser can be approximated as a pure capacitance C in parallel with a leakage resistance R . Then, if \mathbf{I}_R is the current through the resistance and \mathbf{I}_C that through the capacitance,

$$\mathbf{V} = \mathbf{I}_R R = i\mathbf{I}_C X_C = -i\mathbf{I}_0/\omega C.$$

Taking the total current $\mathbf{I} = \mathbf{I}_R + \mathbf{I}_C$, it is found that

$$\mathbf{Z} = \mathbf{V}/\mathbf{I} = R(1 - i\omega CR)/(1 + \omega^2 C^2 R^2),$$

$$Z = R/(1 + \omega^2 C^2 R^2)^{1/2}$$

and

$$\tan \phi = -\omega CR.$$

Complex circuits may be built up of combinations of elements of the type discussed and the impedance of the combination found by the applications of the **Kirchhoff laws** of networks to the instantaneous currents through and potential drops across the elements. When the current variation is more complicated than

that expressed by the simple sinusoidal function, e.g., if it includes a third harmonic:

$$I = I_1 e^{i\omega t} + I_3 e^{3i\omega t},$$

a separate solution may be carried out for each value of ω and the real parts of resulting instantaneous currents and voltages may be added.

At any instant, energy is supplied to a circuit element at the rate

$$\begin{aligned} P_i &= IV = [I_o \cos \omega t][V_o \cos (\omega t + \phi)] \\ &= I_o V_o (\cos^2 \omega t \cos \phi - \sin \omega t \cos \omega t \sin \phi). \end{aligned}$$

This instantaneous power may be either positive or negative; when $\phi \neq 0$ power is delivered to the circuit during part of the cycle and returned to the source during other parts. The net energy delivered during any single cycle is

$$\begin{aligned} E &= \int_0^{2\pi/\omega} P_i dt = I_o V_o \left[\cos \phi \int_0^{2\pi/\omega} \cos^2 \omega t dt \right. \\ &\quad \left. + \sin \phi \int_0^{2\pi/\omega} \sin \omega t \cos \omega t dt \right]. \end{aligned}$$

The average power is $P = Ef + E\omega/2\pi$. As the second integral above is zero, the only contribution comes from the first integral, which has the value π/ω . Hence

$$P = \frac{1}{2} I_o V_o \cos \phi = I_{rms} V_{rms} \cos \phi,$$

where I_{rms} and V_{rms} are respectively the root-mean-square (or effective) current and the root-mean-square voltage. The factor $\cos \phi$, giving the ratio of the power to the product of the effective current and effective voltage, is called the *power factor*. (See also **multiphase circuits**.)

ALTERNATING GRADIENT FOCUSING.

The qualitative concept involved in alternating gradient focusing can best be seen by considering a charged particle moving in the z -direction of a Cartesian coordinate system. If from $z = 0$ to $z = A$ there is a magnetic flux density \mathbf{B} , whose x and y -components are respectively $B_o x$ and $B_o y$ where B_o is a constant, and if from $z = A$ to $z = 2A$ there is a flux density with the x and y -components respectively, $-B_o x$ and $-B_o y$, then the particle which is moving along the z -direction will obtain a velocity directed towards the z -axis by the time it reaches $z = 2A$. In other words, a sequence of alternating gradient fields will tend to focus the particle towards the axis.

This principle is used in high energy accelerators to prevent spreading of the beam.

ALTERNATING GROUP. The group of even permutations of n objects.

ALTERNATING SERIES. A series whose terms are alternately positive and negative. The alternating series test for convergence states that if the terms of an alternating series decrease monotonically in absolute value to zero, then the series converges.

ALTERNATING TENSOR. See **tensor, alternating**.

ALTERNATION OF MULTIPLICITIES. See **multiplicities, alternation of**.

ALTERNATIVE (THEOREM OF THE, FOR LINEAR EQUATIONS). The system

of n linear equations in n unknowns $\sum_{k=1}^n a_{ik}x_k =$

y_i , ($i = 1, 2, \dots, n$) with fixed a_{ij} , either has a unique solution for every set of constants y_i or else the corresponding homogeneous equations (with $y_i \equiv 0$) have a positive number r , with $0 < r \leq n$, of linearly **independent** solutions $x_{11}, x_{12}, \dots, x_{1n}, \dots, x_{r1}, x_{r2}, \dots, x_{rn}$, in which

case the transposed equations $\sum_{k=1}^n a_{ki}z_k = 0$,

also have r linearly independent solutions $z_{11}, z_{12}, \dots, z_{1n}, \dots, z_{r1}, z_{r2}, \dots, z_{rn}$ and the original (non-homogeneous) equations are solvable only if y_1, y_2, \dots, y_n is orthogonal to every

$z_{i1} \dots z_{in}$, that is only if $\sum_{j=1}^n y_j z_{ij} = 0$, $i =$

$1, 2, \dots, r$ the solution then being uniquely determined, except that any solution of the homogeneous equations may be added to it. (Compare **Fredholm theorem for integral equations**.)

ALTITUDE (ASTRONOMIC). The coordinate of a celestial object, on the horizontal system of coordinates, that is measured from the horizon along the vertical circle through the object through 90° . The determination of altitude is the fundamental observation for the determination of a line of position on which the ship (either air or sea borne) is located. The measurement of altitude of the pole star by sailors, for determination of the latitude of their ship, has been referred to in literature for at least 2500 years. The altitude of an object is determined by navigators by the use

of a sextant, either of the mariner's or the bubble type. When the mariner's sextant is used, the altitude of the lower limb of an astronomic object is measured from the apparent horizon. To obtain the astronomic altitude the observed altitude must be corrected for instrumental errors, dip of the horizon, refraction, and semi-diameter (if the altitude of the lower limb of the sun or moon was measured). If the bubble type of sextant is used, corrections must be applied for instrumental errors, refraction, and **Coriolis force**.

AMAGAT COORDINATES. Representation of the equation of state of a substance involving a family of isotherms plotted in a system of coordinates PV versus P . In the case of a perfect gas ($PV = RT$) this gives a family of straight horizontal lines; hence, in the case of a real gas, the diagram shows up clearly the deviations from perfect-gas behavior.

AMAGAT LAW. (Also known as the Leduc law.) The volume of a mixture of (perfect) gases is equal to the sum of the volumes of the components, each taken at the (total) pressure and temperature of the mixture.

AMAGAT UNIT. A unit of volume often used in the study of the equation of state for gases. It is by definition the molar volume of the gas at 0°C and 1 atmosphere. The exact value of this unit depends upon the gas considered, but is approximately equal to 2.24×10^4 cm^3/mole .

AMPERE. A unit of electrical current, abbreviated as A or amp. (1) The absolute ampere is exactly one-tenth of an **abampere**, the electromagnetic unit of current. The absolute ampere has been the legal standard of current since 1950. (2) The International ampere, the legal standard before 1950, is the steady current which must flow across a surface in order that one International **coulomb** of charge shall pass the surface during each second. 1 Int. amp = 0.999835 abs. amp.

AMPERE LAW. The term is used loosely for any one of several expressions that connect the magnetic field produced by a steady current with the magnitude of the current and the geometry of the system. In the following discussion rationalized MKSA units are used; to adapt to other systems see **electromagnetic units**.

The differential form, sometimes called the *Laplace law*, gives the field $d\mathbf{H}$ produced by a current I flowing in a differential length $d\mathbf{l}$ of a filamentary conductor as $d\mathbf{H} = I (d\mathbf{l} \times \mathbf{r}/r^3$, where \mathbf{r} is the (vector) displacement of the point at which the field is measured from the element $d\mathbf{l}$. The differential vector $d\mathbf{l}$ has the same sense as the (positive) current flow. (For meaning of $d\mathbf{l} \times \mathbf{r}$ see **vector product**.) After integration over an infinitely long straight filament, this form of the law yields the **Biot-Savart law**.

The integral, or circuital form of the law states that

$$\oint \mathbf{H} \cdot d\mathbf{s} = I,$$

where the line integral is taken around any closed path that encloses the current I . (For the meaning of $\mathbf{H} \cdot d\mathbf{s}$ see **scalar product**.) The value of this integral is often called the *magnetomotive force*. When this form of the law is combined with a **symmetry argument** it, like the differential form, leads to the Biot-Savart law.

In the course of the development of his electromagnetic theory, Maxwell modified the Ampere law to allow for the effect of **displacement currents**, as well as conductive currents.

The Biot-Savart law is sometimes called the Ampere law.

AMPERE RULE. The magnetic flux generated by a current in a wire encircles the current in the counterclockwise direction, if the current is approaching the observer. This is also referred to as the "right-hand rule," since if the thumb of the right hand is directed along the current, the fingers will curl in the direction of the magnetic flux.

AMPERE THEOREM. The magnetic field due to an electric current flowing in any circuit is equivalent at external points to that due to a simple magnetic shell, the bounding edge of which coincides with the conductor, and the strength of which is equal to the strength of the current. (See **magnetic shell, equivalent**.)

AMPERE TURN. The unit of magnetomotive force in MKSA units. The integral form of Ampere's law gives the magnetomotive force as

$$\mathcal{H} = \oint \mathbf{H} \cdot d\mathbf{s} = I = Ni,$$

where I is the total current enclosed by the line integral. This total current may result from N turns of wire each carrying a current i . Thus a magnetomotive force of 1 ampere turn may result from 1 ampere flowing in 1 turn of wire, from 0.1 ampere flowing in 10 turns of wire, etc.

AMPERE TURN PER METER. The unit of magnetic field strength, \mathbf{H} , in the MKSA system. A magnetic field strength of magnitude equal to that inside a long solenoid having N turns in a length L , where $N/L =$ one meter. (See **ampere turn**.)

AMPERIAN CURRENTS. The complete equivalence between magnetic dipoles of magnetized matter and of circulating electric currents enables one to postulate that the magnetization of matter is due to circulating currents, known as Amperian currents (or *magnetization currents*). Unlike ordinary currents, the flow of Amperian currents is persistent and involves no dissipation. Amperian currents are due to the orbital and spin magnetic moments of electrons.

AMPLIFICATION FACTOR. A measure of the relative effectiveness of voltages on the plate and grid of a vacuum tube, defined as the negative of the ratio of the infinitesimal plate voltage change necessary to counteract a given infinitesimal change in grid voltage in order to keep the plate current constant.

$$\mu \equiv \left(- \frac{\partial V_p}{\partial V_g} \right)_{i_p \text{ const.}}$$

AMPLITUDE. (1) If a complex number is represented in polar coordinates it becomes $r(\cos \theta + i \sin \theta)$ and the angle θ is the amplitude, argument, or phase of the number. (See **de Moivre theorem**.) The term is also used to designate a parameter occurring in **elliptic functions** and **integrals**. (2) The crest or maximum value of a periodic (or specifically a simple harmonic) function of space or time or, more generally, any parameter that when changed, merely represents a change in scale factor. In amplitude-modulation systems, this quantity becomes a function of time, and its instantaneous value is of importance, but it is still referred to as the amplitude.

AMPLITUDE (INITIAL). The maximum displacement from a reference point of a pe-

riodic function. The periodic function can describe the motion of a pendulum point, the motion of a point on a spring or of a point on a mechanical system which is performing oscillatory motion or it may represent the motion of a wave in a medium.

AMPLITUDE EQUATIONS, FINITE ACOUSTIC. See **finite amplitude equations (acoustic)**.

AMPLITUDE OF NORMAL CURVATURE. See **curvature, amplitude of normal**.

AMPLITUDE OF OSCILLATION. The maximum excursion from the mean position is called the amplitude, e.g., A in the **simple harmonic** oscillation $x = A \sin(\omega t + \phi)$. Also used less precisely to denote the excursion, x at any time t .

A.M.U. See **atomic mass unit**.

ANABATIC WIND. An up-slope wind, particularly noticeable on hillsides warmed by sunshine when the air in a valley is stably-stratified or when large stationary convection clouds (cumulus) are situated over the hill-tops.

ANALOG COMPUTER. A computing device in which quantities are directly represented by physical magnitudes: distances, voltages, currents, rotations, etc. Hence the mathematical operations are direct operations upon these magnitudes. Examples are slide rules, differential analyzers, and most special purpose computers, as well as wind tunnels and model basins. Analog computers are to be contrasted with **digital computers**, although hybrid forms exist. Most often, as in digital differential analyzers, in overall use the machine appears as an analog machine but contains components that operate digitally.

ANALOGOUS SYSTEMS (NETWORKS). Systems whose behavior is described by the same type of equations.

ANALOG-TO-DIGITAL CONVERTER. Any device for providing a digital representation of quantities initially represented in analog form, i.e., by physical magnitudes.

ANALYSIS. That branch of mathematics which deals with limit processes. Analysis may thus be regarded as a branch of topology.

Traditionally, the name is given to the study of functions of real or complex variables arising naturally from the differential and integral calculus.

ANALYSIS OF COVARIANCE. An extension of the **analysis of variance**. In the latter the analysis is concerned with sources of variability affecting a set of observations of a single variable y . It may be that there exist variables x (say one for simplicity) which are correlated with y but unaffected by sources of variability; and we wish to abstract the effect of x from y before analyzing the latter. For example, in an agricultural field-trial to test different fertilizers on certain plots, there may be prior differences in fertility in the plots (x) which can be measured and affect the yields (y), whereas our object is to test the effect of treatments on y irrespective of x . The object is attained by finding the **regression** of y on x , removing the effect of x and testing the residual values of y in a variance analysis. The process involves the calculation of variances of x and y and their covariance—hence the name. The procedure can be extended to many variables and exact tests of significance are available.

ANALYSIS OF VARIANCE. Basically an arithmetical technique for segregating the sources of variability affecting a set of observations. Two main types of analysis may be distinguished, and the simplest cases of each are described below.

(1) Suppose we have n observations in each of m classes and assume that the j th observation in the i th class can be written in the form

$$y_{ij} = a + b_i + c_{ij} \\ i = 1 \cdots m; \quad j = 1 \cdots n,$$

where b_i, c_{ij} are variates distributed about zero with variances σ_b^2, σ_c^2 . We can calculate a sum of squares about the overall mean, $\sum_{i,j} (y_{ij} - \bar{y})^2$, with $(mn - 1)$ **degrees of freedom** from the whole set of observations. From each class we can calculate a sum of squares about the class mean, $\sum_{i,j} (y_{ij} - \bar{y}_i)^2$, with $(n - 1)$ d.f.; the corresponding mean square will estimate σ_c^2 , and the best estimate is obtained by pooling these sums of squares and degrees of freedom within classes. In the same way we can calculate a sum of squares between

classes, with $(m - 1)$ d.f., as $n \sum_i (\bar{y}_i - \bar{y})^2$ (in practice, class totals rather than class means would be used in the computation); the **expected value** of the corresponding mean square is $n\sigma_b^2 + \sigma_c^2$. The degrees of freedom and the sums of squares between and within classes should total exactly to the total degrees of freedom and sum of squares. The computations can be conveniently set out in an analysis of variance table as shown:

Source of Variation	D.F.	S.S.	Expected M.S.	M.S.
Between classes...	$m - 1$	$n \sum_i (\bar{y}_i - \bar{y})^2$	$n\sigma_b^2 + \sigma_c^2$	
Within classes...	$m(n - 1)$	$\sum_i \sum_j (y_{ij} - \bar{y}_i)^2$	σ_c^2	
Total...	$(mn - 1)$	$\sum_{i,j} (y_{ij} - \bar{y})^2$		

If $\sigma_b^2 = 0$, the two mean squares form independent estimates of σ_c^2 and their ratio therefore follows the **F-distribution** if we assume normal distributions. An estimate of σ_b^2 is given by

$$\left(\frac{\text{M.S. between classes} - \text{M.S. within classes}}{n} \right)$$

The quantity $\sqrt{(1 - \sigma_c^2 / (\sigma_b^2 + \sigma_c^2))}$ is called the intra-class correlation; it measures the resemblance of two members of the same class as compared with two unrelated individuals.

(2) Suppose that the observations can be classified in two ways and that we can write

$$y_{ij} = a + b_i + c_j + \epsilon_{ij}$$

$$i = 1 \cdots m; \quad j = 1 \cdots n,$$

$$\sum b_i = 0, \quad \sum c_j = 0$$

where a, b_i, c_j are constants and ϵ_{ij} is a random variate with mean zero and variance σ^2 . The observations can now be set out in a two-way table, and if we denote the row and column means by \bar{y}_i, \bar{y}_j , we can calculate two sums of squares

$$n \sum_i (\bar{y}_i - \bar{y})^2, \quad m \sum_j (\bar{y}_j - \bar{y})^2$$

with $(m - 1)$ and $(n - 1)$ d.f. which measure the amount of variation between these means. Subtracting these from the total sum of squares, $\sum_{i,j} (y_{ij} - \bar{y})^2$ with $(mn - 1)$ d.f., we are left with a residual sum of squares with $(m - 1)$

$(n - 1)$ d.f.; the corresponding mean square provides an estimate of σ^2 . The analysis of variance table now takes the form

Source of Variation	D.F.	S.S.	M.S.
Difference between b 's...	$m - 1$	$n \sum_i (\bar{y}_i - \bar{y})^2$	
Difference between c 's...	$n - 1$	$m \sum_j (\bar{y}_j - \bar{y})^2$	
Residual.....	$(m - 1)(n - 1)$	by subtraction	s^2
Total.....	$(mn - 1)$	$\sum_{i,j} (y_{ij} - \bar{y})^2$	

If all the b 's are zero, the first mean square in the table provides an independent estimate of σ^2 , and an overall test of significance for differences between the b 's can thus be derived from **Fisher's distribution**; the c 's can similarly be tested by means of the second mean square. More usefully, the variance of a row mean is estimated as s^2/n and that of a column mean as s^2/m . Fiducial or confidence limits for single mean or for a **contrast** between the means can therefore be derived using the **t-distribution** with $(m - 1)(n - 1)$ d.f.

(3) The analysis of variance can usefully be applied to **regression** problems, of which (2) above is a special case. Suppose that the **normal equations** arising in the regression calculations are

$$a_{11}b_1 + a_{12}b_2 + \cdots + a_{1p}b_p = h_1$$

$$a_{21}b_1 + a_{22}b_2 + \cdots + a_{2p}b_p = h_2$$

$$a_{p1}b_1 + a_{p2}b_2 + \cdots + a_{pp}b_p = h_p$$

Then we can set up an analysis of variance in the form

Source of Variation	D.F.	S.S.	M.S.
Regression....	p	$\sum_i b_i h_i$	
Residual.....	$n - p - 1$	by subtraction	s^2
Total.....	$n - 1$	$\sum (y - \bar{y})^2$	

and the mean square in the second line estimates the variance of the deviations of the observations from their expected values. (See also **analysis of covariance**.)

ANALYTIC CONTINUATION. If the function $f_1(z)$ is analytic in a domain D_1 of the complex plane and $f_2(z)$ in a domain D_2 partly overlapping D_1 , and if $f_1(z) = f_2(z)$ in the overlapping part, then $f_2(z)$ is called the analytic continuation of $f_1(z)$. The method of obtaining $f_2(z)$ from $f_1(z)$ consists of ex-

pressing $f_1(z)$ as a power series with a certain circle of convergence; then re-arranging the series about a different center so that its new circle of convergence extends beyond the old one and so on successively.

ANALYTIC CURVE. A curve whose parametric equations, in three dimensions for example, are of the form,

$$x = x(t), \quad y = y(t), \quad z = z(t),$$

where $x(t)$, $y(t)$, $z(t)$ are analytic functions of the real variable t .

ANALYTIC FUNCTION. A function of a real or complex variable is analytic at a point if it can be represented in a neighborhood of this point by its **Taylor series** about it. A function of a complex variable z , say $w(z)$, is analytic at any point in the z -plane if it is regular there, i.e., if $w(z)$ and $\frac{d}{dz} \{w(z)\}$ are both finite and single-valued at the point. If this is true for all points on a contour or in a certain region, $w(z)$ is analytic on that contour or within that region.

If $z = x + iy$ and $w = u + iv$, where x, y, u, v are real, then $w(z)$ is analytic at any point where the **Cauchy-Riemann relations**

$$\frac{\partial u}{\partial x} = \frac{\partial v}{\partial y} \quad \text{and} \quad \frac{\partial v}{\partial x} = -\frac{\partial u}{\partial y}$$

hold and where the partial derivatives involved are continuous.

ANAMORPHIC SYSTEM. An optical system in which the magnification is a function of direction in the image plane.

ANASTIGMAT. An optical instrument that is corrected for astigmatism and curvature of field, i.e., which satisfies **Petzval's condition**.

ANCILLARY STATISTIC. In the theory of statistical estimation, a function of the observations which adds information additional to that furnished by the statistic used as an estimate. The term was introduced by R. A. Fisher who appears, however, to have altered the meaning so that estimation with the use of an ancillary statistic is now equivalent to **conditional estimation**.

ANELASTIC MATERIAL. A material having a constitutive equation which includes non-elastic effects, such as viscoelasticity or plasticity.

ANEMOMETER LEVEL. (1) A level above the surface of the earth which is taken as the initial point of the **Ekman spiral**. Below this level is the **surface boundary layer**, above it the **Ekman layer**. (2) The height above the ground at which an anemometer is exposed; or, vaguely, the ideal height of exposure.

ANGLE CHANGE, BALANCING. A complementary procedure to **moment distribution** for solving **rigid frame** problems by successive approximations. Angle changes instead of moments are determined. Clockwise rotation is taken as positive (see **slope-deflection**).

ANGLE CHARACTERISTIC FUNCTION. If F, F' are the feet of perpendiculars from the origin onto a ray in object, image space, respectively, then the angle characteristic function T is the optical path length along the ray from F to F' . If (p, q, r) and (p', q', r') are the optical direction cosines of the ray in object and image spaces, then

$$T = T(p, q, r, p', q', r')$$

and T is simply related to the point characteristic function (see **Hamilton's characteristic**.)

$$T = V(x, y, z, x', y', z') + (px + qy + rz) - (p'x' + q'y' + r'z')$$

where (x, y, z) and (x', y', z') are the object and image points on the ray. The properties of T are thus simply obtained from the properties of V , but for many applications T is the most convenient characteristic function. In particular, there is the elimination rule for calculating the angle characteristic of a stratified medium:

Find the characteristic T_i , $i = 1, 2, \dots, n$, for each layer of the stratified medium. The angle characteristic for a pair of consecutive layers is then

$$T_{i, i+1} = T_i + T_{i+1}$$

where the intermediate variables are eliminated by means of equations expressing the fact that the sum so obtained has a stationary value with respect to arbitrary variations of the intermediate variables. Iterating this process leads to the characteristic of the stratified medium.

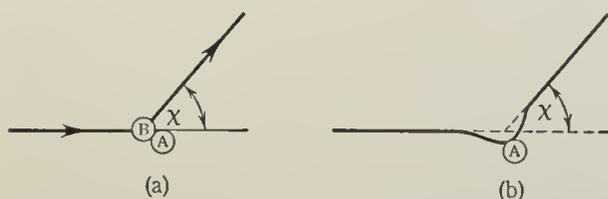

$$T_{1, 2 \dots, n} = T_1 + T_2 + \dots + T_n.$$

ANGLE OF ATTACK. See **angle of incidence**.

ANGLE OF CONTACT. See *capillarity*.

ANGLE OF CONVERGENCE. When the gaze is fixed on a point P in the binocular field of view then the angle between the rays through P and the nodal points of the eyes is the angle of convergence. (See *Vieth-Müller torus*.)

ANGLE OF DEFLECTION. The angle χ between the relative velocity vectors before and after the collision of two molecules. For hard spheres (see *hard sphere model*), χ depends on the *impact parameter* b only. For

Angle of deflection χ in the case of a collision between two hard spheres (a) and in that of a more realistic (attractive + repulsive) potential (b).

more realistic potentials, where the intermolecular forces vary continuously with the distance, it depends on both b and the relative velocity. (See figure.)

ANGLE OF DEVIATION. The angular change in the direction of a ray of light, or other electromagnetic radiation, upon entering another medium. (See *angle of incidence*.)

ANGLE OF DIFFRACTION. The angle between the direction of an incident beam of light and any resulting diffracted beam.

ANGLE OF INCIDENCE. See *incidence, angle of*.

ANGLE OF PRINCIPAL AZIMUTH. Circularly-polarized light incident on a metallic surface at the *angle of principal incidence* will be reflected as plane-polarized light. The angle between the plane of vibration of the reflected light and the plane of incidence is the angle of principal azimuth.

ANGLE OF PRINCIPAL INCIDENCE. Plane-polarized light incident at an angle upon a metallic surface becomes in general elliptically-polarized. There is one particular angle of incidence, called the principal angle of incidence, for which one axis of the ellipse lies in the plane of incidence.

ANGLE OF REFLECTION. The angle between a ray of light, after a reflection at a surface, and the normal to the surface. This angle and the angle of *incidence* are in the same plane, and are equal angles.

ANGLE OF REFRACTION. The angle between a ray of light after *refraction* at an interface between two media and the normal to the interface. This angle and the angle of *incidence* are in the same plane. (See the *Snell law*.)

ANGLE OF SHEAR. See *simple shear*.

ANGLE VARIABLE. In classical mechanics, the dynamical variable w conjugate to the *action variable* J , and thus defined only for periodic motion. For such motion of frequency ν , $w = \nu t + \text{const.}$

ANGSTROM (A). The ångström, or ångström unit, named for the pioneer spectroscopist Ångström, is equal to 0.00000001 cm or 10^{-10} meter, and is therefore sometimes called the "tenth-meter." The unit so defined is the *absolute ångström*. To obviate inconvenience due to variation of spectroscopic wavelengths with air pressure, another unit, the *international ångström*, has been adopted, such that the wavelength of the red line of cadmium is exactly 6438.4696 of these units. The two units are equal only in a vacuum.

ANGSTROM COEFFICIENT. The coefficient A in Ångström's formula for the scattering coefficient for dust in the atmosphere.

$$S = A\lambda^{-B}$$

in which λ is wavelength and B depends on the particle size.

ANGSTROM, INTERNATIONAL. See *ångström*.

ANGULAR ACCELERATION. The time rate of change of *angular velocity* is a vector called angular acceleration.

ANGULAR CORRELATION IN NUCLEAR PHYSICS. Successive radiations emitted by atomic nuclei during radioactive decay or nuclear reactions are usually correlated in angle of emission. A measurement of the correlation gives information on the spins of the nuclear energy levels involved in the process.

ANGULAR DIAMETER. See *apparent diameter*.

ANGULAR DISPLACEMENT. Change in angular position. Finite angular displacement is not a vector quantity, although it has both magnitude and direction.

ANGULAR DISTRIBUTION IN NUCLEAR PHYSICS. In nuclear physics, the distribution in angle, relative to an experimentally specified direction, of the intensity of particles or photons resulting from a nuclear or an extra-nuclear process. Commonly, the specified direction is that of an incident beam, and the angular distribution is that of particles which are scattered or are the products of nuclear reactions. In such cases, the angular distribution in the **laboratory system** will depend upon the momenta and angular momenta of the incident and ejected particles. Alternatively, the specified direction might be that of an applied field, or a direction of polarization, or the direction of emission of an associated radiation. The measurement of the angular distribution of radiations emitted in a nuclear process is a common tool for investigating the spins of **nuclear energy levels**.

ANGULAR IMPULSE. The quantity

$$\sum_i \int (\mathbf{r}_i \times \mathbf{F}_i) dt,$$

the time integral of the moment about a given point. Angular momentum is conserved when the sum of the angular impulses of all forces about a fixed point is zero. In general angular impulse about a fixed point equals change in **angular momentum** about the same point.

ANGULAR MAGNIFICATION. In an axially symmetric optical system, the ratio of the tangent of the angle with the optical axis made by a ray upon emergence from the system to the tangent of the angle for the conjugate incident ray.

ANGULAR MOMENTUM. A **conserved quantity** which remains constant in an isolated system. For a single particle of mass m , rotating in a circle of radius r with an angular velocity ω (in radians/second) the angular momentum is $mr^2\omega$. For a symmetric body rotating about a fixed axis the angular momentum is

$$H = (\sum m_i r_i^2) \omega = I \omega,$$

or in vector notation, $\mathbf{H} = I\boldsymbol{\omega}$, where $\boldsymbol{\omega}$ is a vector whose direction is given by the direction

of progression of a right-handed screw. $I = \sum m_i r_i^2$ is the moment of inertia with r_i being the perpendicular distance of the i^{th} mass m_i to the axis of rotation.

For a body not rotating about a fixed axis, the situation is more complicated. The angular momentum of a single particle about a point, whether or not it be moving about this point, is in vector notation $m\mathbf{r} \times \mathbf{v} = m\mathbf{r} \times (\boldsymbol{\omega} \times \mathbf{r})$ where \mathbf{r} is its vector distance to the point, \mathbf{v} its instantaneous velocity, and $\boldsymbol{\omega}$ its instantaneous angular velocity about the point. For a rigid body, the angular momentum is then given by $H = \sum m_i r_i \times (\boldsymbol{\omega} \times r_i) = \sum m_i [r_i^2 \boldsymbol{\omega} - (r_i \cdot \boldsymbol{\omega}) r_i]$. This can be written as:

$$H_x = I_{xx}\omega_x - I_{xy}\omega_y - I_{xz}\omega_z,$$

$$H_y = -I_{yx}\omega_x + I_{yy}\omega_y - I_{yz}\omega_z,$$

$$H_z = -I_{zx}\omega_x - I_{zy}\omega_y + I_{zz}\omega_z,$$

where the I_{xx} , I_{xy} , etc., are the **moments and products of inertia**. In this case we do not in general have $\mathbf{H} = I\boldsymbol{\omega}$. The angular momentum vector thus does not have the same direction as the angular velocity vector; rather angular momentum vector is related to the angular velocity vector by a linear transformation through the moment of inertia tensor, which is defined by the nine components I_{xx} , etc.

If the principal axes are used, the products of inertia vanish and the angular momentum is given by $H_1 = I_{11}\omega_1$, $H_2 = I_{22}\omega_2$, $H_3 = I_{33}\omega_3$, where ω_1 is the component of $\boldsymbol{\omega}$ along principal axis number 1, etc.; and where I_{11} is the moment of inertia computed about axis number 1, etc. For the special case of a body rotating about a principal axis we again have $\mathbf{H} = I\boldsymbol{\omega}$.

ANGULAR MOMENTUM (ATOMIC AND NUCLEAR PHYSICS). The angular momentum, or moment of momentum, of an elementary particle or system of such particles that either (1) spins about an axis or behaves as though it spins about an axis, or (2) revolves in an orbit or behaves as though it revolves in an orbit. For an elementary particle, the angular momentum associated with axial rotation is called the *intrinsic angular momentum*, or **spin**. When a nucleus is considered as a single particle, its total angular momentum is also referred to as its spin. For an elementary particle, the component in a particular direction of both kinds of angular momentum is quantized; the quantum of spin

angular momentum is $\frac{1}{2}\hbar$, and the quantum of orbital angular momentum is \hbar .

The three Cartesian components of angular momentum are defined in quantum mechanics by the commutator relations

$$[J_x, J_y] = i\hbar J_z \quad (\text{and cyclic permutations})$$

where $2\pi\hbar$ is Planck's constant. It then follows that the square of the total angular momentum

$$\mathbf{J}^2 = J_x^2 + J_y^2 + J_z^2$$

commutes with each of the three components. Simultaneous eigenstates of \mathbf{J}^2 and any one component, say J_z , may then be constructed. They satisfy the eigenvalue equations

$$\mathbf{J}^2\phi(jm) = j(j+1)\hbar^2\phi(jm)$$

$$J_z\phi(jm) = m\hbar\phi(jm)$$

where j is integral or half-integral, and m runs in integer steps from $-j$ to $+j$. The orbital angular momentum $\mathbf{L} = \mathbf{r} \times \mathbf{p}$ satisfies these relations, provided the quantum numbers j and m are in this case integral. The half-integral eigenvalues arise from the spin motion which has to be defined directly through the commutation relations.

ANGULAR MOMENTUM BALANCE. An integral requirement for a system that is characterized by **conservation of angular momentum**. A description of the angular-momentum balance of a physical system includes: (1) a description of the partition of **absolute angular momentum** within the system; and (2) a description of the mechanism by which absolute angular momentum is transferred from one portion of the system to another and also between the system and its surroundings.

ANGULAR MOMENTUM DENSITY (ELECTROMAGNETIC FIELD). For a region free of charge and current, the angular momentum density of the electromagnetic field with respect to the origin of the radius vector \mathbf{r} is given by $\mathbf{M} = \mathbf{r} \times \mathbf{P}$, where \mathbf{P} is the electromagnetic momentum density. (See **energy-momentum tensor**.)

ANGULAR MOMENTUM, ORBITAL. The angular momentum, \mathbf{H} , associated with the motion of a particle moving in an **orbit**.

$$\mathbf{H} = m\mathbf{r} \times \mathbf{v},$$

where m is the mass of the particle, \mathbf{r} its vector displacement from the origin (fixed in an **inertial**

system) and \mathbf{v} is the velocity. (See **angular momentum**; **angular momentum (atomic and nuclear physics)**.)

ANGULAR MOMENTUM VECTORS, QUANTUM THEORETICAL ADDITION OF. Let \mathbf{A} and \mathbf{B} be two angular momentum vectors. Their magnitudes, according to quantum theory are given by $\sqrt{A(A+1)}(h/2\pi)$ and $\sqrt{B(B+1)}(h/2\pi)$, respectively [or approximately by $A(h/2\pi)$, and $B(h/2\pi)$]. Here A and B are the quantum numbers which can be integral, 0, 1, 2, \dots , or half integral, $\frac{1}{2}$, $\frac{3}{2}$, $\frac{5}{2}$, \dots . The resultant \mathbf{C} , of \mathbf{A} and \mathbf{B} , is obtained in the usual way from the parallelogram of vectors. However, \mathbf{C} is again quantized, that is to say, can only take the values $\sqrt{C(C+1)}(h/2\pi)$ [or approximately $C(h/2\pi)$], where C is integral when A and B are both integral or both half integral, but is half integral when only A or only B is half integral. Therefore, in order to obtain the quantized values of \mathbf{C} , \mathbf{A} and \mathbf{B} can be added only in certain directions relative to one another. The possible values of C are

$$C = (A + B), (A + B - 1), \\ (A + B - 2), \dots, (A - B).$$

ANGULAR NEUTRON FLUX. See **flux, neutron, angular**.

ANGULAR RESOLVING POWER. See **resolving power**.

ANGULAR VELOCITY. A quantity relating to rotational motion. Its instantaneous value is defined as the vector, whose magnitude is the time rate of change of the angle θ rotated through, for example, $d\theta/dt$, and whose direction is arbitrarily defined as that direction of the rotation axis for which the rotation is clockwise. The usual symbol is ω or Ω .

The concept of angular velocity is most useful in the case of rigid body motion. If a rigid body rotates about a fixed axis and the position vector of any point P with respect to any point on the axis as origin is \mathbf{r} , the velocity $\dot{\mathbf{r}}$ of P relative to this origin is $\dot{\mathbf{r}} = \boldsymbol{\omega} \times \mathbf{r}$, where $\boldsymbol{\omega}$ is the instantaneous vector angular velocity. This indeed may serve as a definition of $\boldsymbol{\omega}$.

The average angular velocity may be defined as the ratio of the angular displacement divided by the time. In general, however, this is not a vector, since a finite angular dis-

placement is not a vector. The instantaneous angular velocity is more widely used.

Angular velocities, like linear velocities, are vectorially added, for example, if a top is spinning about an axis which is simultaneously being tipped over toward the table, the resultant angular velocity is the vector sum of the angular velocities of spin and of tipping. (This enters into the theory of **precession**.) The derivatives of the **Eulerian angles** are sometimes very useful in describing the angular motion of a rigid body which has components of angular velocity about all its principal axes.

ANGULAR VELOCITY, EFFECTIVE. The effective angular velocity at a point is the root mean square value of the instantaneous **angular velocity** over a complete cycle at the point. The unit is the radian per second.

ANHARMONICITY. (1) The term mechanical anharmonicity refers to a mechanical vibration in which the **restoring force** acting on the system does not vary linearly with the displacement of the system from its **equilibrium position**. (2) A phenomenon to which the term electrical anharmonicity is applied occurs in the calculation of the intensities of infrared bands. This phenomenon is a departure of the variation of **dipole moment** with internuclear distance from a strictly linear relationship.

ANHARMONIC OSCILLATOR. See **oscillator, anharmonic**.

ANHARMONIC TERMS. Terms in the expressions for the potential energy of a molecule or a crystal which depend on the third and higher powers of the displacements of the nuclei.

ANIONS. See **electroneutrality**.

ANISOTROPIC MATERIAL. See **aeotropic material**.

ANISOTROPY ENERGY. The anisotropy energy, or the magneto-crystalline energy, as it is sometimes called, of a ferromagnetic crystal, is the excess energy required to magnetize a crystal along the *hard* directions of magnetization over the energy required to magnetize it along the *easy* directions. In a cubic crystal such as iron, it is a function of the direction cosines α_1 , α_2 , α_3 , which the direction of magnetization makes with the cubic axes. Sym-

metry considerations show that only even powers of each α are involved, and the anisotropy energy f_k can be expressed by the series

$$f_k = K_1(\alpha_1^2\alpha_2^2 + \alpha_2^2\alpha_3^2 + \alpha_3^2\alpha_1^2) \\ + K_2\alpha_1^2\alpha_2^2\alpha_3^2 + \text{terms of higher degree}$$

It is found that the sum of the first two terms gives an adequate description of the behavior in most cases, and that K_1 and K_2 are material properties which depend on temperature.

ANISOTROPY, MAGNETIC. See **magnetic anisotropy**.

ANNIHILATION. See **creation and annihilation operators**.

ANNIHILATION OPERATOR. See **creation and annihilation operators**.

ANNULUS. The part of the plane lying between two concentric circles.

ANOMALISTIC YEAR. See **year**.

ANOMALOUS DISPERSION. An abrupt change in the dispersion $dn/d\lambda$ of the index of refraction n as a function of wavelength λ . Such changes occur in the neighborhood of an absorption band of the spectrum.

ANOMALOUS MAGNETIC MOMENT FOR A SPIN $\frac{1}{2}$ PARTICLE. The **Dirac theory** for a spin $\frac{1}{2}$ charged particle predicts that such a particle should have a magnetic moment equal to

$$\mu_0 = e\hbar/2mc$$

where m is the mass and e the charge of the particle. The difference $\Delta\mu$ between the observed magnetic moment and the value $e\hbar/2mc$ is called the anomalous magnetic moment of the particle. The anomalous moment arises from the interaction of the particle with the vacuum fluctuations of the (quantized) electromagnetic field and with those of any other field with which the particle can interact.

For the case of the electron where only the interaction with the quantized electromagnetic field need be considered, one can treat the modifications of the value of the magnetic moment from the Dirac value by the application of **covariant perturbation theory**. Up to the present the magnetic moment of the electron has been computed to fourth order in the coupling constant,

$$\alpha = \frac{e^2}{4\pi\hbar c} = \frac{1}{137}$$

with the result that

$$\begin{aligned} \Delta\mu &= \left(\frac{\alpha}{2\pi} - 0.328 \frac{\alpha^2}{\pi^2} \right) \frac{e\hbar}{2mc} \\ &= 0.0011596 \frac{e\hbar}{2mc}. \end{aligned}$$

The best experimental value of $\Delta\mu$, as obtained from a measurement of the g factor of free electrons is

$$\Delta\mu_{exp} = (0.001162 \pm 0.000004) \frac{e\hbar}{2mc}$$

in good agreement with the theoretical value.

For the μ -meson there is a contribution to the theoretical value of the anomalous magnetic moment due to its interaction with vacuum fluctuations of the electron-positron field (vacuum polarization effect due to virtual electron-positron creation and annihilation).

The magnitude of this contribution is $\frac{\alpha^2}{\pi^2} \times 1.08\mu_0$ so that the theoretically predicted μ -meson anomalous moment is

$$\begin{aligned} \Delta\mu_\mu &= \left(0.50 \frac{\alpha}{\pi} + 0.75 \frac{\alpha^2}{\pi^2} \right) \mu_0 \\ &= 0.0011654\mu_0. \end{aligned}$$

The best experimental value of the anomalous magnetic moment of the μ -meson at present is 0.0015 ± 0.0006 . The values of the magnetic moment of the neutron and proton are

$$\begin{aligned} \mu_p &= 2.7896 \frac{e\hbar}{2Mc} \\ \mu_n &= 1.9103 \frac{e\hbar}{2Mc} \end{aligned}$$

where M is the proton mass. Their anomalous moment is thus

$$\begin{aligned} \Delta\mu_p &= 1.7896 \frac{e\hbar}{2Mc} \\ \Delta\mu_n &= -1.9103 \frac{e\hbar}{2Mc}. \end{aligned}$$

Due to the largeness of the coupling constant characterizing the interaction of nucleons with mesons, valid and reliable theoretical

computations of the expected anomalous moments of the nucleons based on pseudoscalar meson theory are very difficult to perform and to date no satisfactory calculation has been performed.

No data is as yet available on the magnetic moments of the hyperons.

We next briefly illustrate the type of Feynman diagrams which contribute to the anomalous magnetic moment. To second order in e , the electron's anomalous magnetic moment can be computed from the three Feynman diagrams in Figure 1,

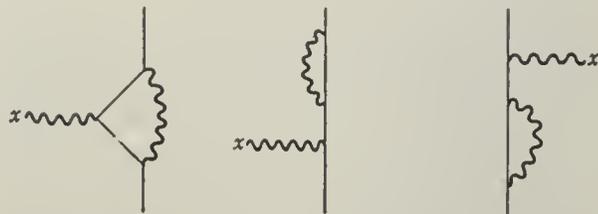

Fig. 1.

where the wavy line with an x denotes an interaction with an external electromagnetic field supposed weak enough to allow a perturbation treatment of its effects. To fourth order in e , but still only considering one interaction with the external field, the diagrams in Figure 2 contribute

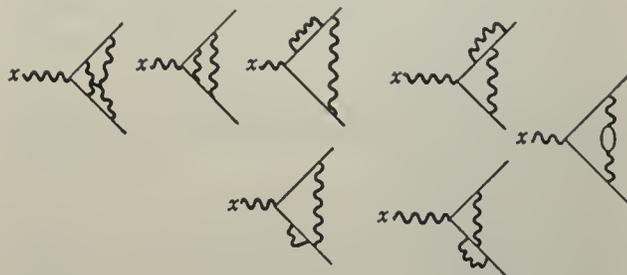

Fig. 2.

For the μ -mesonic calculation all the above diagrams will occur. There is, moreover, the diagram (Figure 3) indicated below (we denote μ -meson lines by double lines) wherein the vacuum polarization effect is due to electrons. This term involves the ratio of the

Fig. 3.

electron mass to that of the μ -meson logarithmically and gives rise to the following contribution to the μ -meson anomalous moment:

$$\delta\mu_{EVP} = \frac{\alpha^2}{\pi^2} \left[\frac{1}{3} \ln \frac{m_\mu}{2m_e} + \frac{1}{3} \log 2 - \frac{2.5}{3.6} \right]$$

$$+ \text{terms of order } \frac{\alpha^2 m_e}{\pi^2 m_\mu}$$

$$\approx \frac{\alpha^2}{\pi^2} 1.08.$$

ANOMALY, TRUE AND ECCENTRIC. In theory Kepler's second law should predict the position of an object moving about the sun in an orbit, provided that one knows the semi-major axis, a , the eccentricity, e , the time that the object was at perihelion, τ , and the orbital period T . Let P represent the position of the object at the time t . The radius vector sweeps out the area ASP in the time $(t - \tau)$ and, by the second law of Kepler, the proportionality relation is

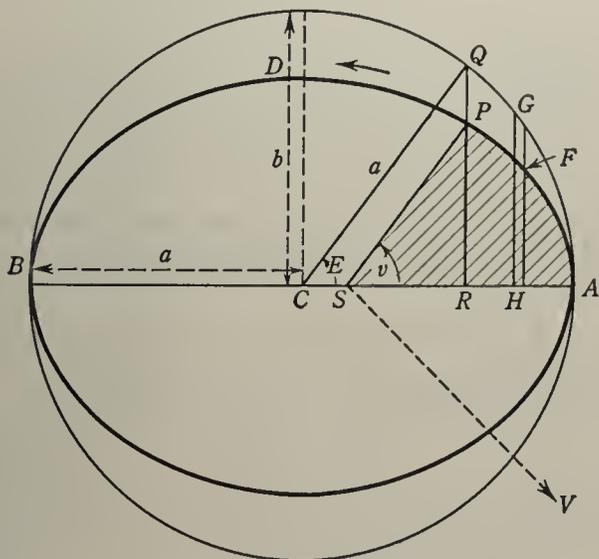

Area ASP :Area of ellipse :: $(t - \tau)$: T
or

$$\text{Area } ASP = \frac{\pi ab}{T} (t - \tau)$$

Introducing the angular motion $n = \frac{2\pi}{T}$

$$\text{Area } ASP = \frac{1}{2} nab(t - \tau)$$

in which $b^2 = a^2(1 - e^2)$. This equation apparently gives the desired position, but in practice it is very inconvenient to use.

Anomaly, true and eccentric.

From the figure: The radius vector makes an angle v with the major axis that is known as the true anomaly. It is linked to the orbital elements since $v = \theta - \omega$.

Now draw a circle of radius, a , centered on C . The line RP , perpendicular to the major axis, is extended to the circle of construction and meets it in Q . The angle E at the center, is known as the eccentric anomaly, E .

Since the orbit is an ellipse, $PR:QR::b:a$ and it may be shown that $r \cos v = a (\cos E - e)$ and

$$r = a(1 - \cos E)$$

and this equation gives the radius vector in terms of the eccentric anomaly E .

Further trigonometric analysis will result in an equation

$$\tan \frac{v}{2} = \sqrt{\frac{1+e}{1-e}} \tan \frac{E}{2}$$

which expresses the true anomaly, v , in terms of the eccentric anomaly E .

Kepler's Equation. From the definition of mean angular motion, $n = \frac{2\pi}{T}$, one defines the mean anomaly M as $M = n(t - \tau)$. Also, the area $SPA = \frac{1}{2}(abM)$. We wish to express this area in terms of the eccentric anomaly, E . The shaded area (in figure) is equal to area PSR plus the area RPA . The area PSR may be shown to be equal to $\frac{1}{2}ab \sin E (\cos E - e)$. The area of RPA is computed as follows: It is bounded by the elliptic arc PFA . Divide it into strips perpendicular to AB , and extend the strips to the circle on AB as a diameter.

Consider the strip FH . Since $FH = \frac{b}{a} GH$, the sum of all of the strips forming the area RPA is equal to $\frac{b}{a}$ times the sum of all the strips forming the area QRA and the area $RPA = \frac{b}{a} QRA$.

The area of QRA is the area of CQA minus the area of QCR . The angle $QCA = \frac{1}{2}a^2E$ and the area of the triangle QCR is $\frac{1}{2}a^2 \sin E \cos E$. One may now determine the area $RPA = \frac{1}{2}ab(E - \sin E \cos E)$. Add RPA to the area of PSR , above, and the result is

$$SPA = \frac{1}{2}ab(E - e \sin E)$$

whence

$$E - e \sin E = M \equiv n(t - \tau)$$

which is Kepler's equation.

Kepler's equation is thus a relation between the eccentric anomaly, E , and the

mean anomaly, M . It should be noted that both E and M are expressed in circular measure. Solutions of this equation for orbit computers are found in many computer tables.

ANTENNA. Any structure used to couple a transmitter or receiver to a medium in which electromagnetic waves can propagate. These structures range in form from simple straight wires, used either singly or in arrays, to quasi-optical devices employing metallic mirrors or dielectric lenses.

ANTENNA RESISTANCE. The quotient of the power supplied to the entire antenna circuit by the square of the effective antenna current referred to a specific point. Contributions to the antenna resistance come from such sources as **radiation resistance**, ground resistance, radio frequency resistance of conductors in the antenna circuit, and equivalent resistance due to corona, eddy currents, insulator leakage and dielectric power loss.

ANTENNA RESONANT FREQUENCY. That frequency or frequencies at which the antenna appears as a pure resistance.

ANTIBONDING ELECTRONS. See **molecular orbital theory of valence**.

ANTIBONDING ORBITAL. See **orbital, bonding**.

ANTICLASTIC CURVATURE. See **curvature, anticlastic**.

ANTICLASTIC SURFACE. A surface or portion of a surface on which the two principal radii of **curvature** at each point have opposite signs. Also called *surface of negative total curvature*.

ANTICOMMUTATION. The anticommutator of two linear operators A and B is the quantity $AB + BA$. Two operators anticommute, if $AB = -BA$. In quantum mechanics, **anticommutation rules** which give the expression for the anticommutator of two operators are sometimes of importance. The **creation** and **annihilation operators** related to the description of a system of **fermions** satisfy simple anticommutation rules.

ANTICOMMUTATION RULES. The commutation rules satisfied by the **creation** and **destruction** operators for particles obeying Fermi-Dirac statistics. Let b_n and b_n^* be the

destruction and creation operator for a (Fermi-Dirac) particle in the (one-particle) state characterized by the observables n . The Jordan-Wigner anticommutation rules then state that

$$[b_n, b_m]_+ = [b_n^*, b_m^*]_+ = 0 \quad (1)$$

$$[b_n, b_m^*]_+ = \delta_{nm} \quad (2)$$

where $[A, B]_+ = AB + BA$. (3)

The anticommutator $[A, B]_+$ is sometimes also denoted by $\{A, B\}$.

Consider the case of the spin $\frac{1}{2}$ particles. In a quantum-field theoretic description, a system of free spin $\frac{1}{2}$ particles of mass m is described by a field operator $\psi(x)$ which is a four component spinor operator satisfying

$$(-i\gamma^\mu \partial_\mu + m)\psi(x) = 0 \quad (4)$$

where $\gamma^\mu \gamma^\nu + \gamma^\nu \gamma^\mu = 2g^{\mu\nu}$, γ^0 is hermitian and γ^j ($j = 1, 2, 3$) anti-hermitian. Let f_n , $n = 1, 2 \dots$, be any infinite set of positive energy solutions of the Dirac equation $(-i\gamma^\mu \partial_\mu + m)f_n(x) = 0$ normalized and orthogonal in the scalar product

$$(f, g) = \int \tilde{f}(x) \gamma^\mu g(x) d\sigma_\mu(x) \quad (5)$$

($\tilde{f} = f^* \gamma^0$). One then can define the destruction operator as follows:

$$a_j = \int \tilde{f}_j(x) \gamma_\mu \psi(x) d\sigma^\mu(x). \quad (6)$$

If the field is neutral (self-charge conjugate, i.e., $\psi^C(x) = \psi(x)$ where $\psi^C(x) = C\psi^*(x)$ and C such that $C^{-1}\gamma^\mu C = -\gamma^{\mu T}$, $C^*C = 1$, $C^T = -C$) then (6) defines all the destruction operators that have to be defined. If the field is charged, the destruction operators for the **anti-particles** are defined by the equation

$$b_j = \int \tilde{f}_j(x) \gamma_\mu \psi^C(x) d\sigma^\mu(x), \quad j = 0, 1, 2 \dots \quad (7)$$

The commutation rules of a_i and b_i are

$$a_j a_k + a_k a_j = 0 \quad (8)$$

$$a_j a_k^* + a_k^* a_j = \delta_{jk} \quad j, k = 1, 2 \dots \quad (9)$$

$$a_j b_k + b_k a_j = a_j^* b_k^* + b_k^* a_j^* = 0 \quad (10)$$

$$b_j b_k + b_k b_j = 0 = b_j^* b_k^* + b_k^* b_j^* \quad (11)$$

$$a_j b_k^* + b_k^* a_j = a_j^* b_k + b_k a_j^* = 0. \quad (12)$$

One notes that the b_j behave like additional a 's associated with the charge conjugate wave

functions. There is therefore no loss of generality in considering the set $a_j, j = 1, 2, \dots$, satisfying (10) and (11). Now define the operator of "the number of particles in state j " by the equation

$$N_j = a_j^* a_j \quad j = 1, 2.$$

It follows immediately from the anticommutation rules that

$$N_j^2 = N_j \quad \text{and} \quad [N_j, N_i] = 0$$

so that the possible occupation numbers for the states can only be one or zero, in accordance with the Pauli principle. It can be demonstrated that every discrete representation of the commutation rules (10), (11) by bounded operators is a direct sum of irreducible representations. The unitarily inequivalent irreducible representations are \aleph_1 in number. For only one of these representations does a nonparticle state (i.e., a state $|0\rangle$ for which $a_j|0\rangle = 0$ for all j) and an operator of the total number of particles, $\sum_{j=1}^{\infty} N_j$, exist.

ANTICYCLONIC MOTION. Circulatory motion relative to the earth in the direction opposite to the vertical component of the earth's rotation; clockwise when viewed from above in the northern hemisphere. Such motion is produced in the atmosphere by horizontal divergence of air at rest, the vortex lines then being compressed vertically.

ANTICYCLONIC VORTICITY. Vorticity relative to the earth in an anticyclonic direction, i.e., in a direction opposite to the vertical component of the earth's rotation.

ANTIDERIVATIVE (OF A FUNCTION). A function whose derivative is the given function.

ANTIFERROELECTRICITY. A dielectric phenomenon in which neighboring lines of spontaneously polarized ions are aligned in anti-parallel directions.

ANTIFERROMAGNETISM. In the Heisenberg theory of ferromagnetism, the spins of electrons on neighboring atoms depends on the sign of the exchange integral. When this integral is positive, ferromagnetism is observed; when it is negative and sufficiently great in magnitude, an anti-parallel arrangement of neighboring spins occurs, and this is

interpreted as leading to the phenomenon of antiferromagnetism. The temperature T_c , at which the susceptibility is a maximum, is referred to as the Curie temperature, or sometimes as the Néel temperature. Simple models of antiferromagnetism lead to the relation

$$\chi_0 = \frac{2}{3}\chi_c$$

where χ_0 is the susceptibility at $T = 0$, and χ_c is the susceptibility at T_c . The relation derived for the susceptibility χ at temperature $T > T_c$ is

$$\chi = \frac{c}{T + aT_c}$$

where c is a constant and, if only coupling between nearest neighbors is considered, a is unity.

ANTI-LINEAR OPERATOR. An operator, T , mapping any linear manifold \mathfrak{M} of a Hilbert space \mathfrak{H} onto another linear manifold $\mathfrak{N} \subseteq \mathfrak{H}$ is called anti-linear if the following relation holds for any vectors f, g , of \mathfrak{M} and complex numbers λ, μ

$$T(\lambda f + \mu g) = \bar{\lambda} T f + \bar{\mu} T g$$

where $\bar{\mu}$ denotes the complex conjugate of μ . Multiplication of an anti-linear operator by a linear operator yields an anti-linear operator, whereas the product of two anti-linear operators is linear. If \mathfrak{M} is dense in \mathfrak{H} , one can define the antihermitian conjugate operator T^\dagger by

$$\begin{aligned} (T f, g) &= (T^\dagger g, f) \\ &= \overline{(f, T^\dagger g)} \end{aligned}$$

ANTILOGARITHM (OF A NUMBER). A number whose logarithm is the given number.

ANTI-NODAL POINTS. In Gaussian optics the anti-nodal points, or negative nodal points, are conjugate points for which the lateral magnification is $(-1)^{\nu} n/n'$ where n, n' are the refractive indices of object and image space, and ν is the number of reflections in the optical system.

ANTIPARTICLES. Every fermion particle which has been discovered thus far seems to have the property that it is a member of a family: together with this particle of mass m , spin $1/2$, charge e , and magnetic moment μ , there exists an "anti-particle" also having a mass m , spin $1/2$, but a charge $-e$, and mag-

netic moment $-\mu$. (This statement has been verified for the case of neutrinos, electrons, μ -mesons (the leptons) and of the protons, neutrons and Λ -particles. To each such fermion family there corresponds in the present formulation of quantum field theory, a **spinor** field operator. This spinor field operator describes simultaneously the two kinds of particles with electric charge and magnetic moment of opposite sign. This is displayed by the decomposition of the (free) field operator in terms of the creation and annihilation operator for the particle and antiparticle

$$\psi(x) = \int \frac{d^3p}{p_0} \left(\frac{m}{E_p}\right)^{1/2} \sum_r \{b_r(\mathbf{p})u_+^r(\mathbf{p})e^{-ipx} + d_r^*(\mathbf{p})v_-^r(\mathbf{p})e^{ipx}\}$$

where $b_r(\mathbf{p})$ is a destruction operator for a particle of momentum \mathbf{p} and spin r and $d^*(\mathbf{p})$ a creation operator for an antiparticle of momentum \mathbf{p} and spin r . (u_+ and v_- are positive and negative energy solutions of the **Dirac equation** for momenta \mathbf{p} and $-\mathbf{p}$ respectively.) (See also **hole theory**.)

ANTI-PRINCIPAL POINTS. In **Gaussian optics** the anti-principal points, or negative principal points, are conjugate points for which the **lateral magnification** is -1 .

ANTIRESONANCE (PARALLEL IMPEDANCE). In general, a condition of maximum impedance, as results when two or more impedors are connected in parallel, under such conditions that (for resistanceless impedors), Z approaches infinity when $\omega_1^2 = 1/LC$. The term antiresonance is commonly used with suitable modifiers.

ANTI-STOKES LINES. Raman lines (see **Raman effect**) displaced toward shorter wavelengths with respect to the incident line.

ANTISYMMETRIC FUNCTION. A function which is transformed into its negative when a pair of the independent variables is interchanged.

ANTISYMMETRIC RELATION. A binary relation R is called antisymmetric (see, e.g., **lattice**) if aRb and bRa imply $a = b$.

ANTISYMMETRIC TENSOR. See **tensor, skew-symmetric**.

ANTISYMMETRIC WAVE FUNCTION. A wave function is antisymmetric if it changes sign in interchanging the variables of two particles: $\psi(x_1, x_2, \dots, x_N) = -\psi(x_2, x_1, \dots, x_N)$, where x_i stands for all the variables of the i^{th} particles. The states of a system of N fermions is described by such an antisymmetric wave function. (See also **exchange energy**.)

ANTITRIPTIC WIND. A wind in which the pressure gradient force is almost balanced by the drag at the ground, other forces and accelerations being small by comparison.

ANTI-UNITARY OPERATOR. An operator W is said to be anti-unitary if it maps the Hilbert space \mathcal{H} onto itself and obeys

$$\begin{aligned} (Wg, Wf) &= (f, g) \\ &= \overline{(Wf, Wg)} \end{aligned} \quad (\text{a})$$

for every f and g in \mathcal{H} . It follows from the definition that W is an anti-linear operator, and that it has an inverse W^{-1} , which is identical with the antihermitian conjugate operator W^\dagger . (See **time inversion operation**.)

APERTURE. (1) In general, an opening allowing the passage of radiant energy. (2) In particular for axially symmetrical optical systems, the aperture, or the aperture stop, is a circle in a plane perpendicular to the axis that just allows the passage of a minimal axial bundle of rays. The size of the aperture is specified by either the angular aperture (aperture angle) or the angle of projection. (See **aperture angle**.)

APERTURE ANGLE. The angle subtended by the radius of the **entrance pupil** of an optical instrument at an axial object point. The **projection angle** is similarly associated with the **exit pupil** and an image point.

APERTURE, EXIT. See **exit aperture**.

APLANAT. An optical system, in which the first two **Seidel aberrations** (spherical aberration and coma) are reduced to very small values and the largest remaining aberration is the off-axis astigmatism, used to flatten the field.

APLANATIC POINTS OF A SPHERE. Consider a sphere of radius R separating two

media of refractive indices n_0 and n_1 . There exist two points at distances

$$r_0 = \frac{n_0}{n_1} R, r_1 = \frac{n_1}{n_0} R,$$

from the center of the sphere so that a spherical wave diverging from either point is refracted at the surface of the sphere into a spherical wave apparently diverging from the second point. The two points are virtual **conjugate points**. (See also the definition following.)

APLANATIC SURFACE. A surface separating two media is an aplanatic surface under refraction (or reflection) if there exist two **conjugate points** (either real or virtual). The aplanatic surfaces of revolution are the **Cartesian surfaces**.

APOCHROMATIC SYSTEM. An optical system having the same focal length for at least three wavelengths. An apochromatic system is thus more highly corrected for chromatic aberration than an **achromatic system**.

APODIZATION. A modification of the amplitude transmittance of the **aperture** of an optical system for the purpose of reducing or suppressing the energy content of the diffraction rings relative to that of the central maximum or **Airy disc**.

APPARENT DIAMETER. The angle subtended, at the eye of an observer, by a diameter of an object is the apparent diameter or *angular diameter* of the object.

APPARENT MAGNITUDE. See **stellar luminosities**.

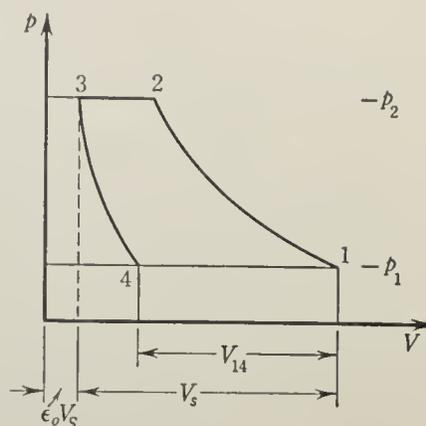

APPARENT VOLUMETRIC EFFICIENCY. Ratio of effective swept volume to total swept volume of a compressor or a four-stroke internal combustion engine. The effective swept volume V_{14} is smaller than the swept volume V_s owing to the effect of the clearance volume $\epsilon_0 V_s$. Hence the apparent volumetric efficiency

$$\mu = V_{14}/V_s$$

is a measure of the influence of clearance on delivery. Assuming that compression 12 and expansion 34 are polytropic ($pV^n = \text{const}$) it is found that the apparent volumetric efficiency is reduced to zero when the pressure ratio

$$\frac{p_2}{p_1} = \left(\frac{1}{\epsilon_0} + 1 \right)^n.$$

This puts an upper limit on the pressure ratio p_2/p_1 which can be used with a given **clearance ratio** ϵ_0 . In practice, the pressure ratio p_2/p_1 is kept well below this limit for other

reasons (lubrication, thermal stresses, saving in work through interstage cooling), and when high values of p_2/p_1 are required it is necessary to employ multi-stage compressors.

APPLICABLE SURFACES. Two surfaces are said to be applicable to each other, if there exists a one-to-one correspondence between the points on the two surfaces such that the lengths of corresponding linear elements on the two surfaces are equal.

APPLIED FORCE. See **force, applied**.

APPROXIMATION IN THE MEAN. A function $f(x)$ is approximated in the mean by the sum

$$\sum_{i=1}^n a_i u_i \quad \text{if} \quad \lim_{n \rightarrow \infty} \int (f - \sum a_i u_i)^2 w dx = 0$$

where w is the appropriate **weighting function**.

APSE LINE. The line joining the centers of two molecules at the point of closest approach during a collision. A unit vector \mathbf{k} along the apse line is frequently used, together with the initial relative velocity, to characterize the collision.

ARAGO SPOT. If an object casts a circular shadow on a plane when illuminated by a point source, then a bright region, called the Arago spot, appears in the diffraction pattern at the center of the shadow. (See **diffraction cvolute**.)

ARCH. A curved bar or truss subjected to combined compression and bending produced by forces in its plane. In a masonry or **Voussoir arch** which is unable to carry tensile stress, the **pressure line** or funicular polygon must be inside the arch from the crown or highest point to the springing or juncture with the foundation. When the moving or live load is large compared with the dead weight, appreciable binding occurs and reinforced concrete or steel arches are required.

Arches may be classified as fixed or hinged. A fixed support resists rotation and translation. It exerts thrust, transverse force and moment. A hinged support permits rotation and exerts thrust and transverse force only. A fixed arch is fixed at both supports. A two-hinged arch is hinged at both supports. A three-hinged arch has a third hinge, usually at the crown and is a statically determinate structure. When foundation conditions are unfavorable, the outward thrust of the arch may be carried by a tension member between supports. Such a structure is called a **tied arch**.

ARCH, HINGED. See **arch**.

ARCHIMEDES PRINCIPLE. The resultant upward force due to fluid pressure, on a body wholly or partially submerged in a stationary fluid, is equal to the weight of the fluid displaced by the body. (See also **stability of a floating body**.)

ARCH, TIED. See **tied arch**.

ARC-SINE DISTRIBUTION. A probability distribution which arises in the theory of recurrent events. It is of the form

$$p(x \leq x_0) = \frac{2}{\pi} \arcsin \sqrt{x_0}, \quad 0 \leq x \leq 1.$$

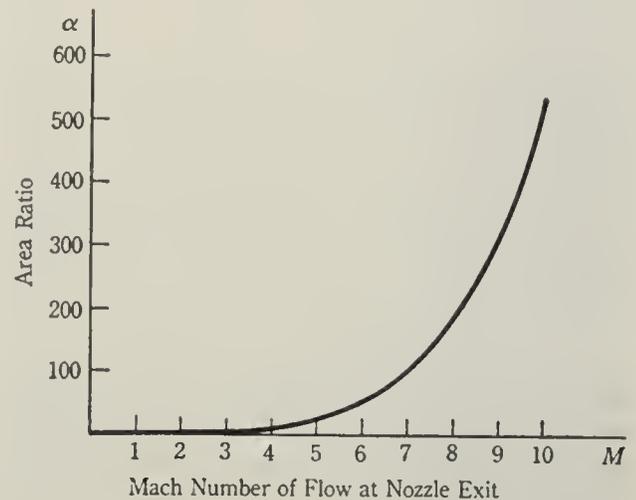

ARC SPECTRUM. The spectrum of the neutral atom of an element. (See also **spark spectrum**.)

AREA, CENTER OF. See **centroid (of a geometrical figure)**.

AREAL VELOCITY. See **velocity, areal**.

AREA RATIO. In a convergent-divergent nozzle, the ratio of the exit area to the throat area. The area ratio determines the **Mach number** of the flow at exit on condition that the flow in the throat is sonic. The diagram

gives the relation between the exit Mach number and the area ratio α for *isentropic flow* and for a perfect gas with constant specific

heats and a value of the specific heat ratio (γ) of 1.4.

AREA RATIO, NOZZLE. See **area ratio; nozzle area ratio**.

ARGAND (OR GAUSS) PLANE. A mapping of the complex numbers onto a Cartesian plane (a **Euclidean plane** with **Cartesian coordinates**) is called the Argand plane (or the Gauss plane) if the complex number $z = x + iy$ corresponds to the vector (or alternatively to its end-point) issuing from the origin with end-point x, y . The x -axis is the *real axis* and the y -axis is the *imaginary axis*. The length $r = (a^2 + b^2)^{1/2}$ of the vector gives the *modulus* or *absolute value* of z , and the angle θ between the real axis and the vector gives the *argument* of z . The resulting diagram is of great aid to visualization because it allows a simple geometric interpretation of the multiplication of complex numbers; for then, in polar form, $z = r(\cos \theta + i \sin \theta) = re^{i\theta}$, and if $\zeta = \rho(\cos \phi + i \sin \phi) = \rho e^{i\phi}$ then $z\zeta = r\rho e^{i(\theta+\phi)}$ which means that the moduli have been multiplied and the arguments have been added.

ARITHMETIC MEAN. The arithmetic mean of a number of observations x_i ($i = 1, \dots, n$) is the simple average $\Sigma x_i/n$. Thus if a and b are the first and last terms respectively of an **arithmetic progression**, then the intermediate terms are said to be arithmetic means between a and b . In particular $\frac{a+b}{2}$ is the arithmetic

mean between a and b . The arithmetic mean is commonly referred to simply as the mean.

The arithmetic mean is the most generally used **measure of location**. In samples from a normal distribution, the mean is an efficient, and indeed sufficient, estimate of the location parameter, though in other distributions other estimators may be preferable. If \bar{x} is the mean of a sample drawn from a finite population of N members, $N\bar{x}$ is an unbiased estimate of the population total.

A useful generalization of the arithmetic mean is the weighted mean. If each observation x_i has attached to it a weight w_i the weighted mean is given by $\Sigma w_i x_i / \Sigma w_i$, observations with large weights being given greater influence. If we have a set of estimates x_i of a quantity ξ , and if the variance of x_i is σ^2/w_i with w_i known, the estimate of ξ with least variance is the weighted mean of the x_i , and the variance of this estimate is $\sigma^2/\Sigma w_i$.

ARITHMETIC PROGRESSION. A sequence of numbers $a, a + d, a + 2d, \dots, a + (n - 1)d$ in which each term is greater than its predecessor by a constant d , called the common difference.

ARITHMETIC UNIT. The portion of a stored-program computer devoted to the actual execution of the commands.

ARRHENIUS EQUATION. See order of chemical reactions.

ARTICULATION POINT. See vertex, cut.

ARZELA THEOREM. Same as Ascoli theorem.

ASCOLI THEOREM. If $f_1(x), f_2(x), \dots$ is any set of functions defined and equicontinuous on a closed interval $[a, b]$, then there exists a subsequence $f_{i_1}(x), f_{i_2}(x), \dots$ which converges uniformly on $[a, b]$ to a limit function $f(x)$. The theorem can be extended directly to any number of independent variables.

ASPECT RATIO (OF WING). For a wing of span b and area S the aspect ratio is equal to b^2/S . For a wing of rectangular plan form this is simply the ratio span/chord.

ASPIRATION PSYCHROMETER. An instrument used to measure the humidity of air. It consists of two thermometers, wet-bulb and dry-bulb, over which a stream of the air whose humidity is to be measured is maintained by

a small blower. The wet-bulb thermometer has its bulb covered with an envelope which is kept soaked with moisture. The knowledge of the two different temperatures is sufficient to determine the humidity. (See psychrometry, psychrometric chart, wet-bulb temperature, Mollier H, S diagram, adiabatic cooling limit.)

ASSEMBLY. (1) A thermodynamic macroscopic system. (2) An ensemble.

ASSEMBLY STRESSES. Stresses set up during fabrication by glueing, bolting, riveting, or welding due to initial mismatch, permanent deformation or differential cooling. Stresses over large areas may be termed **reaction stresses** to distinguish them from **residual stresses** which are localized.

ASSOCIATE BERTRAND CURVES. See Bertrand curves.

ASSOCIATED POLYNOMIALS (OR FUNCTIONS). See under the respective names; e.g., for associated Legendre polynomials, see Legendre polynomials, similarly for Laguerre, etc.

ASSOCIATED TENSORS. See tensors, associated.

ASSOCIATED VECTORS. See vectors, associated.

ASSOCIATE MATRIX. See hermitian conjugate.

ASSOCIATION. In statistics this expression has a precise meaning, namely, the relationship between variables which are simply dichotomized. In a 2×2 table of the following kind

	Attribute		Totals
	A	not A	
Attribute B	a	b	$a + b$
not B	c	d	$c + d$
Totals	$a + c$	$b + d$	N

where, for example, a is the number of individuals bearing attributes A and B , there is said to be positive or negative association according as a is greater than or less than $(a + b)(c + d)/N$. Various coefficients can be constructed to measure the intensity of associa-

tion, the commonest being the *coefficient of association*

$$Q = \frac{ad - bc}{ad + bc}$$

ASSOCIATIVE LAW. An operation, denoted, for example, by \circ , obeys the associative law if $(a \circ b) \circ c = a \circ (b \circ c)$ for all a, b, c in its domain. Thus, in elementary arithmetic:

$$a + (b + c) = (a + b) + c;$$

$$(ab)c = a(bc) = abc.$$

ASTIGMATIC DIFFERENCE. The distance between the **tangential** and **sagittal foci** on a ray.

ASTIGMATISM. (1) Qualitatively, astigmatism is the image error due to the lack of coincidence of the **sagittal** and the **tangential foci** on a ray. (2) Quantitatively, the third of the five **Seidel aberration functions** is the astigmatism function of a system. The astigmatism is also measured by the **astigmatic difference**. (See also the astigmatism of a surface.)

ASTIGMATISM OF A SURFACE. The astigmatism of an optical surface separating two media with relative index of refraction n is $(n - 1)|\kappa_1 - \kappa_2|$ where κ_1, κ_2 are the principal curvatures of the surface. For a surface given explicitly, $z = z(x,y)$, the astigmatism is approximately

$$(n - 1)\sqrt{(z_{xx} - z_{yy})^2 + (2z_{xy})^2}$$

if the surface is nearly flat in the sense that $(z_x)^2, (z_y)^2, (z_x z_y)$ are negligible.

ASTRONOMICAL COORDINATE SYSTEMS. The table at the bottom of this page presents the spherical coordinate systems in common use in astronomy and navigation. The corresponding terrestrial coordinates are shown for the purpose of clarity.

ASTRONOMICAL DISTANCE UNITS. (1) *The Astronomical Unit.* The mean distance of the earth from the sun, 92,900,000 miles, is known as the astronomical unit. It is used for distances within the solar system and, in a few cases, for stellar distances.

(2) *Stellar Parallax.* The angle subtended at a star by the mean distance of the earth from the sun, i.e., one astronomical unit, is the stellar parallax of the star and is symbolized by p'' .

$$\text{Distance (in astronomical units)} = 206265/p''$$

(3) *The Parsec.* The distance at which one astronomical unit would subtend one second of arc is known as the parsec.

$$1 \text{ parsec} = 3.08 \times 10^{13} \text{ km}$$

$$= 1.92 \times 10^{13} \text{ miles.}$$

(4) *The Light Year.* The distance that would be covered by an object moving with the velocity of light in one year is defined as the light year.

$$1 \text{ light year} = 9.46 \times 10^{12} \text{ km}$$

$$= 5.88 \times 10^{12} \text{ miles.}$$

$$\text{Distance (in parsecs)} = 1''/p''$$

$$\text{Distance (in light years)} = 3''.26/p''$$

ASTRONOMICAL COORDINATE SYSTEMS

EARTH	CELESTIAL EQUATOR	HORIZON	ECLIPTIC	GALACTIC
Equator	Celestial equator	Horizon	Ecliptic	Galactic equator
Poles	Celestial poles	Zenith, nadir	Ecliptic poles	Galactic poles
Meridians of longitude	Hour circles, celestial meridians	Vertical circles	Circles of latitude	
Prime meridian, meridian of Greenwich	Hour circle of Greenwich meridian, local celestial meridian	Principal vertical circle, prime vertical circle	Circle of latitude through the Vernal equinox.	Great circle through galactic poles and intersection of galactic equator and celestial equator at about <i>SHA</i> 80°
Parallels of latitude	Parallels of declination	Parallels of altitude	Parallels of latitude	
Latitude	Declination	Altitude	Celestial latitude	Galactic latitude
Colatitude	Polar distance	Zenith distance	Celestial colatitude	Galactic colatitude
Longitude	<i>SHA, R.A., GHA, LHA, t.</i>	Azimuth, azimuth angle, amplitude	Celestial longitude	Galactic longitude

ASTRONOMICAL REFRACTION. In any type of astronomical observing the light from the external object must pass through the atmosphere of the earth. The index of refraction of the atmosphere increases from zero at the point of entry to the value at the observer. The rate of increase of this index of refraction depends upon a number of variables that are very imperfectly known at the present time.

The major effect of this atmospheric refraction is to cause objects to appear to be at a greater altitude than they would be if there were no atmosphere. The amount of this refraction is zero for an object in the zenith, and it increases with diminishing altitude. Below altitude 15° the value of the refraction is uncertain, although some tables of refraction include values for less than 15° .

As a result of a number of long series of observations at various observatories all over the earth, tables of "mean refraction" have been published. Corrections to the mean refraction for the air temperature and barometric pressure of the observer's station are published with the tables.

A fair approximation to mean refraction, corrected for the observer's air temperature and barometric pressure, may be obtained from the relationship

$$R = \frac{983B}{460 + T} \cot h_o$$

in which B is the barometric pressure in inches, T is the air temperature on the Fahrenheit scale, h_o is the observed altitude of the object, and R is the refraction in seconds of arc. The corrected altitude would be $h = h_o + R$.

Since refraction is along a vertical circle, the azimuth is not affected by refraction. To determine the effects of refraction on the celestial coordinates other than those in the altazimuth system, the astronomical spherical triangles must be solved.

ASTRONOMICAL UNIT. See astronomical distance units.

ASYMMETRIC TOP MOLECULE. See polyatomic molecules, types of.

ASYMPTOTE. The limiting position of a tangent to a curve, where the point of contact is at an infinite distance from the origin. Where there are no infinite branches, as in the

cases of the circle and the ellipse, there is no real asymptote.

Suppose the equation of a given curve can be expanded in a power series

$$y = f(x) = \sum_{k=0}^n a_k x^k + \sum_{k=1}^{\infty} b_k/x^k = S_1 + S_2.$$

Then, if $\lim_{x \rightarrow \infty} S_2 = 0$, the equation of the asymptote is $y = S_1$. If this equation is linear, the asymptote is a straight line; otherwise, it is a more complicated curve. In the linear case, the equation of the asymptote may be written as

$$y = mx + b; \quad m = \lim_{x \rightarrow \infty} f'(x);$$

$$b = \lim_{x \rightarrow \infty} [f(x) - xf'(x)].$$

For example, for the hyperbola $x^2/a^2 - y^2/b^2 = 1$, we have

$$y = \pm \frac{b}{a} \sqrt{x^2 - a^2} = \frac{b}{a} (x + \frac{1}{2}x^{-1} + \dots),$$

so that the equations of the asymptotes are

$$y = \pm \frac{b}{a} x.$$

ASYMPTOTIC CONDITION. The requirement that a field theory (see relativistic quantum field theory) have an interpretation in terms of asymptotic particle observables. The asymptotic particle observables are a set of operators which represents the observables of stationary incoming and outgoing beams of particles having a sharp mass, and the same transformation, statistical, and orthogonality properties as free particles.

ASYMPTOTIC DIRECTION. See conjugate directions.

ASYMPTOTIC LINE (ON A SURFACE). A curve whose tangent at each point lies in an asymptotic direction at that point.

ASYMPTOTIC REACTOR THEORY. The mathematical formulation of neutron transport theory in which the behavior of the neutron flux, which is generally agreed to hold far from boundaries and sources, is assured to hold throughout the system. In particular, it is assured that the flux is separable into space and energy factors, and that the space factor follows the equation $(\nabla^2 + B^2)\psi(\mathbf{r}) = 0$. (See buckling; first fundamental theorem.)

ASYMPTOTIC SERIES. A divergent series of the form

$$A_0 + A_1/x + A_2/x^2 + \cdots + A_n/x^n + \cdots$$

is an asymptotic representation of a function $f(x)$ if

$$\lim_{x \rightarrow \infty} x^n [f(x) - S_n(x)] = 0$$

for any value of n , where S_n is the sum of the first $(n + 1)$ terms of the series. For any fixed value of x , there is a corresponding value of n for which the "error" $|f(x) - S_n(x)|$ is a minimum, and, by taking x sufficiently large, we may make this minimum error as small as desired.

A familiar example of an asymptotic series is the **Euler-Maclaurin formula**.

Asymptotic expansions are unique; that is, a given function can be represented by only one such series. They may be integrated, two or more of them may be multiplied together, but in general they may not be differentiated.

ATHERMAL SOLUTIONS. A class of non-ideal solutions for which the excess Gibbs free energy (see **excess functions**) is mainly due to the excess entropy

$$g^E \approx -T_s^E.$$

Such a behavior is found in mixtures of macromolecules for which the deviations from ideality are mainly due to the difference in size between solvent and solute. (See **polymer mixtures**.)

ATHERMANOUS. Opaque to infrared radiation. (See **diathermanous**.)

ATMOSPHERE. (1) The layer of air which surrounds the earth. (2) A gaseous envelope surrounding a body, or a mass of gas occupying a region. Hence (3), the gas filling or circulating through a furnace to provide desired conditions during heating or for metallurgical purposes. (4) A standard unit of pressure (see **atmosphere, standard**). (5) In Germany, the pressure of 1 kp/cm², i.e., of one kilopond (kilogram force) per one square meter.

ATMOSPHERE, STANDARD. (1) A unit of pressure, defined as the pressure exerted by a column of mercury 760 mm high, having a density of 13.5951 gm cm⁻³ and subject to

gravitational attraction of 980.665 dyne gm⁻¹, which is equal to 1.013250×10^6 dyne cm⁻². (2) In meteorology, an atmosphere having a sea-level pressure of 1.013250×10^6 dyne cm⁻² (1,013.25 millibars); a sea-level temperature of 15°C; and a lapse-rate of 6.5°C up to 11 km. 1 atm = 1.013250 bar = 101325 N/m² = 1013250 dyne/cm² = 1.03323 kp/cm² = 760 Torr = 14.6960 lbf/in².

ATMOSPHERIC PRESSURE-ALTITUDE RELATIONS. Pressure-altitude relations in the atmosphere are mathematically precise and can be determined from the hydrostatic equation

$$\frac{\partial p}{\partial h} = -\rho g,$$

and the equation of state for air

$$p = \rho RT,$$

which leads to the relation

$$p = p_0 \left[\frac{T_0 - \lambda h^{gm/R\lambda'}}{T_0} \right].$$

where λ is the lapse rate, m is the molecular weight of the air sample, and the zero subscripts denote conditions at height zero. In terms of γ , the ratio of specific heat at constant pressure to that at constant volume, the derivation is

$$dp = -\rho g dh \quad (1)$$

where ρ is density at height h .

Since for adiabatic expansion

$$p\rho^{-\gamma} = p_0\rho_0^{-\gamma} \quad (2)$$

where the subscript ₀ denotes sea-level conditions, then (1) becomes,

$$dp = \left(\frac{p}{p_0} \right)^{1/\gamma} \rho_0 g dh \quad (3)$$

which yields on integration

$$\left(\frac{p}{p_0} \right)^{\frac{\gamma-1}{\gamma}} = 1 - \frac{\gamma-1}{\gamma} \frac{\rho_0 g h}{p_0}, \quad (4)$$

For use as a convenient reference, various standard atmospheres have been established. That of the NACA is given on the next page.

NACA STANDARD ATMOSPHERE

An arbitrary and fictitious atmosphere established for comparison purposes. At sea level, a pressure of 29.92 inches (760 mm) of mercury, a temperature of 50°F (15°C), with the air perfectly dry is the beginning assumption. This state is considered to be the average condition prevailing at 40° North latitude. The temperature in the *standard atmosphere* decreases with altitude. At 40°N latitude it drops approximately 1.98°C for each 1000 feet increase in altitude until 35,332 feet is reached. After this the temperature remains at -55°C. The *meteorological average* temperature decrease is calculated at 0.5°C per 100 meters increase in altitude (or about 1°F per 300 feet). This amounts to 1.52°C for each 1000 feet increase in altitude. The following table gives the values of various parameters as established for the Standard Atmosphere:

Altitude (Feet)	Temperature (°F)	Pressure				Density (Slugs/ft ³)
		Psia	Inches mercury	Millibars	Atmospheres	
0	59.0	14.7	29.92	1013	1.0	0.002378
2,500	50	13.4	27.3	930	.910	
5,000	41.2	12.2	24.89	850	.850	0.002047
7,500	32	11.11	22.4	750	.750	
10,000	23.3	10.11	20.58	699	.688	0.001755
15,000	5.5	8.29	16.88	571.62	.564	0.001496
20,000	-12.3	6.75	13.75	465.63	.459	0.001268
25,000	-30	5.45	11.1	375.89	.371	0.001068

90,000	-67	.26				0.000055
100,000	-67	.16				0.000035

ATOM, BOHR. A model of the hydrogen atom (and of hydrogen-like ions such as He⁺ and Li⁺⁺) based on the nuclear atom of Rutherford, and on classical mechanics except for the superposition of non-classical, quantum, conditions. An electron of charge $-e$ and mass m experiences a **Coulomb force** of attraction to a nucleus of positive charge $+Ze$ (where Z is 1 for hydrogen, 2 for ionized helium (He⁺), etc.) given (in mksa units) by $F = Ze^2/4\pi\epsilon_0 r^2$. This attractive force provides the centripetal force necessary for the electron to move in a circle of radius r , i.e., $Ze^2/4\pi\epsilon_0 r^2 = mv^2/r$. Classically, an electron moving in a circular orbit would radiate electromagnetic waves and hence would spiral into the nucleus. Bohr assumed as his first non-classical condition that this classical radiation law did not hold if the electron were in one of a discrete set of "stationary" orbits determined by a quantum condition on its angular momentum,

i.e., if $mvr = nh/2\pi$, where h is the Planck constant. This condition, together with the force equation, leads to the expression for the radii of the allowed orbits: $r_n = n^2 h^2 \epsilon_0 / \pi e^2 n$ ($n = 1, 2, \dots$) and to the expression for the energy of the electron when it is in one of the allowed orbits: $E_n = -me^4/8n^2 h^2$ ($n = 1, 2, \dots$) (in mksa units). The negative sign results from the fact that the zero of potential energy has been taken at infinity.

The second non-classical condition imposed by Bohr was that a photon of radiation is emitted in the transition from a higher to a lower stationary state, with the frequency, f , of the radiation being given by the Planck law, i.e., $f = \Delta E_m - n/h = (E_m - E_n)/h$.

In a modified form the Bohr atom can include elliptic as well as circular orbits accounted quite well for the spectra of hydrogen and hydrogen-like ions, but was unable to account for many of the features of more com-

plex atoms. It has been superseded by the quantum mechanical theory of the atom. (See also *wave mechanics*; *Schrödinger equation*.)

ATOM, BOHR-SOMMERFELD. A modification of the Bohr model of the atom (see *atom, Bohr*), in which quantized elliptic orbits, as well as circular orbits, are allowed. The quantum conditions of the Bohr-Sommerfeld quantum theory were applied to the radial and angular components of the motion, leading to two quantum numbers instead of one, the radial quantum number (n') and the azimuthal quantum number (k). The principal quantum number $n = n' + k$ largely determines the energy of the stationary states as in the Bohr atom. However, there is a small relativistic effect on the energy expressed in terms of the *fine structure* constant and of both n and k . The quantum number n can take on values 1, 2, \dots , and the quantum number k can take on the values 1, 2, \dots , n .

In addition to the principal and azimuthal (angular momentum) quantum numbers, n and k , a third, the magnetic quantum number m appeared as a result of space quantization. Thus, the component of the angular momentum in some given direction can only take on discrete values, $+mh/2\pi$, where $m = 0, 1, 2, \dots, k$.

The Bohr-Sommerfeld model of the atom has been replaced by the wave-mechanical or quantum mechanical atom, yet as a modelistic visual aid it is still used (with caution), e.g., in the vector model of the atom. Its major fault lies in the fact that it assigns precise orbits to the electrons and is therefore in violation of the Heisenberg *uncertainty principle*. (See also *atom, de Broglie*; *atom, vector model of*; *quantum numbers of electrons in atom*.)

ATOM, DE BROGLIE. Similar in all respects to the Bohr atom (see *atom, Bohr*) except that the quantum condition on the angular momentum electron, $mvr = nh$, results not as an *ad hoc* assumption but as a result of imposing a condition on the wavelength of the de Broglie wave associated with the electron. This wavelength, λ , should fit an integral number of times into the circumference of the circular orbit, thus $2\pi r = n\lambda$. If this condition is combined with the de Broglie relation between wavelength and momentum, $mv = h/\lambda$, the Bohr condition results.

ATOM, ELECTRON SHELLS IN. See *electron shells in atom*.

ATOM, EVEN TERM OF. See *even term of an atom*.

ATOMIC ABSORPTION COEFFICIENT. See *absorption coefficient*.

ATOMIC BOND (ALSO CALLED HOMOPOLAR BOND, OR COVALENT BOND). The chemical bond between two neutral atoms. While ionic binding of atoms in a molecule can be explained on a classical basis, the fact that neutral atoms can attract one another strongly and form very stable (homopolar) molecules such as, for example, H_2 , N_2 and CO , can be explained only on the basis of quantum mechanics. Rigorous theoretical treatment of homopolar binding is possible only in the simplest cases (H_2^+ and H_2). For the discussion of more complicated cases various approximation methods have been developed. (See *atomic bond energy*; *hydrogen molecule, Heitler-London theory for*; *Heitler-London theory of valence*; *orbital theory of valence*.)

ATOMIC BOND ENERGY. The molecular wave function is approximated in the *Heitler-London* method (see also *valence bond method*) by a superposition of possible "*atomic*" and "*ionic*" configurations of the molecule. Each of these corresponds to a possible situation of the system electrons + nuclei at infinite separation of the nuclei. In the case of the H_2 molecule, for example, if A and B refer to the nuclei, and 1 and 2 to the electrons, the symmetrical wave function is:

$$\psi = a_1\psi_A(1)\psi_B(2) + a_2\psi_A(2)\psi_B(1) \\ + a_3\psi_A(1)\psi_A(2) + a_4\psi_B(1)\psi_B(2).$$

The two first terms of the right hand side of this equation correspond to atomic configurations at infinite separation, since each electron is linked to a nucleus. Their contribution to the bond energy is called the *atomic, homopolar, or covalent bond energy*. (For further treatment, see *hydrogen molecule, Heitler-London theory for*.)

The other two terms represent ionic configurations ($H^+ + H^-$) at infinite separations of the nuclei, and their contribution to the bond energy is called the *ionic bond energy*. The ratio of the atomic to ionic bond energies

varies from one molecule to another. (See **ionic bond character**.) Note that the ionic configurations are responsible for the **electric dipole moment** of heteropolar molecules.

ATOMIC CONFIGURATION. See **configuration, atomic**; **atomic bond energy**.

ATOMIC ENERGY. (1) The constitutive internal energy of the atom, which would be absorbed when the atom is formed from its constituent particles, and released when it is broken up into them. This is identical with the binding energy and is proportional to the mass defect. (2) Energy released as the result of the disintegration of atomic nuclei, particularly in large scale processes.

ATOMIC ENERGY LEVELS. (1) The values of the energy corresponding to the stationary states of an isolated atom. (2) The set of stationary states in which an atom of a particular species may be found, including the ground state, or normal state, and the excited states.

ATOMIC ENERGY LEVELS, STATISTICAL WEIGHT. See **statistical weight of atomic energy levels**.

ATOMIC EXCITATION FUNCTION. See **excitation function, atomic**.

ATOMIC FREQUENCY. Each atom in a solid vibrates about its equilibrium position with a frequency ν characteristic for that solid.

Estimations of atomic frequencies may be made in several ways including:

(1) Measurement of the elastic constants of the solid, which are related to the **Debye temperature** Θ (and hence ν) by

$$\Theta = h\nu/k = 35.74 \times 10^{-4} M^{-1/2} \kappa^{-1/2} \rho^{-1/6} [f(\sigma)]^{-1/2}$$

where

$$f(\sigma) = 2[2(1 + \sigma)/3(1 - 2\sigma)]^{3/2} + [(1 + \sigma)/3(1 - \sigma)]^{3/2}$$

where M is atomic weight, κ is compressibility, ρ is density, σ is Poisson's ratio, k is Boltzmann's constant, and h is Planck's constant.

(2) Measurement of the compressibility κ of the solid, when

$$\nu^2 = AN^{2/3} V_a^{1/3} M^{-1} \kappa^{-1}$$

where V_a is atomic volume, N is Avogadro's number, and A is **Madelung's constant**.

(3) Measurement of the coefficient of expansion α of the solid, when

$$\nu = 2.91 \times 10^{11} (C_v/V_a^{2/3} \alpha)^{1/2}$$

where C_v is the molar specific heat at constant volume.

(4) Determination of the melting point, T_m , of the solid, when

$$\nu = K(T_m/MV_a^{2/3})^{1/2}$$

where K is a constant which must be determined experimentally.

(5) From measurement of the wavelengths of the "residual rays" remaining after several reflections of infrared radiation from the solid. The rays are caused by resonance of the atomic ions so that their wavelength is directly related to the atomic frequency.

ATOMIC (SPECIFIC) HEAT. See **Dulong-Petit rule**.

ATOMIC HEAT OF FORMATION. Of a substance, the difference between the enthalpy of one mole of that substance and the sum of the enthalpies of its constituent atoms at the same temperature; the reference state for the atoms is chosen as the gaseous state. The atomic heat of formation at 0°K is obviously equal to the sum of all the bond energies of the molecule, or to the sum of all the dissociation energies involved in any scheme of step-by-step complete dissociation of the molecule. (See also **bond energy**; **dissociation energy**.)

ATOMIC LINE STRENGTH. See **line strength, atomic**.

ATOMIC MASS. The mass of an atom or nuclide expressed in **atomic mass units**, usually on the physical scale (a.m.u.). Examples (E. R. Cohen and W. M. DuMond, 1955, *Encycl. Phys.*, Springer-Verlag, Berlin):

Atomic mass of neutron:

$$M_n = 1.008982 \pm 0.000003$$

Atomic mass of hydrogen:

$$M_H = 1.008142 \pm 0.000003$$

Atomic mass of deuterium:

$$M_D = 2.014735 \pm 0.000006$$

Atomic mass of proton:

$$M_p = 1.007593 \pm 0.000003$$

Atomic mass of electron:

$$Nm = (5.48763 \pm 0.00006) \times 10^{-4}$$

(N is Avogadro's constant, m is electronic rest mass.)

ATOMIC MASS CONVERSION FACTOR.

The ratio r of the values for the atomic mass in terms of the chemical scale and in terms of the physical scale, respectively. The chemical scale is based on an atomic weight 16 for oxygen in its natural isotopic composition, the physical scale on an atomic weight 16 for the oxygen isotope of mass 16. Since the isotopic composition of oxygen varies slightly with its source, experimentally determined values of r vary somewhat ($r = 1.000278$ for air and carbonates, $r = 1.000268$ for water and rocks). R. T. Birge (1942) gives $r = 1.000272$ on the basis of the abundance ratio $O^{16}:O^{18}:O^{17} = 506:1:204$. Adoption of a definite value for r by international agreement is pending at the time of writing (1959).

ATOMIC MASS UNIT (a.m.u.). The unit of atomic mass in terms of the physical scale, i.e., the weight, in grams, of an atom of atomic weight 1, based on an atomic weight 16.0000 for the oxygen isotope O^{16} .

$$1 \text{ a.m.u.} = 1.67330 \times 10^{-24} \text{ g.}$$

(See also **atomic mass conversion factor**.)

ATOMIC MULTIPLETS, HUND RULES FOR. See **Hund rules for atomic multiplets**.

ATOMIC NUMBER. The atomic number Z , the ordinal number of an element in the periodic system, is equal to the electric charge of the nucleus in terms of the electronic charge, and gives the number of electrons surrounding the nucleus in a neutral atom.

ATOMIC NUMBER, EFFECTIVE. A number calculated from the atomic numbers of a compound or mixture, giving the latter's characteristics as an x-ray absorbing medium. An element of this atomic number would interact with photons in the same way as the compound or mixture. Various formulae for this number have been developed, of which the following are perhaps best known:

Spier: Based on theoretical considerations involving absorption and scattering coefficients (*Brit. J. Radiol.* **19**, 52, 1946):

$$\begin{aligned} Z &= \text{effective atomic number} \\ &= (a_1 Z_1^{2.94} + a_2 Z_2^{2.94} + \dots)^{1/2.94} \end{aligned}$$

where Z_1, Z_2 , etc., are atomic numbers of individual constituents, and a_1, a_2 , etc., the fractional electron contents of elements Z_1, Z_2 , etc., in the compound.

Fricke and Glasser: Based on theoretical considerations of photoelectron production (*Fortsch. a. d. Gebiete der Roentgenstrahlen*, **33**, 243, 1925):

$$Z = \sqrt[3]{\frac{a_1 Z_1^4 + a_2 Z_2^4 \dots}{a_1 Z_1 + a_2 Z_2 \dots}}$$

where Z_1, Z_2 , etc., are the atomic numbers of the constituents, and a_1, a_2 , etc., their fractions by weight.

ATOMIC ORBITAL. See **orbital**.

ATOMIC RADIUS. The length of a chemical bond can often be evaluated as a sum of two radii characteristic of the atoms involved in the bond, and of the type of bond (single, double or triple). Tables of such radii and an additivity rule allow one to predict the size of the skeleton of many molecules with reasonable accuracy, except when appreciable resonance with neighboring bonds takes place. (See also **bond length; bond character**.)

ATOMIC REFRACTION. The product of the **specific refraction** of an element by its atomic weight.

ATOMIC SCATTERING FACTOR (ATOMIC SCATTERING POWER). A quantity defined as the ratio of the amplitude of the radiation scattered by an atom to that scattered by a single electron. For radiation of wavelength λ , scattered at an angle θ , the scattering factor is given by the relation

$$f = \int_0^\infty U(r) \frac{\sin kr}{kr} dr$$

where $k = 4\pi \sin \theta / \lambda$. $U(r)$ is a radial distribution function, such that $U(r)dr$ represents the number of electrons between spherical surfaces of radii r and $r + dr$, with their centers at the nucleus of the atom. It may be noted that only at $\theta = 0$ is f equal to Z , the number of electrons in the atom; for all other angles of scattering $f < Z$.

ATOMIC SPECTRA. The radiation absorbed or emitted by (free) atoms and ions, corresponding to transitions between two electronic states (see **combination principle**). If both electronic states involved are stable atomic states the corresponding radiation consists of discrete lines; if the transition involves the removal of an electron (ionization) the emitted

or absorbed radiation is continuous. Atomic spectra in the usual sense of the term are the spectra in the optical and x-ray regions, corresponding to electronic transitions between atomic energy levels of considerably different energy (i.e., different electronic orbitals). For atoms and ions with comparatively simple electronic structure, especially hydrogen, helium, the alkali metals, the alkaline earths, and the corresponding ions (see **Sommerfeld-Kossel displacement law**) these spectra form characteristic series of lines whose separation and intensity decreases in regular manner towards shorter wavelengths. At the point of convergence, the series limit, the series merge into regions of continuous absorption or emission. (See also **Rydberg equation**, **Ritz formula**, **Hicks formula**.) In a wider sense the term atomic spectra includes radiation in the millimeter and centimeter region, corresponding to transitions between component levels of the same multiplet or of the same hypermultiplet.

ATOMIC SPECTRA, BURGER-DORGELO-ORNSTEIN SUM RULE FOR. See **Burger-Dorgelo-Ornstein sum rule for atomic spectra**.

ATOMIC SPECTRA, FINE STRUCTURE OF. See **fine structure**.

ATOMIC STATE, MEAN LIFETIME OF. See **mean lifetime of an atomic state**.

ATOMIC STRUCTURE, COUPLING IN. See **coupling in atomic and molecular structure**.

ATOMIC TERM SYMBOLS. The different energy levels of an atom are designated S , P , D , F , \dots terms according as the quantum number of the resultant electronic orbital angular momentum has the values $L = 0, 1, 2, 3, \dots$. The value of the multiplicity $2S + 1$ (S , quantum number of the resultant electron spin) is added to the symbol for L as a left superscript, the value of J , the quantum number of the resultant total electronic angular momentum, as right subscript.

ATOMIC UNITS (HARTREE). In atomic problems it is often convenient to use the set of units; \hbar , the quantum of angular momentum (Dirac \hbar); m , the mass of the electron; and e , the charge on the electron, rather than the esu, emu, or mksa systems. In the atomic system of units, the unit of length is the radius of the

first Bohr orbit $a = \hbar^2/mc^2$, and the unit of time is $t = \hbar^3/mc^4$, which is the time for the electron to travel one radian in the first Bohr orbit.

ATOMIC WEIGHT. The mass of an atom of any element, the mass of the oxygen atom being taken at 16 atomic mass units. The atomic weight is also called the equivalent weight or the relative weight. Since many elements, as they commonly occur in nature, are mixtures of isotopes, the accepted values of their atomic weights are in reality mean values of the isotopic atomic weights of the various isotopes present. The atomic weight, as defined above, is often called the "chemical atomic weight," taking as its basis a value of 16, for ordinary atmospheric oxygen. Since atmospheric oxygen consists of a mixture of 3 different isotopes, a "physical atomic weight" scale has been established which assigns to the lowest mass isotope the value 16. (See next entry.)

ATOMIC WEIGHT UNIT (a.w.u.). The unit of atomic mass in terms of the chemical scale, i.e., the weight, in grams, of an atom of atomic weight 1, based on the atomic weight 16 for oxygen of the isotopic composition found in natural substances (e.g., fresh lake or rain water).

$$1 \text{ a.w.u.} = 1.6738 \times 10^{-24} \text{ g.}$$

(See also **atomic mass conversion factor**.)

ATOMIZER. See **air injection**.

ATOM, ODD TERM OF. See **odd term of an atom**.

ATOM, RUTHERFORD. A theory of the structure of the atom in which a small nucleus concentrates practically all the mass, and has a positive charge equal to the atomic number. An equal number of electrons, surrounding the nucleus, fill the major part of the atomic volume. This idea is the basis of the **Bohr-Sommerfeld atom**, and of all subsequent theories.

ATOM, THOMSON. An early model of an atom in which the positive charge was considered to be distributed continuously throughout the volume of a sphere, and in which negative electrons (of sufficient number to give electric neutrality) were imbedded. The electrons normally occupied positions of equilibrium, but were capable of executing harmonic

motions about their equilibrium positions when disturbed (e.g., by an incident electromagnetic wave).

ATOM, VECTOR MODEL OF. In quantum mechanics, as in classical physics, **angular momentum** is a vector quantity whose direction, for a particle moving in a plane orbit, is perpendicular to the plane of the orbit and with a sense given by the progression of a right-handed screw. In quantum mechanics, however, angular momenta (both orbital and spin) are quantized in magnitude and direction and special rules have to be set up for their vector addition (see **angular momentum, coupling of**). The anomalous **Zee-man effect** spectral doublets, **hyperfine structure**, and many other spectral phenomena are explained in terms of the vector addition of the various vector contributions to the total angular momentum of atoms, nuclei, etc. (See also Semat, *Introduction to Atomic and Nuclear Physics*, Rinehart and Co., 1954.)

ATTACK, ANGLE OF. See **incidence, angle of**.

ATTENUATION. (1) The decrease of flux density (as, for example, light in an absorbing medium) with the distance propagated. (2) In statistics, the weakening (lowering in absolute value) of a **correlation** coefficient due to errors of observation in the variables. (3) For attenuation of sound, see **acoustic attenuation coefficient**.

ATTENUATION CONSTANT. See **propagation constant**.

ATTENUATION FACTOR. (1) In traversing a distance x in a medium with absorption coefficient α the amplitude of vibration of light is damped by the factor $\exp(-\alpha x)$, called the attenuation factor. (2) A measure of the opacity of a layer of material to sound waves traveling through it. It is equal to I_0/I where I_0 and I are the sound intensities of the wave entering and leaving the layer, respectively.

AUDIBILITY, THRESHOLD OF (THRESHOLD OF DETECTABILITY). For a specified signal, the minimum effective sound pressure of the signal that is capable of evoking an auditory sensation in a specified fraction of the trials. The characteristics of the signal, the manner in which it is presented to the

listener, and the point at which the sound pressure is measured should be specified.

Unless otherwise indicated, the ambient noise reaching the ears is assumed to be negligible. The threshold may be expressed in **decibels** relative to 0.0002 **microbar** or to 1 **microbar**. Instead of the method of constant stimuli, which is implied by the phrase "in a specified fraction of the trials," another psychophysical method (which should be specified) may be employed.

AUDIOGRAM. A graph showing **hearing loss**, percent hearing loss, or percent hearing (see **hearing, percent**) as a function of frequency.

AUGER COEFFICIENT. The ratio of Auger yield to fluorescence yield, which is also expressed quantitatively as the ratio of the number of Auger electrons to the number of x-ray photons ejected. (See **Auger effect**.)

AUGER EFFECT. (Also called auto-ionization or pre-ionization.) The radiationless transition in an atom from a discrete electronic level to a continuous (ionized) level of the same energy. Levels for which the probability of radiationless transition is high are broadened, with consequent broadening of spectral lines corresponding to radiative transitions involving this level. The selection rules for radiationless transitions are

$$\Delta J = 0; \quad \Delta S = 0; \quad \Delta L = 0; \quad \text{even} \leftarrow | \rightarrow \text{odd.}$$

AUGER YIELD. The Auger yield for a given excited state of an atom of a particular element is the probability of deexcitation by the **Auger effect** rather than by x-ray emission; it is the difference between unity and the **fluorescence yield** for that state, and also equals the sum of the Auger yields for the various possible Auger transitions from that state.

AUGMENTED THRUST RATIO. The ratio of thrust obtained by a turbojet with its afterburner operating to that without. It is given by the relationship:

$$F_a/F = \frac{V_{ja} - V}{V_j - V} = \frac{\sqrt{T_{ea}/T_e} - \nu}{1 - \nu},$$

where F_a is the thrust with afterburner operating, F is the thrust without, V_{ja} is the exhaust jet velocity with afterburner operating, V_j is

the exhaust jet velocity without, V is the inlet velocity (velocity of vehicle), T_{ea} is the exit temperature ($^{\circ}\text{R}$) with afterburner operating, T_e is the exit temperature without, and ν is the ratio V/V_j .

AUTOBAROTROPY. The state of a fluid which is characterized by both **barotropy** and **piezotropy** when the coefficients of barotropy and piezotropy are equal. This condition indicates that the fluid will remain barotropic.

AUTOCORRELATION. The **correlation** of the members of a time-series among themselves. More precisely, if $\{x_t\}$ is the **realization** of a stochastic process with mean m and variance σ^2 , the autocorrelation coefficient of order k is ρ_k , the limiting value, as $n \rightarrow \infty$, of

$$\frac{1}{n\sigma^2} \sum_{t=1}^n (x_{t+k} - m)(x_t - m).$$

The expression is also used for a sample value of ρ_k derived from a realization of finite length n , the quantities m and σ^2 then being replaced by estimators calculated from the realization. An alternative name for the sample value is *serial correlation*.

AUTOCORRELATION COEFFICIENT IN TURBULENCE. A coefficient relating a fluctuating quantity with its value at another point separated by a fixed interval of time or space, used in the statistical theory of **turbulence**. Assuming that mean values can be properly defined, i.e., that

$$\bar{Q} = \frac{1}{2\Theta} \int_{-\Theta}^{\Theta} Q(\theta) d\theta$$

is independent of Θ for a wide range of values of Θ , Taylor's (Lagrangian) autocorrelation coefficient R_ξ for a single particle moving in a field of turbulent motion is definable at time t by

$$R_\xi = \overline{u'(t)u'(t + \xi)/u'^2}$$

where u' is the fluctuating velocity component being analyzed, and ξ is a time interval. This coefficient, being a characteristic of the turbulence, must yield a **mixing length** which is also a measure of the turbulence. Since $R_\xi \rightarrow 0$ as $\xi \rightarrow \infty$ it is reasonable to suppose that $\int_0^t R_\xi d\xi$ tends to a definite limit as $t \rightarrow \infty$, in which case, together with the turbulent intensity $(\overline{u'^2})^{1/2}$, it yields the length

$$l = (\overline{u'^2})^{1/2} \int_0^\infty R_\xi d\xi.$$

The measurement of the Lagrangian autocorrelation coefficient presents serious practical difficulties; it is therefore more convenient to use the Eulerian coefficient defined by a space interval x ; thus

$$r_x = \overline{u'(X)u'(X + x)/u'^2},$$

the fluctuations u' at X and $X + x$ being measured simultaneously.

Still easier to measure is the correlation with the same quantity observed at the same point after an interval τ , which we may define as

$$r_\tau = \overline{u'(t)u'(t + \tau)/u'^2},$$

but its interpretation requires that the frequency analysis of the local velocity fluctuations be approximately identical with that produced when the wave-number analysis of the instantaneous variation of velocity along a line in the direction of the mean motion is advected with the mean velocity. This is only true if the fluctuations are small compared with the mean flow. In that case x is assumed to be the same as $\bar{u}\tau$ where \bar{u} is the mean velocity.

The above definitions are strictly applicable only to homogeneous isotropic turbulence.

AUTOCORRELATION FUNCTION. A function used, for example, in statistics and in information theory of the form

$$\phi_{11}(\tau) = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T f(t)f(t - \tau) dt$$

where τ is a time-delay parameter. The function $f(t)$ is considered to be continuous, and the function rejects phase information in regard to $f(t)$.

The autocorrelation function is related to the power spectrum of $f(t)$ by the Fourier-transform pair

$$\phi_{11}(\tau) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \Phi_{11}(\omega) e^{j\omega\tau} d\omega$$

$$\Phi_{11}(\omega) = \int_{-\infty}^{\infty} \phi_{11}(\tau) e^{-j\omega\tau} d\tau$$

where $\Phi_{11}(\omega)$ represents the power density spectrum of $f(t)$.

AUTOFRETTAGE. The process of inducing a favorable distribution of initial or residual

stress in a tube. Compressive hoop stresses which reduce the tension caused by interior pressure may be produced at the inside diameter by winding the tube with wire under tension, by shrinking one or more tubes on the outside of the inner one, or by applying interior pressure above the elastic limit but below the flow limit or collapse load.

The plastic **limit load** or pressure is not altered by autofrettage but the **fatigue** life under lower pressure is increased.

AUTO-IONIZATION. See **Auger effect**.

AUTOMORPHISM. See **group (or homomorphism)**.

AUTOMORPHISM GRAPH. See **graph, automorphism**.

AUTOREGRESSION. A **regression** relationship connecting the members of a time-series whereby the value at one point, say u_t , is expressible in terms of values at previous points, u_{t-1}, u_{t-2}, \dots , plus a **stochastic** term. The commonest case is that of *linear autoregression* exemplified by

$$u_t = \alpha_1 u_{t-1} + \alpha_2 u_{t-2} + \dots + \alpha_k u_{t-k} + \epsilon_t$$

where the α 's are parameters and ϵ is a **random variable**. A series obeying such a relation may be regarded as the realization of a particular kind of stochastic process, known as an autoregressive process. The simple case when $k = 1$ is usually known as a *Markov scheme*; that for $k = 2$ is called a *Yule scheme*.

AUXILIARY EQUATION. Using the symbol $D = d/dx$, a given linear **differential equation** with constant coefficients may be written in the form

$$D^n y + a_1 D^{n-1} y + \dots + a_n y = 0.$$

The auxiliary equation is

$$r^n + a_1 r^{n-1} + a_2 r^{n-2} + \dots + a_n = 0,$$

regarded as an algebraic equation in the unknown r . If the roots of this auxiliary equation are r_1, r_2, \dots, r_n , then the general solution of the original differential equation is

$$y = \sum_i c_i e^{r_i x}$$

the c_i 's being arbitrary constants, provided the roots are all unequal. If one of them, r_g is repeated g times the corresponding terms in the general solution of the differential equation are

replaced by $c_g(1 + a_1 x + a_2 x^2 + \dots + a_{g-1} x^{g-1})e^{r_g x}$. Imaginary roots, if they occur, have the form $r_{\pm} = A \pm iB$ and the term in the solution becomes $e^{Ax}(c_+ \cos Bx + c_- \sin Bx)$.

AVAILABILITY. See **available energy**.

AVAILABLE ENERGY. The maximum quantity of work which can be performed by a closed system in a given state (energy E , volume V , etc.) as it undergoes a transformation at the end of which it is in thermodynamic and mechanical equilibrium with the surroundings, usually the terrestrial atmosphere. The surroundings is imagined to be in thermal equilibrium, and infinite in extent, its pressure and temperature being p_o and T_o , respectively. Denoting the properties of the system by subscript o when it has reached equilibrium with the surroundings, it can be shown that the available energy

$$\alpha = W_{max} = (E + p_o V - T_o S) - (E_o + p_o V_o - T_o S_o).$$

The preceding relation is derived from the second law of thermodynamics, and hence is a consequence of it under the specified conditions, that is, in particular when the system interacts with one source of heat at temperature T_o , that of the surroundings. It is implied that the process from state (E, V, S) to state (E_o, V_o, S_o) is reversible and that the change in the sum of the entropies of the system and its surroundings is zero.

AVAILABLE POTENTIAL ENERGY. That portion of the total **potential energy** which may be converted to **kinetic energy** in a **closed system**.

AVERAGE DEVIATION. The average deviation (A.D.) of a number of like quantities X_j is the average of the absolute departures of their individual values from their mean

$$\text{A.D.} = \frac{\sum_{j=1}^n |X_j - \bar{X}|}{n},$$

where the mean

$$\bar{X} = \frac{\sum_{j=1}^n X_j}{n}.$$

The A.D. is a measure of the expected departure of any single observation of a series from the "true" value which would be obtained by the averaging of an infinite series of observations. The average deviation of the mean (a.d.) is

$$\text{a.d.} = \text{A.D.} \sqrt{n - 1}.$$

A.D. and a.d. are related to other measures of uncertainty if the individual values are distributed according to a particular rule, such as the Gaussian error function.

AVERAGE POTENTIAL MODEL FOR MIXTURES. Statistical treatments of mixtures (Prigogine, Bellemans, Scott) are usually based on the statistical theorem of corresponding states and on the introduction of *average-composition-dependent interaction constants*. If limited to first-order terms, they reduce to the theory of conformal solutions but they give also an approximate estimate of higher order terms in the difference of intermolecular forces.

AVOGADRO HYPOTHESIS. Equal volumes of gases under the same conditions of pressure and temperature contain the same number of molecules. (See Avogadro number.)

AVOGADRO NUMBER. The number of molecules in a mole ($N = 6.0248 \times 10^{23}$ mole⁻¹). It is equal to the ratio of the gas constant R to the Boltzmann constant k .

A.W.U. See atomic weight unit.

AXES, MOVING. See moving axes.

AXES OF MOLECULES, PRINCIPAL. See moments of inertia of molecules.

AXIAL BUNDLE. A bundle of rays emanating from an object point on the axis of an axially symmetric optical system.

AXIAL-FLOW COMPRESSOR. A rotary compressor in which the fluid flows mainly in the axial direction, in contrast to a centrifugal compressor in which the flow is mainly radial.

AXIAL-FLOW TURBINE. A turbine in which the fluid flows mainly in the axial direction in contrast with a *Ljungström turbine* in which the flow is mainly radial.

AXIAL LOAD. A tensile or compressive force applied along the effective centerline of a straight member. The term may also be employed for an eccentric load parallel to the

axis, with the term central axial load used to indicate the absence of bending.

AXIAL MAGNIFICATION. The ratio of the interval between two adjacent image points on the axis of an optical instrument to the interval between the conjugate object points.

AXIAL RAY. (1) Two linearly independent optical paths, one from an axial object point and one from an off-axis object point, determine all paraxial optical paths in the Gaussian optics of a system. These are referred to as the axial and field rays, respectively. (2) In general, a meridional ray of an optical system intersecting the axis in the object plane is an axial ray.

AXIAL THRUST. The axial component of force exerted on a nozzle, turbine or turbo-compressor by the fluid passing through it. It consists of a term due to change of momentum and a term due to a difference in pressures at inlet and exit.

AXIAL VECTOR. See pseudovector.

AXIS, CENTROIDAL. See centroidal axis.

AXIS, NEUTRAL. See neutral axis.

AXIS, OPTIC(AL). (1) A direction through a doubly-refracting crystal along which no double refraction occurs. A uniaxial crystal has one such direction, a biaxial crystal has two such directions. (2) The surface of a mirror and all surfaces of a lens or lens system are usually figures of revolution about a common axis, called the optical axis.

AXIS, PRINCIPAL. A line for which some quantity or property has a maximum, minimum or stationary value. *Principal axes of stress* for a point of a body are directions in which the principal stresses act. *Principal axes of inertia* for a point of a body are axes about which the moment of inertia is stationary; they are the axes of the inertia ellipsoid associated with the point. (See Mohr circle.)

AXIS, STRONG. The cross section of any beam in bending will have one line through its centroid about which the area moment of inertia

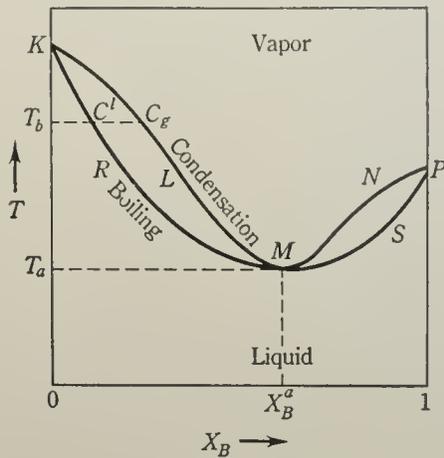

$$I_x = \int_A y^2 dA$$

is maximum. This line is known as the strong axis. In an I-beam it is the line in the cross

section perpendicular to the web at the mid-height of the beam and often called the 1-1 or $x-x$ axis.

AXIS, WEAK. The line in the cross section about which the area **moment of inertia** is least. In an I-beam cross section it is the bisector of the web perpendicular to the flanges and often is called the 2-2 or $y-y$ axis.

AZEOTROPIC SYSTEMS. Consider a mixture of water and alcohol in the presence of the vapor. This system of two phases and two components is *divariant* (see **phase rule**). Now choose some fixed pressure and study the composition of the system at equilibrium as a function of temperature. The experimental results are shown schematically on the figure.

Azeotropic system.

The vapor curve $KLMNP$ gives the composition of the vapor as a function of the temperature T , and the liquid curve $KRMSP$ gives the composition of the liquid as a function of the temperature. These two curves have a common point M . The state represented by M is that in which the two states, vapor and liquid, have the same composition x_B^A on the mole fraction scale. Because of the special

properties associated with systems in this state, the point M is called an *azeotropic point* and the system is said to form an *azeotrope*. In an azeotropic system, one phase may be transformed to the other at constant temperature, pressure and composition without affecting the equilibrium state. This property justifies the name *azeotropy*, which means a system which boils unchanged.

AZEOTROPY. See **azeotropic systems**.

AZIMUTH (ASTRONOMIC). The coordinate in the horizontal system of coordinates that is measured westward in the plane of the horizon from the prime vertical (prime meridian or south point of the horizon) to the intersection of the vertical circle through the object, with the horizon.

The *azimuth angle* is measured at the center of the celestial sphere in the plane of the horizon from the direction of the elevated pole (north or south to agree with the latitude) east or west through 180° .

The *altitude of an object* is the arc of the horizon either east or west to the intersection of the vertical circle through the object with the horizon.

Any of these quantities may be expressed in terms of arcs of the *almucantor* (parallel plane to the equator) through the object.

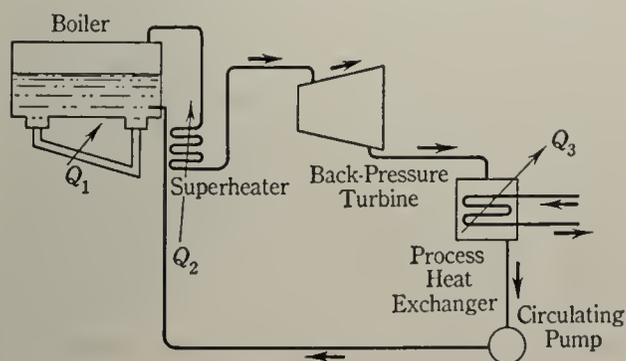

AZIMUTH ANGLE. (1) The angle ϕ in the **spherical coordinate system**. (2) For **plane-polarized light** incident on the surface of a dielectric, the angle between the plane of vibration and the normal to the plane of incidence. This same word applies to incident, reflected and refracted light. (3) When a celestial object is located with respect to the horizon and a meridian plane, the azimuthal angle is that between the meridian and the vertical plane through the body and the zenith.

B

BABINET PRINCIPLE. Two diffraction screens are complementary if the clear regions of the first are opaque regions of the second and *vice versa*. J. Babinet proved that the **Fresnel diffraction** patterns of a point source, due to complementary screens, are identical except for a region near the central image.

BACK FOCAL LENGTH. The axial distance between the last optical surface in an axially symmetrical optical system and the second (or image space) focal point.

BACK-PRESSURE TURBINE. In industrial processes and in building heating, it is necessary to supply heat at a moderate temperature only, namely at a temperature far below that which can be maintained in a furnace. Consequently, supplying heat directly constitutes a loss from the point of view of the second law of **thermodynamics**, because the temperature difference could be made use of for the production of work. It is more economical to produce steam at the highest temperature possible and to expand it in a back-pressure turbine to the temperature required for heating or processing. The latter temperature determines the back pressure for the turbine.

Back-pressure turbine.

(See also **extraction turbine**.)

BACK-SCATTERING (BACKWARD SCATTERER). The scattering of radiant energy into the hemisphere of space bounded by a plane normal to the direction of the incident radiation and lying on the same side as the incident ray; the opposite of forward scatter.

tion and lying on the same side as the incident ray; the opposite of forward scatter.

BACK-SCATTERING COEFFICIENT B (ECHOING AREA). For an incident plane wave, the back-scattering coefficient B is 4π times the ratio of the reflected power per unit solid angle (Φ_r) in the direction of the source divided by the power per unit area (W_i) in the incident wave:

$$B = 4\pi \frac{\Phi_r}{W_i} = 4\pi r^2 \frac{W_r}{W_i},$$

where W_r is the power per unit area at distance r . For large objects, the back-scattering coefficient of an object is approximately the product of its interception area by its scattering gain in the direction of the source, where the interception area is the projected geometrical area and the scattering gain is the reradiated power gain relative to an isotropic radiator.

BACKWARD DIFFERENCE OPERATOR. See **difference operators**.

BACKWARD DIFFERENCES. See **difference operators**.

BAIRSTOW METHOD. A method for finding complex roots of an algebraic equation.

Let $z^2 + az + b$ be a trial divisor of $f(z)$ and form

$$f(z) = (z^2 + az + b)^2 Q(z) + (z^2 + az + b)q(z) + r(z),$$

where

$$r(z) = r_1z + r_0, \quad q(z) = q_1z + q_0.$$

This means that r is the remainder after dividing f by $z^2 + az + b$, and q the remainder after dividing the quotient. Solve

$$(aq_1 - q_0)\delta a - q_1\delta b = -r_1,$$

$$bq_1\delta a - q_0\delta b = -r_0$$

for δa and δb ; then $z^2 + (a + \delta a)z + b + \delta b$ will be, in general, closer to a true divisor. The

method is an adaptation of the Newton method to finding complex roots and was originally described by Bairstow; later by Hitchcock.

BALANCE. A horizontal shaft with attached masses (as, for example, the armature of a motor or the rotor of a turbine) is said to be in *static balance* if at rest there is no turning moment about the axis of the shaft in any angular position. A rotor in static balance may produce oscillating bearing reactions when the shaft rotates. The reduction of these oscillatory forces to an acceptable value is called *dynamic balancing*. Balance is achieved when a **principal axis of inertia** of the rotor coincides exactly with the axis of the shaft.

BALANCED DESIGN. See **incomplete block**.

BALANCING, DETAILED. See **detailed balancing**.

BALMER SERIES. Series of lines in the spectra of atomic hydrogen and the hydrogen-like ions He^+ , Li^{++} , \dots . The wave numbers $\nu_n = \frac{1}{\lambda_n}$ are given by the formula

$$\nu_n = RZ^2 \left[\frac{1}{2^2} - \frac{1}{n^2} \right], \quad (n = 3, 4, \dots),$$

where R stands for the **Rydberg constant** and Z for the **atomic number**.

The first lines of the Balmer series of hydrogen ("Balmer lines") were discovered early as strong absorption lines in the visible region of the solar spectrum, and are traditionally denoted as $\text{H}_\alpha(\lambda, 6563 \text{ \AA})$, $\text{H}_\beta(\lambda, 4861 \text{ \AA})$, $\text{H}_\gamma(\lambda, 4340 \text{ \AA})$, etc.

BALMER TERMS. The energy levels of the hydrogen atom and of the hydrogen-like ions, without consideration of fine structure, i.e., the energy of the **Bohr orbits**

$$E_n = - \frac{2\pi^2 \mu e^2 Z^2}{h^2 n^2}.$$

Here h is Planck's constant, e is the electronic charge, Z is the atomic number, n is the principal quantum number

$$n = 1, 2, 3, \dots,$$

and μ is the reduced mass of the electron

$$\mu = \frac{mM}{m + M},$$

(m and M are electronic and nuclear mass respectively).

BANACH SPACE. A complete, **normed vector space**. The most important examples of Banach spaces have functions for their elements, e.g., the space C of functions continuous on a closed interval with norm equal to maximum of absolute value. A **Hilbert space** is a particular example of a Banach space.

BAND. In the spectrum of a molecule, a group of closely spaced lines, corresponding to the possible transitions from the rotational energy levels belonging to one vibrational level to the rotational levels of another vibrational level (see **molecular energy levels**, **vibrational energy levels of a molecule**, **rotational energy levels of a molecule**). The rotational fine structure of a band depends on the **selection rules** which are valid for the transition concerned, and varies widely between the bands of different molecules, and between bands corresponding to different types of transitions in the same molecule. (For more detail see **rotation-vibration spectra of molecules**.) Lines having the same difference $\Delta J = J' - J''$ between the rotational quantum numbers of the upper and lower state form series of regularly spaced lines, called branches (Q -branch for $\Delta J = 0$, R - and P -branch for $\Delta J = +1$ and -1 , respectively, S - and O -branch for $\Delta J = +2$ and -2 , respectively, \dots).

BAND, CONDUCTION. See **conduction band**.

BAND EDGE ENERGY. The energy of the edge of the **conduction band** or **valence band** in a solid; that is, the minimum energy required by an electron in order that it may be free to move in a semiconductor or the maximum energy it may have as a valence electron.

BAND, FUNDAMENTAL. See **fundamental band**.

BAND ORIGIN. See **zero line of a band**.

BAND PRESSURE LEVEL. The effective sound pressure level (see **sound pressure, effective**) for the sound energy contained within a specified frequency band of a given sound. Both the width of the band and the reference pressure should be stated.

BAND SEQUENCES. See **band system**.

BANDS, OVERTONE. See *overtone bands*.

BAND SPECTRA. See *band system; molecular spectra*.

BAND SYSTEM. In the spectrum of a molecule, a band system consists of the bands corresponding to all the transitions possible between the **vibrational energy levels** of one electronic state to the vibrational levels of another electronic state. (For formulas representing the wave numbers of the **zero lines** of a band system, see **electronic spectra of molecules**.) In the case of a diatomic molecule the wave numbers of the zero lines (or of the band heads) of the bands belonging to a band system are conveniently arranged in a table (Deslandres table) such that bands with the same lower vibrational quantum number v'' and increasing upper vibrational quantum number v' (v' progressions) form vertical columns, and bands with the same upper vibrational quantum number v' and increasing lower vibrational quantum number v'' (v'' progressions) form successive horizontal rows. The differences between successive columns or successive rows of wave numbers correspond to the differences between successive vibrational energy levels of the lower and upper electronic states, respectively. The bands forming diagonals in the Deslandres table correspond to transitions with $v' - v'' = \text{const.}$ (*Band sequences*.)

BAND THEORY OF SOLIDS. Electrons in a periodic lattice of ions occupy energy levels which fall into groups or bands. In the *allowed bands*, the energy levels are closely spaced, and form effectively a continuum. There are, however, ranges of energy in which there are no levels at all, and these are called *forbidden bands* or *energy gaps*. The electrical properties of the material depend on how the electrons are distributed in the various bands. Thus, when only the lower bands are filled, and there is a wide energy gap above them, the material behaves as an *insulator*. When the gap is narrower, or when impurity centers are present, which create extra levels, some electrons may be raised to the **conduction band**, where they can carry current. The material is then a *semiconductor*. In metals, there is a partially-filled band in which the electrons behave as if they were free.

BANDWIDTH. (1) The number of cycles per second expressing the difference between the limiting frequencies of a frequency band. (2) For an amplifier or other device, the range of frequencies for which some characteristic (such as gain) falls within specified limits (e.g., not less than one half of its maximum value). (3) In radio communication usage the number of cycles per second required to convey the information being transmitted, either visual or aural.

BANDWIDTH, EFFECTIVE. (1) For a specified **transmission system**, the bandwidth of an ideal system which (a) has uniform transmission in its **pass band** equal to the maximum transmission of the specified system, and (b) transmits the same power as the specified system when the two systems are receiving equal input signals having a uniform distribution of energy at all frequencies. This may be expressed as follows:

$$\text{Effective bandwidth} = \int_0^{\infty} Gdf$$

where f is the frequency in cycles per second and G is the ratio of the power transmission at the frequency f , to the transmission at the frequency of maximum transmission.

(2) For a band-pass filter (see **filter, band-pass**) the width of an assumed rectangular band-pass filter having the same **transfer ratio** at a reference frequency, and passing the same mean-square value of a hypothetical current and voltage, having even distribution of energy over all frequencies.

BANDWIDTH OF A WAVE. The least frequency interval outside of which the **power spectrum** of a time-varying quantity is everywhere less than some specified fraction of its value at a reference frequency. This definition permits the spectrum to be less than the specified fraction with the interval. Unless otherwise stated, the reference frequency is that at which the spectrum has its maximum value.

BAND, ZERO LINE OF. See *zero line of a band*.

BAR. The general term for a structural member whose length is much greater than its cross-sectional dimensions. A bar under compression may be called a **column** or a **strut**. A

bar in bending is a **beam**, a bar in torsion is a **shaft**, a bar in tension may be called a **tie**.

BARBA LAW. The statement that geometrically similar bars of the same material but of different size deform similarly. Deviations from similarity are labeled as **size effects**.

BARDEEN-COOPER-SCHRIEFFER THEORY OF SUPERCONDUCTIVITY (1957).

An extension of the ideas of the Fröhlich-Bardeen theory in which the exchange of virtual phonons and the short range Coulomb repulsions between the members of a pair of electrons having spins in opposite directions lead to a correlation of the electrons in a superconductor. The correlation leads to stable electron pairs having energies near the **Fermi level** and seems to account satisfactorily for the major properties of superconductivity.

BARN. The unit of nuclear cross section, equal to 10^{-24} square centimeter. The most common sub-unit is the millibarn, equal to 10^{-27} cm².

BAROCLINIC. Possessing density gradients; when applied to the atmosphere implying the presence of horizontal temperature gradients and therefore of vertical gradients of horizontal wind. Potential energy is stored in a baroclinic airstream, and a measure of the availability of this for the production of wind systems is the **Richardson number**, $Ri = g\beta/U'^2$. Here

$$\beta = \frac{1}{\theta} \frac{\partial \theta}{\partial z}$$

is the static stability represented by the vertical gradient of potential temperature θ , and U' is the wind shear representing, through the thermal wind equation, the horizontal gradient of temperature. Thus for geostrophic winds

$$Ri = f^2 \theta \frac{\partial \theta}{\partial z} / g \left(\frac{\partial \theta}{\partial x} \right)^2,$$

where z is measured vertically, and x horizontally normal to the isotherms. f is twice the vertical component of the earth's rotation. The instability of a baroclinic airstream increases with decreasing Ri and disturbances like extra-tropical depressions may arise in baroclinic airstreams whose **Rossby number** is of the order of unity.

BAROCLINITY. The state of being **baroclinic**.

BAROMETER FORMULA. Equation for the density $\rho(z)$ of an isothermal gas at a height z in the earth's gravitational field (constant gravitational acceleration g),

$$\rho = Ce^{-\beta mgz},$$

where $\beta = 1/kT$ (k is Boltzmann's constant, T , absolute temperature), m , the mass of one atom of the gas, and C , a normalizing constant.

BAROTROPIC. Of uniform density; when applied to the atmosphere implying the absence of horizontal temperature gradients and therefore of vertical gradients of horizontal wind because of the absence of a **thermal wind**. A barotropic atmosphere moves horizontally with a velocity independent of height.

BAROTROPIC INSTABILITY. The hydrodynamic **instability** arising from certain distributions of **vorticity** in a two-dimensional non-divergent flow. This is an **inertial instability** in that kinetic energy is the only form of energy transferred between current and perturbation. The variation of vorticity (i.e., shear) in the basic current may be concentrated in discontinuities of the horizontal wind shear (to be distinguished from **Helmholtz instability**, where the velocity itself is discontinuous) or may be continuously distributed in a curved velocity profile. A well known necessary condition for barotropic instability is that the vorticity must change sign (i.e., vanish) at a point of maximum shear.

In barotropically unstable flow, certain isolated characteristic wavelengths are associated with **neutral waves**, separating the damped from the amplified waves. Applications to atmospheric jet-stream wind profiles have calculated neutral wavelengths to be of the order of 9000 km, with shorter waves damped and longer waves amplified. It has been suggested therefore that the shorter cyclone waves provide a source of kinetic energy to the jet stream.

BAROTROPIC MODEL. Any of a number of model atmospheres in which some of the following conditions exist throughout the motion: coincidence of pressure and temperature surfaces; absence of vertical wind shear; absence of vertical motions; absence of horizontal velocity **divergence**; and conservation of the vertical component of **absolute vorticity**.

Certain of these models would be more prop-

erly called **autobarotropic** models; often the barotropic model is the same as the **equivalent-barotropic model** used in numerical forecasting.

BAROTROPIC PRESSURE FUNCTION.

The scalar function in a **barotropic** fluid, the gradient of which is equal to the specific pressure force:

$$\nabla\pi = \alpha\nabla p,$$

where π is the barotropic pressure function, α , the specific volume, and p , the pressure.

BAROTROPIC VORTICITY EQUATION.

The **vorticity equation** in the absence of horizontal divergence and vertical motion, so that the absolute vorticity of a parcel is conserved,

$$\frac{d}{dt}(\zeta + f) = 0,$$

where ζ is the **relative vorticity** and f the **Coriolis parameter**. This equation may also be interpreted as governing vertically-averaged flow in which divergence is present but wind direction is constant with height. (See also **equivalent-barotropic model**.)

BAROTROPY. The state of being **barotropic**.

BARREL DISTORTION. See **geometric distortion**.

BARRIERS, NOISE LEVEL REDUCTION OF. See **noise level reduction of barriers**.

BARTLETT FORCE. A central force between two nucleons which is derivable from a potential containing an operator which exchanges the **spins** of the two particles but not their positions. Nuclear forces are known to be spin-dependent, and some of their properties can be described in terms of the Bartlett force.

BARYCENTRIC PARALLAX. A small oscillatory motion of the earth around its orbit about the sun due to the fact the center of mass of the earth-moon system does not coincide with the center of the earth, but moves about as the moon rotates around the earth. The period of this motion is one synodic month. Data on the barycentric parallax are chiefly of use in calculating the mass ratio of earth and moon.

BARYON. The generic name of the "elementary" particles of mass in the interval from the nucleonic mass up to (but not including) the deuteron mass. The word "elementary particle" is here used in the sense of a system having a definite mass and spin, a lifetime long compared to **strong interaction** times (which are of the order $\sim 10^{-23}$ sec) and having a well defined charge and other electromagnetic properties. At present (1960) eight such particles are known. They are listed in Table 1 below.

The six particles listed in Table 1 which are heavier than the neutron or proton are called *hyperons*.

BASE OF A SYSTEM OF LOGARITHMS. See **logarithm**.

BASE OF A SYSTEM OF NUMBERS. See **radix**.

BASES. See **acids and bases, definitions of Brønsted and Lewis**.

BASE VECTORS (FOR A COORDINATE SYSTEM). If \mathbf{r} denotes the vector position relative to a fixed origin, of a point P in space and x^i are the contravariant coordinates of P in a curvilinear coordinate system x , then for each value of i , $\partial\mathbf{r}/\partial x^i$ is a vector tangential to the coordinate line x^i through P . The vectors $\partial\mathbf{r}/\partial x^i$ are called the base vectors for the curvilinear coordinate system x .

TABLE I

Particte	Mass (in electron masses)	Mean life (in seconds)	Charge (in multiple of e)
p (proton)	1836.12 ± 0.04	stable $> 4 \times 10^{23}$ years	+1
n (neutron)	1838.65 ± 0.04	1050 ± 200	0
Λ^0	2182.5 ± 0.4	$2.9 \pm 0.2 \times 10^{-10}$	0
Σ^0	2329.9 ± 0.3	$< 2 \times 10^{-12}$	0
Σ^+	2327.9 ± 0.6	$0.7 \pm 0.1 \times 10^{-10}$	+1
Σ^-	2341.6 ± 0.8	$1.6 \pm 0.2 \times 10^{-10}$	-1
Ξ^-	2585 ± 6	$\sim 3 \times 10^{-10}$	-1
Ξ^0	$\sim 2587 \pm 10$?	0

BASE VECTORS, RECIPROCAL (FOR A COORDINATE SYSTEM IN THREE-DIMENSIONAL SPACE). The vectors \mathbf{a}^i given by

$$\mathbf{a}^i = \frac{\mathbf{a}_2 \times \mathbf{a}_3}{[\mathbf{a}_1 \mathbf{a}_2 \mathbf{a}_3]}, \text{ etc.,}$$

where \mathbf{a}_i are the base vectors, $[\mathbf{a}_1 \mathbf{a}_2 \mathbf{a}_3]$ is the scalar triple product of these and $\mathbf{a}_2 \times \mathbf{a}_3$ is the vector product of \mathbf{a}_2 and \mathbf{a}_3 .

BASIC STIMULUS. The standard stimulus (usually **achromatic**) used to determine the units of the reference stimuli of any **trichromatic system**.

BATHO FORMULA. The average shear stress in a thin-walled tube subject to torsion without appreciable distortion of the tube is $\tau = 2G\theta A/s$ where s is the mean perimeter, θ , the angle of twist per unit length, A the cross-sectional area and G the **shear modulus**.

BAUER-WACH TURBINE. A turbine driven by the exhaust steam from a reciprocating steam engine. (See **exhaust-gas turbine**.)

BAUSCHINGER EFFECT. Reduction of the yield stress for reversed loading after plastic flow. More generally, the reduction of the **yield limit**, when the yield stress system changes, or changes direction from that of first loading.

BAY. The portion of a structure between two adjacent **bents** or **frames**.

BAYES' SOLUTION. In the theory of statistical decision-functions, a Bayes' solution is one which minimizes the average risk involved, the average taking place over some prior probability distribution.

BAYES' THEOREM. Let $c_1, c_2, c_3 \dots c_s$ be some s mutually exclusive random events such that one of them must happen and let $P(c_i)$ be the **probability** of c_i . These events we shall describe as causes. Let E be some event which can be directly observed and let $P(E|c_i)$ be the probability that E will occur on the assumption that c_i has already happened. Let $P(c_i|E)$ be the probability of c_i after E has occurred. The probabilities $P(c_i)$ are called "a priori" probabilities, i.e., probabilities not at all dependent on the event E , whereas $P(c_i|E)$ are called "a posteriori" probabilities

since these depend on the event E having occurred. Bayes' theorem states

$$P(c_i|E) = \frac{P(c_i) \cdot P(E|c_i)}{\sum_{j=1}^s P(c_j)P(E|c_j)}$$

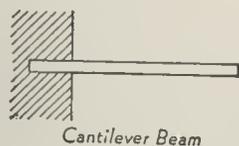

The theorem states exactly how the probability of a certain "cause" changes as different events actually occur. The theorem was published posthumously in 1764. When all conditions of the theorem are fulfilled there is no objection to Bayes' theorem. The difficulties in applying the theorem depend upon the fact that $P(c_i)$, the "a priori" probabilities, are not known and are assumed often to be equal in the absence of other knowledge. This is known as *Bayes' postulate*, or the "equidistribution of ignorance." Many statisticians find it unacceptable and most modern theories of inference attempt to avoid it.

BEAM. A body bounded by a right cylindrical (or prismatic) surface and by two parallel planes which are normal to the generators of the cylindrical surface, the dimension of the body parallel to the generators being large compared with the characteristic dimensions perpendicular to them. Also called *rod*, *shaft* or *bar*. By an extension of meaning, the cross-sectional form may vary, if explicitly stated, as when the term is used to designate certain rolled or extruded sections, such as I-beams, WF-beams, T-beams, etc. Frequently, the term beam is reserved for a **bar** subjected primarily to bending so that its curvature changes. For pure bending about a principal axis in the elastic range $1/\rho = M/EI$ for an initially straight beam where ρ is the radius of curvature, M is the **bending moment**, EI is the **flexural rigidity** (E is **Young's modulus** and I is **area moment of inertia**.) The curvature $1/\rho$ is approximated by d^2y/dx^2 in most problems. Maximum bending stress in an elastic beam is given by Mc/I where c is the distance from the **neutral axis** to the extreme fiber.

BEAM, BENDING OF. See **flexure, simple (of a beam)**.

BEAM, CANTILEVER. A beam which is rigidly connected at one end to a fixed support and free to move at the other end. This theoretically fixed condition rarely occurs because of deformation of the supporting ma-

material. The maximum **bending moment** and maximum **shear** occur simultaneously at the face of the support. The usefulness of this

type of beam is demonstrated in structures such as canopies, unbraced airplane wings and cantilever retaining walls.

BEAM-COLUMN. A beam-column is a **bar** subject to appreciable axial compression P , as well as bending. Non-linear problems arise because the transverse deflections y which occur increase the bending moment significantly by the addition of a Py term. The elastic deflections which would be found in the absence of P are magnified by $1/(1 - P/P_E)$ approximately, where P_E is the **Euler buckling load**. (See **critical load—Southwell's method**.)

BEAM, COMPOSITE. A beam which is composed of two materials properly bonded together and having different properties. **Reinforced concrete** beams, steel beams mechanically bonded to a concrete deck, and wood beams reinforced with steel plates are typical examples. It has become a rather prevalent practice in recent years to provide for composite action between the steel stringers and concrete floor of highway bridges. This permits the use of lighter beams than would otherwise be possible.

The analysis of composite beams depends on the assumption that a plane section before bending remains plane after the **load** is applied. Therefore the two materials must be connected in such a way that they will act as a unit. This condition is realized in the reinforced concrete beam by means of the bond (see **bond stress**) between the reinforcing rods and the concrete. In the case of reinforced wood beams the parts are connected by bolts properly spaced to resist the shearing forces (see **shear**) between the plates and the beam. Steel beams are bonded to the concrete flange by means of lugs or spirals welded into the top flange of the steel beam.

The flexure formula is applicable to composite elastic beams if the beam is transformed into an equivalent homogeneous section by means of the transformed area method

which is found in texts on strength of materials and reinforced concrete design.

BEAM, CONJUGATE. The equations for small deflections of **beams**

$$\frac{d^2y}{dx^2} = \frac{d\theta}{dx} = \frac{M}{EI}$$

and the relation between moment, M , shear, V , and transverse load per unit length

$$\frac{d^2M}{dx^2} = \frac{dV}{dx} = q$$

show that the shear and bending moment in a conjugate beam loaded by M/EI is the slope and deflection of the actual beam, respectively. Boundary conditions for the conjugate beam must be chosen appropriately. An actual hinged end transforms to a hinged end, a fixed end becomes free, and conversely.

BEAM, CONTINUOUS. A **beam** which has more than two supports and therefore is statically **indeterminate** unless hinges are inserted. The continuity over the supports increases the load-carrying capacity. The junction conditions at a support are continuity of moment, except when an external moment is applied, and continuity of slope in the elastic range. (See **Clayton theorem of three moments**.)

BEAM CURVATURE. See **curvature of beam**.

BEAM, CURVED. A **beam** curved in the plane of bending. Although displacement may vary linearly, the strain distribution is non-linear because of this initial curvature. (See **Winkler-Bach formula**.) When the depth of the beam is small compared to its radius of curvature, the non-linearity is negligible and the equations for straight beams apply with change in curvature replacing curvature.

BEAM, DEEP. A beam whose length is a small multiple of its depth, say less than five, and which carries transverse load by a combination of beam and arch action. For such a short or deep beam, the assumption of plane cross sections remaining plane does not give good answers for the maximum stresses induced.

BEAM EQUATIONS OF MOTION. The differential equation of small motion of a beam, ignoring rotary inertia and shear, is

$$\frac{\partial^2}{\partial x^2} \left(EI \frac{\partial^2 y}{\partial x^2} \right) + \rho A \left(\frac{\partial^2 y}{\partial t^2} \right) = f(x, t)$$

where EI is the flexural rigidity, ρ is the mass density, A is the cross-sectional area and f is the applied force per unit length of beam.

BEAM, FIXED-ENDED OR ENCASTRÉ.

A beam with ends so firmly connected to the supports that in the elastic range the end

Fixed-ended beam.

tangents remain fixed in direction. At loads sufficient to produce plastic hinges at the ends of the beam, the supports are presumed capable of carrying the full plastic moment.

BEAM, HAUNCHED. A beam whose thickness increases toward its supports. Tables and graphs are available for both reinforced concrete and metal beams to permit the designer to employ the same techniques as for the simpler problems of uniform cross section.

BEAM ON ELASTIC FOUNDATION. The term elastic foundation usually refers to the simplest type in which the local foundation reaction ky is proportional to the local deflection y . The governing differential equation for the bending of an elastic beam of flexural rigidity EI then is

$$\frac{\partial^2}{\partial x^2} \left(EI \frac{\partial^2 y}{\partial x^2} \right) + ky = q(x)$$

where q is the applied load per unit length.

BEAM, OVERHANGING. A beam which extends beyond its support at one or both ends. The overhang is a cantilever whose support end is not fully fixed. (See **bending moment**.)

BEAM, SHORT. A deep beam.

BEAM, SIMPLE. A beam which rests on two end supports in such a manner that its ends are free to rotate on the supports. Since riveted

connections are elastic, the end restraint offered by this type of connection is not very reliable. Therefore, beams and girders which

are riveted to supports are generally assumed to be simply supported unless a special type of moment connection is used.

BEARING. (1) Any member used to support, guide, or restrain a moving part of a mechanism. (2) That part of a structure that transmits load to the supports, such as a pedestal under a bridge. A compressive force or stress is often referred to as a *bearing stress*. Also the load-carrying capacity under thrust as for a footing or a pile foundation is called *bearing capacity*. (3) A term used in navigation, surveying, and a variety of other activities to describe direction. Various methods are used to define bearing. Frequently *true bearing* is defined as the direction measured from the north to the east through 360° . However, one might well find a southeast direction described as bearing 135° , 135° true, southeast, south 45° east, north 135° east, etc., etc.

Bearing may be determined by compass, in which case it must be corrected for deviation and variation to obtain a true bearing.

Bearing may be *relative*, in which case other information must be furnished before the actual direction can be found. For example, a look-out on a ship on heading 045° true and an object is seen 65° to the right of the bow. In this case he might report as 065° right, in which the deck officer would interpret this direction as 110° true.

The various professions dealing with directions have their own schemes for naming a direction. Astronomers seldom use the term bearing, preferring azimuth, measured from the north to the right (i.e., to the east) through 360° .

BEAT(S). A series of alternate maxima and minima in **vibration** amplitude, produced by the **interference** of two wave trains of different frequency.

BEAT FREQUENCY. The difference frequency resulting from the combination of two applied frequencies.

BEATTIE AND BRIDGEMAN EQUATION.

A form of the **equation of state**, relating the pressure, volume, and temperature of a gas, and the **gas constant**. The Beattie and Bridgeman equation applies a correction for reduction of the effective number of molecules by molecular aggregation, due to various causes.

It has been stated in more than one form, an example of which is:

$$P = \frac{RT(1 - \epsilon)}{V^2} (V + B) - \frac{A}{V^2}$$

in which P is the pressure, T is the absolute temperature, V is the volume, R is the gas constant and A , B and ϵ are quantities defined in terms of five empirical constants, A_0 , B_0 , a , b , and c by the following relationships:

$$A = A_0 \left(1 - \frac{a}{V}\right)$$

$$B = B_0 \left(1 - \frac{b}{V}\right)$$

$$\epsilon = \frac{c}{VT^3}$$

BEER LAW. The law discovered by Beer in 1852, that the absorption coefficient for light passing through a solution of a given salt in a non-absorbing solvent is proportional to the concentration. The absorption coefficient a of the Bouguer law can therefore be expressed as αc , where α is the molar absorption coefficient and c is the concentration in moles per liter. Sometimes written

$$I = I_0 e^{-\alpha c x}$$

where I is the intensity of light transmitted, I_0 is the intensity of the incident light, e is the natural logarithmic base, c is the concentration of the solution in moles per liter, x is the thickness of the transmitting layer, and α is the molar absorption coefficient.

In general Beer's law is used for light of a particular narrow wavelength band and then α is the specular molar absorption coefficient.

The Beer law is also written

$$I = I_0 10^{\epsilon c x}$$

where ϵ is known as the molar extinction coefficient. Not all solutions obey the Beer law. (See also the **Bouguer law**.)

BEHRENS-FISHER TEST. A statistical test of significance for the difference between the means of two samples which emanate from normal (Gaussian) populations with different variances. The test is based on fiducial probability (see **fiducial inference**) and is not universally accepted as valid.

BEI. The imaginary part of the **Bessel function** $J_n(xe^{\pm 3\pi i/4}) = \text{ber}_n(x) \pm i \text{bei}_n(x)$, where the real part is denoted by **ber**.

BEL. See **gain**, **gain ratio**.

BELLEVILLE SPRING. A sprung flat disc or washer in the form of a conical shell or an assemblage of shells. (See **springs**.)

BELTRAMI DIFFERENTIAL PARAMETERS. If ϕ and ψ are invariant functions of position on a surface for which the contravariant **metric tensor** is $a^{\alpha\beta}$, then $a^{\alpha\beta}\phi_{,\alpha}\phi_{,\beta}$ is a surface invariant called Beltrami's first differential parameter of ϕ . $a^{\alpha\beta}\phi_{,\alpha\beta}$ is a surface invariant called Beltrami's second differential parameter of ϕ . $a^{\alpha\beta}\phi_{,\alpha}\psi_{,\beta}$ is a surface invariant called Beltrami's mixed differential parameter of ϕ and ψ . In a surface coordinate system u^α , $\phi_{,\alpha}$ denotes $\partial\phi/\partial u^\alpha$ and $\psi_{,\beta}$ denotes $\partial\psi/\partial u^\beta$.

BELTRAMI-ENNEPER THEOREM. The torsions of the two **asymptotic lines** through a point on a surface are the positive and negative square roots of the negative of the Gauss curvature. (See **curvature of a surface**, **second**.)

BELTRAMI FLOW. A fluid motion in which the **vorticity** vector is parallel to the velocity vector at every point of the fluid.

BELTRAMI-MICHELL COMPATIBILITY EQUATIONS. Differential equations which must be satisfied by a static stress field in a body of isotropic elastic material satisfying the **generalized Hooke law**. In a rectangular Cartesian coordinate system x , they may be written, using the **indicial notation** and **summation convention**, as

$$\begin{aligned} \frac{\partial^2 \sigma_{ij}}{\partial x_k \partial x_k} + \frac{1}{1 + \nu} \frac{\partial^2 \sigma_{kk}}{\partial x_i \partial x_j} \\ = - \frac{\nu}{1 - \nu} \delta_{ij} \frac{\partial F_k}{\partial x_k} - \left(\frac{\partial F_i}{\partial x_j} + \frac{\partial F_j}{\partial x_i} \right), \end{aligned}$$

where σ_{ij} denotes the stress components and F_i the components of the body forces per unit volume in the system x ; ν is **Poisson's ratio** and δ_{ij} is the **Kronecker delta**. The equation represents six independent equations. It is derived from the equation of compatibility of strain for infinitesimal deformations by using the **generalized Hooke law** and the equations

of equilibrium to effect substitutions. Also called *equations of compatibility of stress*

BÉNARD CELLS. The configuration assumed when slow overturning motion is induced in a viscous fluid by heating it below. The cells are usually square or hexagonal when the fluid is confined between horizontal planes, the hexagonal form requiring a slightly smaller **Rayleigh number** to produce the motion.

In a fluid in which the viscosity decreases as temperature increases, the motion is upwards in the center of the cells and downwards at the edges. In a gas it is usually downwards in the center.

The motion is slow, so that the inertia forces are negligible and the viscous stresses are balanced by the pressure gradients produced by the density variations. The heat is transported from the hot to the cold surface partly by convection and partly by conduction.

The cells are about 2½ times as wide as they are deep and the precise configuration depends on the conditions imposed on the velocity and temperature at the bounding surfaces.

If both upper and lower surfaces are perfectly conducting and the cells of square plan, the ratio, *a*, of cell width to height and the Rayleigh number, required just to produce motion, are as follows:

Upper Boundary	Lower Boundary	<i>a</i>	Rayleigh Number
free	free	$\pi/\sqrt{2} = 2.22$	$27\pi^2/4 = 651$
free	rigid	2.67	1100
rigid	rigid	3.14	1708

where at a rigid boundary the velocity is zero and at a free boundary there is no shear stress, while the temperature is uniform in both cases.

In this case the Rayleigh number is defined as $g\beta\alpha h^4/\kappa\nu$, α being the coefficient of cubical expansion, β the vertical temperature gradient, h the depth, and κ and ν the thermometric conductivity and dynamic viscosity of the fluid.

BENDING. Change of **curvature**. When produced by a transverse load, bending is accompanied by shearing deformation, which is not generally of great importance except in short or deep **beams** or in beams whose web is designed explicitly to carry the shear with minimum material.

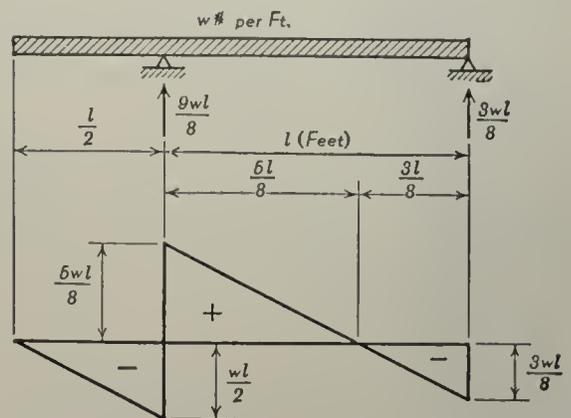

BENDING A LENS. In the approximation of thin lens theory, i.e., negligible lens thickness,

the power of a lens with spherical surfaces of radii r_1, r_2 is $\phi = (n - 1) (r_1^{-1} - r_2^{-1})$ where n is the index of refraction. By bending the lens of an axially symmetric lens system is meant varying the curvatures of the spherical surfaces so that $(r_1^{-1} - r_2^{-1})$ is an invariant for each component lens of the system. Then the **power**, the **Petzval sum**, and the longitudinal and lateral chromatic variations of focus remain constant, while in general the **spherical aberration**, **coma**, **astigmatism**, and **distortion** of the system vary. As a result, bending the component lens of a system is a basic perturbation method in lens design.

BENDING, MEMBRANE ANALOGY. See **membrane analogy bending**.

BENDING MOMENT. The bending moment at any cross section of a beam is the component in the cross section of the vector sum of the moments of all the forces acting on the beam to one side of the section about the **centroid** of the cross section. An internal resisting moment at any section is the sum of the moments of the normal or bending stresses about an axis in the cross section passing through the centroid.

A graphical representation of the variation of bending moment on a beam is called a *bending moment diagram*. An illustration of a bending moment diagram is given below for an overhanging beam with a uniformly dis-

Bending moment diagram.

tributed load covering the entire length of the beam. The maximum bending moments which are indicated on the diagram occur where the **shear** changes sign. Since the product of a force and distance is a moment, bending moments are expressed as foot-pounds, inch-pounds, etc.

BENDING OF A BEAM. See flexure, simple (of a beam).

BENDING, PURE. Bending unaccompanied by shear or normal force. The bending moment is constant so that plane cross sections must remain plane because of symmetry.

BENDING, UNSYMMETRICAL. See unsymmetrical bending.

BENEDICT-WEBB-RUBIN EQUATION. An empirical equation of state for a gas of the form

$$p = R\rho T - \left(B_o RT - A_o - \frac{C_o}{T^2} \right) \rho^2 + (bRT - a)\rho^3 + a\alpha\rho^6 + [(1 + \gamma\rho^2)c\rho^3/l^3] \exp(-\gamma\rho^2),$$

where R , B_o , A_o , C_o , b , a , c , α , γ are empirical constants, different for every gas. The equation is nearly of the virial form (except for the last term) and covers a wide range of pressures and temperatures. It is particularly useful for mixtures of inert gases, when the following empirical combination rules apply:

If X denotes any of the constants A_o , C_o , γ , then for the mixture (no subscript) in terms of two components (subscripts 1 and 2), we can write

$$X = (x_1 X_1^{1/2} + x_2 X_2^{1/2})^2.$$

Here x_1 and x_2 are the respective mole fractions. If Y denotes any one of b , a , c , α then

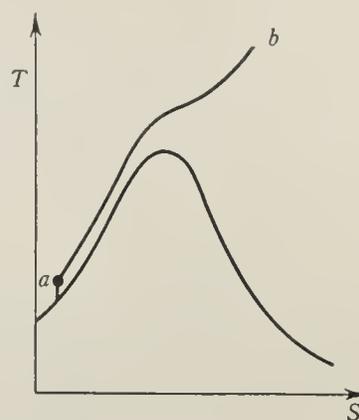

$$Y = (x_1 Y_1^{1/3} + x_2 Y_2^{1/3})^3,$$

etc., for n components. The constant B_o can be calculated from

$$B_o = x_1 B_{o1} + x_2 B_{o2}.$$

BENSON BOILER. A boiler in which steam is generated at a pressure higher than the critical ($= 3206.2 \text{ lbf/in}^2 = 225.65 \text{ kp/cm}^2 = 218.39/\text{atm}$). In this manner the transition from the liquid to the superheated vapor phase is continuous and no bulky boiler drum is required. The sequence of states traversed by the working liquid in a Benson boiler is shown in the figure. The boiler can be operated without trouble also at pressures somewhat lower than the critical, because the change in volume on evaporation is still quite small. The boiler can be regulated by regulating its pressure.

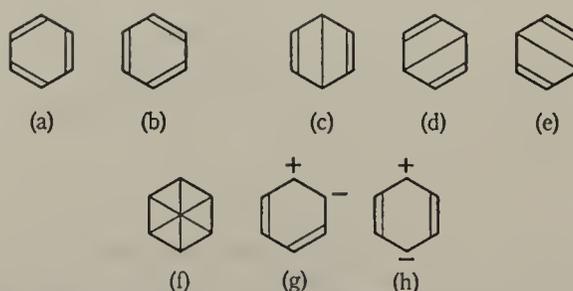

The power consumption of the high-pressure pump is considerable.

T,S diagram for Benson boiler. (Point a , compressed water; curve b , superheated steam.)

BENT. A transverse frame which forms an integral part of a structural unit or supports another structural unit. Bents are designed to carry lateral as well as vertical loads, and are made of structural steel, reinforced concrete, prestressed concrete, or wood. They are used extensively in connection with viaducts and industrial buildings. Viaduct bents consist of columns held firmly together by bracing in horizontal and vertical planes. Bents in buildings are composed of a roof truss and the supporting columns or of a roof girder rigidly attached to the columns so as to form a rigid frame. The bents support longitudinal beams, commonly called purlins, on which the roof is laid.

BENZENE, STRUCTURES OF. In order to explain the observed stability of the benzene molecule (and of other aromatic molecules), different structures have been suggested in the pioneer days of organic chemistry.

Structures proposed for the benzene molecules. [(a and b), Kekulé structures; (c, d and e), Dewar structures; (f), Claus structure; (g and h), Ionogenic structures.]

The valence bond method calculates the energy of these molecules by means of a

weighted average of such configurations. The better known of these are the two *Kekule* and the three *Dewar structures* (a, b, and c, d, e of the figure, respectively). The structure (f) proposed by *Claus* must not be considered in the valence bond method, since it can be expressed as a linear combination of the other five configurations. *Ionogenic structures* (g, h) have also been considered.

BERGMANN SERIES. A series of lines in the spectra of the simpler atoms, the alkalis, alkaline earths, helium, etc., corresponding to transitions from an upper *F* state to a lower *D* state. (Also called **fundamental series**.)

BERNOULLI DISTRIBUTION. See **binomial distribution**.

BERNOULLI EQUATION. A first order non-linear differential equation

$$\frac{dy}{dx} + f(x)y = g(x)y^n.$$

It may be made **linear** by the substitution $y = u^{n-1}$, giving

$$\frac{du}{dx} + (1 - n)f(x)u = (1 - n)g(x).$$

BERNOULLI EQUATION APPLIED TO FLUIDS. An integrated form of the equation of steady motion, viz.

$$\int \frac{dp}{\rho} + \frac{1}{2}v^2 + \Omega = \text{const.}$$

along a streamline or vortex line, where Ω is the potential of the body forces. If the motion is irrotational there are no vortex lines and the expression is constant throughout the fluid. In general it is constant on a surface composed of all the vortex lines through a streamline, called a *Bernoulli surface*.

In a liquid of constant density moving irrotationally under gravity

$$p + \frac{1}{2}\rho v^2 + g\rho z = p_0$$

where p_0 is the **stagnation pressure** at the height $z = 0$. The effect of gravity may be removed by writing $p' = p + g\rho z$. p' is then the departure of the pressure from the hydrostatic value, and the Bernoulli equation is

$$p' + \frac{1}{2}\rho v^2 = p'_0$$

and p'_0 is then called total pressure.

BERNOULLI METHOD. Given the algebraic equation

$$(1) \quad x^n + a_1x^{n-1} + \dots + a_n = 0,$$

let h_0, h_1, \dots, h_{n-1} be arbitrary numbers, not all zero, and form h_n, h_{n+1}, \dots , by

$$h_{n+\nu} + a_1h_{n+\nu-1} + \dots + a_nh_\nu = 0.$$

If (1) has a unique root of largest modulus, then in general the quotients $h_{\mu+1}/h_\mu$ approach that root. The method can be extended to transcendental equations. Let

$$(2) \quad f(z) \equiv 1 + c_1z + c_2z^2 + \dots$$

converge in some circle about the origin in the complex plane, and let

$$(3) \quad g(z) \equiv g_0 + g_1z + g_2z^2 + \dots$$

represent any function analytic in the same circle, and having no zero in common with $f(z)$. Let

$$h_0 = g_0,$$

$$c_1h_0 + h_1 = g_1,$$

$$c_2h_0 + c_1h_1 + h_2 = g_2$$

$$\dots \dots \dots$$

Then if $f(z)$ has a unique zero of smallest modulus lying within that circle, then $h_\mu/h_{\mu+1}$ approaches that zero. If there are two zeros whose moduli are less than those of all others, then the roots of

$$\begin{vmatrix} z^2 & h_\mu & h_{\mu+1} \\ z & h_{\mu+1} & h_{\mu+2} \\ 1 & h_{\mu+2} & h_{\mu+3} \end{vmatrix} = 0$$

approach those zeros of $f(z)$. Likewise one can form cubics whose roots approach the three smallest roots. (See Alston S. Householder, *Principles of Numerical Analysis*, McGraw-Hill Book Company, 1953.) The QD algorithm improves upon this principle. (See National Bureau of Standards, *Further contributions to the solution of simultaneous linear equations and the determination of eigenvalues*, NBS Appl. Math. Series 49, 1958.)

BERNOULLI NUMBERS. Coefficients B_ν of the **Bernoulli polynomials**. Except for B_1 , those with odd subscripts vanish. The values of the first several are

$$B_0 = 1, \quad B_1 = -\frac{1}{2}, \quad B_2 = \frac{1}{6}, \quad B_4 = -\frac{1}{30},$$

$$B_6 = \frac{1}{42}, \quad B_8 = -\frac{1}{30}, \quad B_{10} = \frac{5}{66}.$$

They are the coefficients in the expansion

$$u/(e^u - 1) = \sum_0^{\infty} B_\nu u^\nu / \nu!$$

They occur in the **Euler-Maclaurin formula**. (See Niels Erik Nörlund, *Vorlesungen über Differenzenrechnung*, Berlin, Springer, 1924.)

BERNOULLI POLYNOMIALS. These polynomials $B_\nu(x)$ of degree ν occur as coefficients in the expansion

$$ue^{xu}/(e^u - 1) = \sum_0^{\infty} u^\nu B_\nu(x) / \nu!$$

They satisfy the differential equations with boundary conditions

$$B'_\nu(x) = \nu B_{\nu-1}(x), \quad B_\nu(1) = (-1)^\nu B_\nu(0),$$

and can be written symbolically in the form $B_\nu(x) = (B + x)_\nu$, where the right member is to be expanded as though ν were an exponent:

$$(B + x)_\nu = B_\nu + \nu x B_{\nu-1} + \frac{\nu(\nu-1)}{2} x^2 B_{\nu-2} + \dots$$

and the coefficients are the **Bernoulli numbers**. In the same fashion a recursion for the Bernoulli numbers is

$$B'_\nu = (B + 1)_\nu, \quad \nu > 1.$$

Both the **Bernoulli numbers** and the Bernoulli polynomials are defined in other ways. They are used in numerical integration formulas and in the calculus of finite differences. (See Niels Erik Nörlund, *Vorlesungen über Differenzenrechnung*, Berlin, Springer, 1924.)

BERNOULLI PROBABILITY FUNCTION. See **binomial distribution**.

BERNOULLI THEOREM. This theorem was published posthumously in 1713. Let the **probability** of an event p be constant from trial to trial, and the probability of failure be denoted by q . Let the **relative frequency** be denoted by $\frac{x}{s}$ where x is the number of successes in s trials. Let $P\left(\left|\frac{x}{s} - p\right|\right)$ denote the probability of obtaining the absolute value of the deviation $\frac{x}{s} - p$. Usually this deviation will be small. Bernoulli's theorem states that as the number of trials s increases, the probability of a

difference in absolute value more than a stated positive amount ϵ approaches zero. In symbols

$$\lim_{s \rightarrow \infty} P\left(\left|\frac{x}{s} - p\right| > \epsilon\right) = 0.$$

It should be clear that the theorem does not state

$$\lim_{s \rightarrow \infty} \frac{x}{s} = p.$$

The theorem states roughly that if s is sufficiently large usually $\frac{x}{s}$ will not differ much from p . However, cases may occur though quite infrequently when $\frac{x}{s}$ will differ considerably from p . Bernoulli's theorem is one of the "laws of large numbers."

BERNOULLI TRIAL SOLUTION. See **separation of variables**.

BERNSTEIN POLYNOMIAL. Given a function $f(x)$ defined on the closed interval $[0,1]$ the polynomial

$$B_n(x) = \sum_{i=0}^n f(i/n) \binom{n}{i} x^i (1-x)^{n-i},$$

where $\binom{n}{i}$, is the binomial coefficient, is the Bernstein polynomial of order n for the function $f(x)$. These polynomials are important in the theory of probability in the summation of divergent series, and in the theory of approximation.

BERTHELOT'S EQUATION OF STATE. A form of the **equation of state**, relating the pressure, volume, and temperature of a gas, and the gas constant R . The Berthelot equation is derived from the **Clausius equation** and is of the form

$$PV = RT \left[1 + \frac{9PT_c}{128P_c T} \left(1 - 6 \frac{T_c^2}{T^2} \right) \right]$$

in which P is the pressure, V is the volume, T is the absolute temperature, R is the gas constant, T_c is the critical temperature, and P_c the critical pressure.

BERTRAND CURVES. A pair of curves having their principal normals in common are called *associate*, or *conjugate*, *Bertrand curves*.

BESSEL FUNCTION. The differential equation

$$x^2y'' + xy' + (x^2 - n^2)y = 0, \quad n = \text{const.}$$

is called Bessel's equation of order n . Certain of its solutions (see below) are called Bessel functions. The general solution is

$$y = AJ_n(x) + BY_n(x)$$

where

$$J_n(x) = \sum_{k=0}^{\infty} \frac{(-1)^k}{\Gamma(k+1)\Gamma(k+n+1)} \left(\frac{x}{2}\right)^{n+2k}$$

and $Y_n(x) = J_{-n}(x)$ if n is not an integer. These functions are called Bessel functions of the first kind. If n is an integer, then $J_{-n}(x) = (-1)^n J_n(x)$, so that $Y_n(x)$ is defined as

$$Y_n(x) = \lim_{k \rightarrow n} \frac{J_k(x) \cos kx - J_{-k}(x)}{\sin k\pi}$$

which is called a Bessel function of the second kind. The functions, much used in physics,

$$H_n^{(1)}(x) = J_n(x) + iY_n(x) \quad i = \sqrt{-1}$$

$$H_n^{(2)}(x) = J_n(x) - iY_n(x)$$

are Bessel functions of the third kind; they are also called Hankel functions of the first and second kind, respectively. Other combinations of Bessel functions are also given names. These functions have certain standard properties of recurrence, orthogonality, etc. (See **special functions**.)

BESSEL FUNCTION, MODIFIED. The modified Bessel function of the first kind is

$$I_n(z) = i^{-n} J_n(iz),$$

and that of the second kind is

$$K_n(z) = \frac{1}{2}\pi (\sin n\pi)^{-1} [I_{-n}(z) - I_n(z)].$$

BESSEL FUNCTION, SPHERICAL. The function,

$$j_n(z) = \sqrt{\frac{\pi}{2z}} J_{n+\frac{1}{2}}(z),$$

where $J_{n+\frac{1}{2}}(z)$ is a **Bessel function** of half integral order.

BESSEL INEQUALITY. Let u be a vector in Euclidean n -space with length $\|u\|$ and let $u_1, u_2 \dots u_r$ be an orthonormal set of vectors.

Then Bessel's inequality states that

$$(u, u_1)^2 + \dots + (u, u_r)^2 \leq \|u\|^2,$$

where the parentheses denote scalar product.

The particular case $r = n$, for which equality holds, is called the Pythagorean theorem or Parseval's equation. Similarly, if u_1, u_2, \dots is a complete orthonormal set in **Hilbert space**, then Bessel's inequality states that $(u, u_1)^2 + (u, u_2)^2 + \dots \leq \|u\|^2$.

For example, if scalar product is defined by integration as in the case of a standard Fourier series, then $(u, u_i) = \int f u_i dx$ and Bessel's inequality states that $\sum_{i=1}^{\infty} \left(\int f u_i dx\right)^2 \leq \int f^2 dx$.

BESSEL INTERPOLATION FORMULA.

$$E^u = E^{1/2} \left[\mu + (u - \frac{1}{2})\delta + \binom{u}{2} \mu \delta^2 + \frac{u - \frac{1}{2}}{3} \binom{u}{2} \delta^3 + \binom{u+1}{4} \mu \delta^4 + \frac{u - \frac{1}{2}}{5} \binom{u+1}{4} \delta^5 + \dots \right].$$

(For notation see **difference operators**.)

The formula is most useful for $0 < u < 1$. Taking $v = u - \frac{1}{2}$, an alternative, and more symmetric, expression is

$$E^u = E^{1/2} \left[\mu + v\delta + \frac{1}{2!} (v^2 - \frac{1}{4}) \mu \delta^2 + \frac{1}{3!} v(v^2 - \frac{1}{4}) \delta^3 + \frac{1}{4!} (v^2 - \frac{1}{4})(v^2 - \frac{9}{4}) \mu \delta^4 + \frac{1}{5!} v(v^2 - \frac{1}{4})(v^2 - \frac{9}{4}) \delta^5 + \dots \right].$$

BETA DISINTEGRATION (BETA-DECAY).

The process whereby a nucleus disintegrates spontaneously with the emission of β -particles (i.e., electrons or positrons) and neutrinos (see **radioactivity**). Since electrons and neutrinos cannot exist within the nucleus, they are assumed to be emitted by means of a weak coupling between the electron and neutrino fields on the one hand, and the neutron and proton fields on the other, in much the same way as electromagnetic radiation can be emitted when a charged particle changes its state of motion.

Thus, the process of β -decay involves the simultaneous interaction of four fields. The strength of the coupling is far weaker than the coupling between the electron and photon fields. The exact nature of the coupling is not yet certain; but recently it has been found that parity is violated in the process of β -decay, and this discovery is likely to lead to a better understanding of the process itself.

BETA DISINTEGRATION ENERGY. (1)

The disintegration energy of a beta-decay process; symbol Q_β . For negatron emission it is equal to the sum of the kinetic energies of the β -particle, the neutrino, and the recoil atom (usually negligible), and is obtained experimentally from the maximum energy of the β -particle spectrum. For positron emission, the energy equivalence of two electron rest-masses must be added to the aforementioned sum, since the products include the positron and one negative electron in addition to the neutral product atom, the energy equivalent to their masses ultimately appears as radiant energy of annihilation radiation. For electron capture, the disintegration energy is equal to the sum of the kinetic energy of the neutrino and the electronic excitation energy of the product atom (usually, the binding energy, in the neutral product atom, of an electron equivalent to that which was captured).

(2) Often, implicitly, the ground-state β -disintegration energy, which is the total energy released in a β -transition between isobars in their ground states; symbol Q_{β_0} . It includes the energies of any γ -radiation and associated radiations following the β -process itself.

BETA DISTRIBUTION. A statistical distribution of the form

$$dF = \frac{1}{B(\alpha, \beta)} x^{\alpha-1} (1-x)^{\beta-1} dx, \quad 0 \leq x \leq 1.$$

Another form of the type

$$dF = \frac{y^{\alpha-1}}{B(\alpha, \beta)(1+y)^{\alpha+\beta}} dy, \quad 0 \leq y \leq \infty,$$

is sometimes known as a beta distribution of the second kind. The first form is also known as a Pearson Distribution of Type I and the second form as a Pearson Distribution of Type VI.

BETA FUNCTION. An improper integral

$$B(m, n) = \int_0^1 x^{m-1} (1-x)^{n-1} dx; \quad m > 0, n > 0.$$

It can be expressed in terms of the gamma function by the equation

$$B(m, n) = \frac{\Gamma(m)\Gamma(n)}{\Gamma(m+n)}.$$

BETA-RAY SPECTRUM. See spectrum, beta-ray.

BETHE METHOD. In the theory of the slowing down of neutrons at large distances from a source, one of the effective analytical methods. The starting point of the analysis of the transport equation is the integral equation form and its goal, the elucidation of the constants in an expression such as,

$$N(x, E) \cong Ax^{-1/2} \exp \left(B \ln \left(\frac{E_0}{E} \right) - C |x| \right)$$

for the neutron density at large distance x from a plane isotropic source. Bethe's method is particularly effective at distances such that

$$\frac{\lambda}{3M^2} |x| \gtrsim 1,$$

where λ is the mean free path (assumed) independent of energy, and M^2 is the slowing down area.

BETHE-SALPETER EQUATION. The relativistic equation describing the evolution and properties of a two-particle system. Consider for example the case of two fermions, described by quantized fields $\psi^a(x)$ and $\psi^b(y)$, respectively, which interact through the medium of a boson field ϕ .

Let the equation of motions of these operators be

$$\left. \begin{aligned} (-i\gamma^\mu \partial_\mu + m_a)\psi^a(x) &= J^a(x) \\ (-i\gamma^\mu \partial_\mu + m_b)\psi^b(y) &= J^b(x) \\ (\square + \mu^2)\phi(x) &= j(x) \end{aligned} \right\} \quad (1)$$

where J^a , J^b and j are the sources of the ψ^a , ψ^b and ϕ fields, respectively, and are operator functions of ψ^a , ψ^b , ϕ . The Bethe-Salpeter amplitude for the two particle state $|\Psi\rangle$ is then defined as

$$\chi(x, y) = (\Psi_0, T(\psi^a(x)\psi^b(y))\Psi). \quad (2)$$

where T denotes the **chronological operator**, and $|\Psi_0\rangle$ is the vacuum state vector. The Bethe-Salpeter equation is the equation obeyed by this amplitude and is of the form

$$(-i\gamma^\mu\partial_{x\mu} + m_a)(-i\gamma^\mu\partial_{y\mu} + m_b)\chi(x,y) = -i\int d^4x' \int d^4y' K(x,y; x',y')\chi(x',y') \quad (3)$$

where K is a kernel determined from the right-hand side of Equation (1).

BETTI NUMBER. See **graph**, **nullity**.

BETTIS RECIPROCAL THEOREM. See **reciprocal theorem**.

BEV. Symbol for one thousand million (i.e., one billion) electron volts, a unit of energy equal to 1.602×10^{-3} erg. Sometimes denoted by **Gev**.

BIANCHI IDENTITY. The relation

$$B^i_{ajk,l} + B^i_{akl,j} + B^i_{alj,k} = 0$$

between covariant derivatives of the **curvature tensor** B^i_{jkl} .

BIAXIAL CRYSTAL. A crystal which has two distinct **optic axes**.

BIAXIAL STRESS. See **stress**, **combined**.

BIEDENHARN IDENTITY. The relation

$$\begin{aligned} \left\{ \begin{matrix} abc \\ def \end{matrix} \right\} \left\{ \begin{matrix} abc \\ d'e'f' \end{matrix} \right\} &= \sum_k (-1)^{a+b+c+d+e+f+d'+e'+f'} \\ &\cdot (2k+1) \left\{ \begin{matrix} gee' \\ aff' \end{matrix} \right\} \left\{ \begin{matrix} gff' \\ bdd' \end{matrix} \right\} \left\{ \begin{matrix} gdd' \\ cee' \end{matrix} \right\} \end{aligned}$$

between the six-j symbols of Wigner, which was derived by Biedenharn (1953) and also by Elliott (1953). It should be noted that the six-j symbol is given by Racah's symmetrized W coefficient (1957):

$$\mathbb{W} \left\{ \begin{matrix} abc \\ def \end{matrix} \right\} \equiv \left\{ \begin{matrix} abc \\ def \end{matrix} \right\}.$$

BIENAYMÉ-CHEBYSHEV INEQUALITY. If x is a random variable with mean m and variance σ^2 , the inequality states that

$$P\{|x - m| > t\sigma\} \leq 1/t^2, \quad \text{all } t > 1.$$

It is a particular case of **Chebyshev inequality**.

BIGIT. A binary digit. This term has been proposed in order to reserve **bit** for use only as a measure of information.

BIHARMONIC EQUATION. The partial differential equation

$$\partial^4\phi/\partial x^4 + 2\partial^4\phi/\partial x^2\partial y^2 + \partial^4\phi/\partial y^4 = 0$$

satisfied, for instance, by small deflections of a plate. The usual coefficients for a square mesh are in the form (see **star**)

$$\begin{array}{ccccc} & & 1 & & \\ & 2 & -8 & 2 & \\ 1 & -8 & 20 & -8 & 1 \\ & 2 & -8 & 2 & \\ & & 1 & & \end{array}$$

BILATERAL. This term has rather wide usage in the same sense as the term **reciprocal**, meaning that the reciprocity principle applies, and that the network to which the term refers is capable of transmission equally in two directions between a specified pair of ports.

BILINEAR CONCOMITANT. See **adjoint equation**; **Sturm-Liouville problem**.

BINARY. In the binary representation of numbers, the **radix** is 2, this being used in many digital computers.

BINARY MIXTURE CYCLES. Engine or refrigeration cycles which involve the use of solutions. The saturation temperature of a solution (binary mixture) is higher, at a given pressure, than that of the liquid and in this manner superheated vapor can be obtained at a lower operating pressure. For example a 84.6% KOH solution in water boils at 900°F under a pressure of 215 lbf/in², giving off steam at that temperature. Pure water boiling at that pressure could yield steam at 384°F only. The steam obtained in this way could be made to perform work in a suitable engine, and the condensate could be re-absorbed in a concentrated solution. In the process a considerable quantity of heat of absorption would be liberated, and that heat could be utilized for the evaporation of water. Binary mixture cycles have been proposed, but not actually used for the generation of power; the reverse cycle is realized in an **absorption refrigerator**.

BINARY POINT. The radix point in the representation of a number with the **radix** 2.

BINARY STARS. The term binary star was apparently first introduced by Sir William Herschel in 1802 to designate "a real double

star—the union of two stars that are formed together in one system by the laws of attraction.” When the relative motion of the components of a double star is established, systematic observations are begun. Usually one of the components is brighter than the other and this is considered as stationary and known as the *primary*. The angular distance of the secondary from the primary is called the *distance*. The direction of the secondary from the primary is known as the *position angle*. Position angle is measured from the direction of the north celestial pole toward the east through 360° .

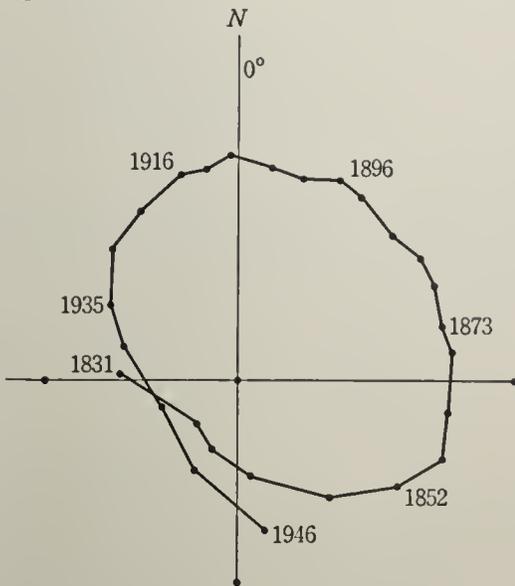

Fig. 1. Binary star—observed position.

Figure 1 shows the observations of a binary star extending from 1831 to 1946. Proper “smoothing” of the data will provide what is called the apparent orbit. This orbit will be an ellipse, and the Keplerian law of areas will be maintained by the line joining the stars in direction, length, and time. However, it is very unlikely that the primary star will be at the focus of the apparent ellipse as determined by the measurements.

To determine the apparent orbit of a binary star, i.e., the ellipse that will best fit the observations, one must first fit an ellipse to the plotted points by estimation. Figure 2 shows such an ellipse. In the fitting of the ellipse to the observations the position of the primary is ignored.

Letting the direction defining the position angle 0° be considered as the x -axis of a coordinate system and position angle 90° be the direction of the y -axis, a plane is defined that is perpendicular to the line of sight. The origin

of this system is the primary star, which is assumed to be fixed. Points on the ellipse that best fit the observations can be referred to the Cartesian system. If the length of SC is ρ and KSC is the angle θ then for C : $x = \rho \cos \theta$ and $y = \rho \sin \theta$. Five such measurements spread

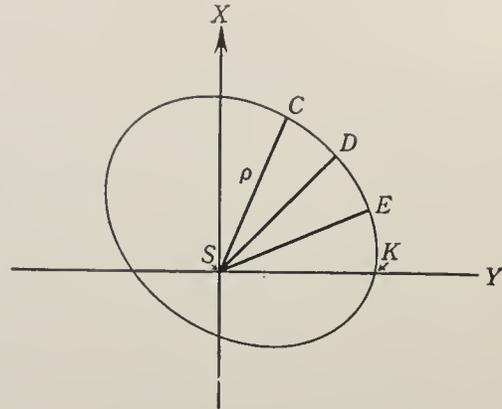

Fig. 2. Binary star—orbital ellipse fitted to observed position.

out over the ellipse are enough to determine the equation of the ellipse as $Ax^2 + 2Hxy + By^2 + 2Gx + 2Fy + 1 = 0$. In actual practice there are a great many observations and each one will yield xy coordinates to be represented. Many methods have been used by different computers. There is a further consideration to use in testing the apparent ellipse. Kepler's second law provides that equal areas are swept out in equal times by the radius vector of an ellipse. In projection the ratio of areas will be maintained. Hence, if t_1, t_2, t_3 are the times at which the companion star is at points C, D, E then the ratio of the area CSD to the area DSE must be equal to the ratio of $(t_2 - t_1)$ to $(t_3 - t_2)$. This can be carried on for points all around the ellipse, determining the areas with a planimeter. This is, of course, only an apparent orbit.

There are many methods for the determination of the true orbit of a binary star. However, they are essentially exercises in geometry and trigonometry. (C.f. **spectroscopic binary stars**; **eclipsing binary stars**.)

BINARY STARS, DYNAMIC PARALLAX OF. See **dynamic parallax (of binary stars)**.

BINARY STARS, ECLIPSING. See **eclipsing binary stars**.

BINARY STARS, SPECTROSCOPIC. See **spectroscopic binary stars**.

BINAURAL PHASE EFFECT. If the sound intensity at the ears is maintained alike and differences in phase are introduced, there is an angular displacement θ of the apparent sound source from the median plane. The relation between this angle and the phase difference ϕ is given by

$$\theta = K\phi,$$

where K depends upon frequency.

BINDING ENERGY. This term is used in atomic physics with two closely related meanings: the binding energy of a particle (or other entity) is the energy required to remove the particle from a system; the binding energy of a system is the energy required to disperse the system into its constituent entities. Explicit definitions are obviously necessary.

Some explicit definitions for the binding energies of particles are the following:

(1) The **electron** binding energy is the energy necessary to remove an electron from an atom. It is identical with the **ionization potential**.

(1a) The total electron binding energy is the energy necessary to remove all the electrons from an atom to infinite distances, so that only the nucleus remains. It is equal to the sum of the successive **ionization potentials** of that atom.

(2) The **proton** binding energy is the energy necessary to remove a single proton from a nucleus. Most known proton binding energies are in the range 5–12 mev, although that for H^2 is 2.23 mev, that for He^4 is 19.81 mev, and those for Li^5 and Be^9 are negligible.

(3) The **neutron** binding energy is the energy required to remove a single neutron from a nucleus. Most known neutron binding energies are in the range 5–8 mev, though that for H^2 is 2.23 mev, that for Be^9 is 1.67 mev, and that for C^{12} is 18.7 mev.

(4) The **alpha-particle** binding energy is the energy required to remove an alpha-particle from a nucleus. For most light nuclides the alpha-particle binding energy is positive and is equal to several mev. For nuclides of mass number about 125, it is approximately zero. For nuclides of mass number about 150 to 200, it is negative by about 1 to 3 mev, but the lifetimes for alpha-disintegration are generally too long for detection of alpha-activity. For most nuclides of mass number exceeding 200, the alpha-particle binding energy is negative

by about 4 to 8 mev, leading to observable alpha-activity.

Some explicit definitions for the binding energies of systems are:

(1) The nuclear binding energy is the energy that would be necessary to separate an atom of **atomic number** Z and **mass number** A into Z hydrogen atoms and $A-Z$ neutrons. This energy is the energy equivalent of the difference between the sum of the masses of the product hydrogen atoms and neutrons, and the mass of the atom; it includes the effect of electronic binding. (See total electron binding energy above.)

(2) The binding energy of a solid is the energy required to disperse a solid into its constituent atoms, against the forces of cohesion. In the case of ionic crystals, it is given by the **Born-Mayer equation**.

BINGHAM MATERIAL. A material exhibiting a **yield limit** σ_0 and viscous resistance to flow for stresses above this limit:

$$\begin{aligned} \dot{\epsilon} &= \frac{1}{\nu}(\sigma - \sigma_0), & \sigma > \sigma_0 \\ \dot{\epsilon} &= 0, & \sigma < \sigma_0. \end{aligned}$$

BINODALS. Consider the volume-composition diagram of a binary mixture for states corresponding to the coexistence of a liquid and of a gaseous phase. If the temperature is below the critical region (see **critical point; critical phenomena in the vaporization of mixtures**) one obtains a diagram of the form represented in Figure 1.

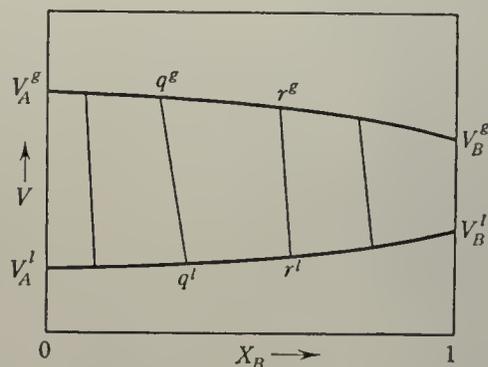

Fig. 1. Volume-composition diagram of a binary mixture below the critical region.

The line $V_A^g V_B^g$ corresponds to the molar volumes of the vapor phase, while $V_A^l V_B^l$ relates to the liquid phase. The lines such as r^l-r^g , q^l-q^g , etc., joining two phases in equilibrium are called binodals by the Dutch School

(van der Waals, Kohnstamm). In the critical region the diagram takes the form indicated in Figure 2. K is the critical point. The curve $V_A^g-K-V_A^l$ is the *saturation curve*. (See also *spinodal curve*.)

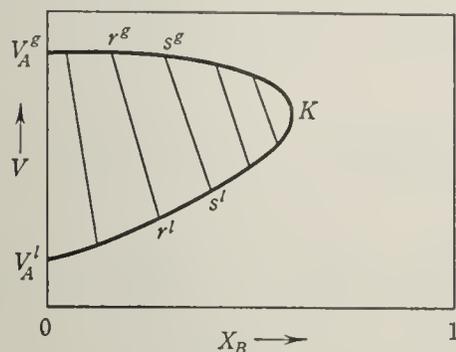

Fig. 2. Volume-composition diagram of a binary mixture in the critical region.

BINOMIAL COEFFICIENT. The coefficient of the variable in a **binomial series** $(a + x)^n$. The $(k + 1)$ th coefficient of order n is $\frac{n!}{k!(n - k)!}$,

usually designated by the symbol $\binom{n}{k}$. It equals the number of **combinations** of n things taken k at a time. Properties of the coefficients include

$$\binom{n}{0} = \binom{n}{n} = 1; \quad \binom{n}{k} + \binom{n}{k+1} = \binom{n+1}{k+1}; \quad \binom{n}{n-k} = \binom{n}{k}.$$

BINOMIAL DISTRIBUTION. If a trial can have one of two mutually exclusive results (say "success" and "failure") and if the probability p of a "success" is constant over a series of n independent trials, then the probability of obtaining r "successes" is

$$P_r = \frac{n!}{r!(n - r)!} p^r q^{n-r}$$

where $q = 1 - p$. This function is sometimes called the *Bernoulli probability function*, and the probability distribution of r is called the *binomial distribution* since the probabilities can be obtained by expanding $(q + p)^n$ by the binomial formula. The mean of the distribution is np , the variance npq . It is sometimes known as the *Bernoulli distribution*.

The *negative binomial distribution* has formally the same probability function but p

and n are negative and n is not restricted to integral values.

BINOMIAL THEOREM. The theorem that

$$(a + x)^n = \sum_{i=0}^n \binom{n}{i} a^{n-i} x^i,$$

where $\binom{n}{i}$ is a binomial coefficient.

BINORMAL. The **normal to a space curve at a point**, which is perpendicular to the osculating plane at that point. The *unit binormal* to the curve at P is a unit vector in the direction of the binormal, usually chosen so that the unit tangent, unit normal and unit binormal form a right-handed system.

BIOT NUMBER. In solid propellant rocket propulsion, a parameter describing the rate of transfer of heat from the center of a burning grain to the outer cylindrical surface. It is given by:

$$\mathfrak{B} = \frac{hR_e}{\lambda}$$

where \mathfrak{B} is the Biot number, h is the heat transfer coefficient, R_e is the external radius of grain, and λ is the thermal conductivity.

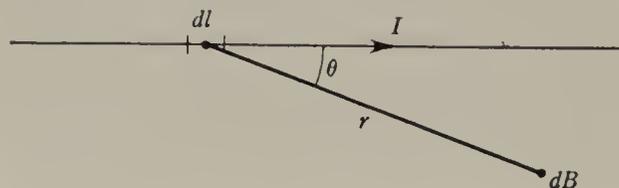

BIOT-SAVART LAW. A law giving the magnetic field in the neighborhood of a long, straight conductor carrying a steady current I . This law, discovered experimentally, may be written

$$B = \frac{\mu_0 I}{2\pi r}$$

where r is the normal distance from the conductor and I is the magnitude of the current flowing in the conductor. The above can be derived from the relationship

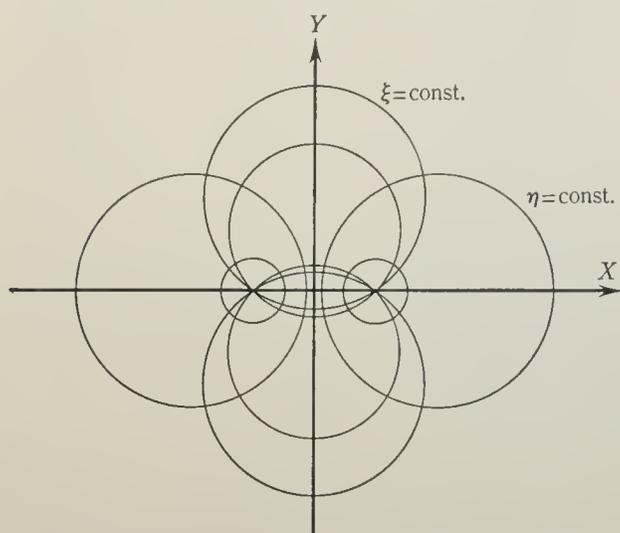

$$dB = \frac{\mu_0 I dl \sin \theta}{4\pi r^2}$$

which gives the incremental magnetic field due to a current element of length dl and strength I in terms of distance r and angle θ in the figure (dB is directed into the page).

This incremental law was first proposed by Biot, but it is often referred to as the *Ampere law* or *Ampere formula*.

BIPOLAR COORDINATES. Choose two points $\pm a$ on the X -axis of a rectangular coordinate system. Then any point in the XY -plane could be measured in either of two polar coordinate systems where the poles are at $x = \pm a$; the polar axis in both systems is the X -axis; the two polar angles are θ_1, θ_2 ; the two

Bipolar coordinate system.

radius vectors are r_1, r_2 . Define the parameters $\xi = \theta_1 - \theta_2$; $\eta = \ln r_2/r_1$ and, in terms of these parameters,

$$x = \frac{a \sinh \eta}{\cosh \eta - \cos \xi}; \quad y = \frac{a \sin \xi}{\cosh \eta - \cos \xi}$$

which are families of circles along the X - and Y -axes, respectively. Translation of these circles along the Z -axis produces the curvilinear coordinate system known as bipolar coordinates. They are families of right circular cylindrical surfaces with axes parallel to the Z -axis and centers at $y = 0, x = 0$, respectively ($\xi, \eta = \text{constant}$), where

$$0 \leq \xi \leq 2\pi; \quad -\infty \leq \eta \leq \infty.$$

The third surface is a plane perpendicular to the Z -axis ($z = \text{constant}$).

BIPRISM. An optical prism with a vertex angle only slightly less than 180° , devised by Fresnel to produce a double virtual image of a point source.

BIQADRATIC EQUATION. An algebraic equation of the fourth degree in one or more

variables, also called a quartic equation. If, as is usually the case, only one variable occurs, its general form is $a_0x^4 + a_1x^3 + a_2x^2 + a_3x + a_4 = 0$. The transformation $x = y - a_1/4a_0$ removes the term in x^3 , so that the equation becomes $a_0y^4 + b_2y^2 + b_3y + b_4 = 0$. The standard form is $y^4 + py^2 + qy + r = 0$, where $p = b_2/a_0, q = b_3/a_0, r = b_4/a_0$.

BIQUINARY. A form of number representation combining the radices 2 and 5. (See radix.)

BIREFRINGENCE. A synonym for double refraction.

BIREFRINGENCE, FLOW. In the flow of viscous liquids, composed of anisotropic molecules, the forces of shear tend to orient the molecules, leading to birefringence.

BIRTH-AND-DEATH PROCESS. A stochastic process, usually Markovian, which describes a "population" the members of which may "die" or "give birth" to new individuals. A great many processes are of this type, e.g., epidemics, sub-atomic showers and certain kinds of factory production. The limiting case where no "deaths" occur is known as a birth process.

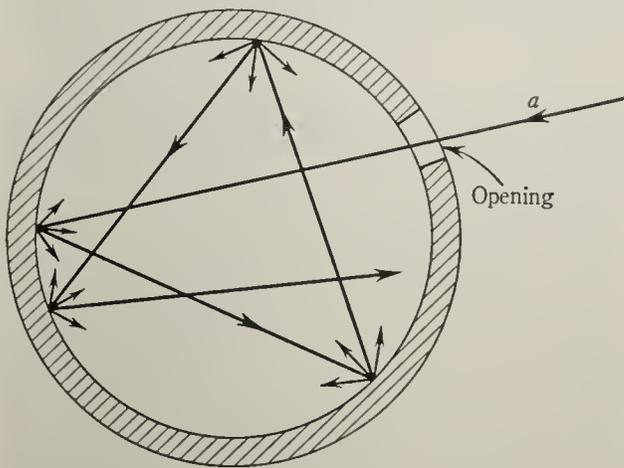

Its mathematical description is as follows: The system described by a birth-and-death process changes only through transitions from states E_n to their next neighbors E_{n+1} or E_{n-1} . If at any time t the system is in state E_n , the probability that during $(t, t+h)$ the transition $E_n \rightarrow E_{n+1}$ occurs equals $\lambda_n h + o(h)$, and the probability of $E_n \rightarrow E_{n-1}$ equals $\mu_n h + o(h)$. The probability that during $(t, t+h)$ more than one change occurs is $o(h)$. Here, the term $o(h)$ denotes a quantity which is of smaller order of magnitude than h . The definition of a birth process follows analogously.

BISERIAL CORRELATION. The correlation between two variables when one of them can take only one of two values or is a simple dichotomy. Earlier forms of biserial correlation coefficients depended on the assumption that the dichotomy was based on an underlying normal (Gaussian) distribution. The so-called point biserial coefficient assigns the values 0 and 1 to the dichotomic classification and proceeds to calculate a product-moment correlation coefficient on that basis.

BIT. (1) A unit of measure of information; viz., that amount represented by one of two alternatives. A binary digit, i.e., 0 or 1, in number representation with the **radix 2**. (2) In digital computer terminology, the term bit has been extended to denote a character (in a two-character language), an abbreviation for "binary digit," or a unit of storage capacity.

BIVARIANT SYSTEM. See **phase rule**.

BLACK BODY. A body whose surface absorbs all radiation and does not reflect any. Ideal black bodies do not exist in nature, but a very good approximation is obtained at a small opening of a hollow box, like the one shown in the figure. The interior of the hollow

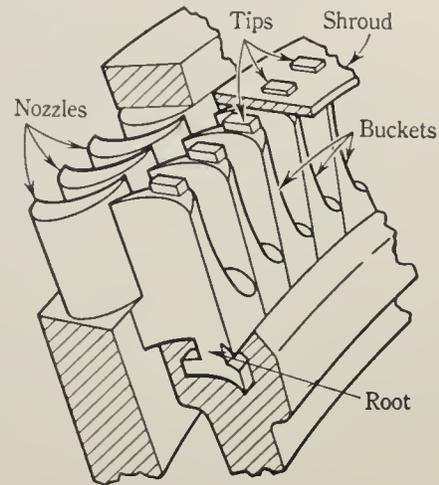

Black body.

box is made of an irregular surface of reasonably high absorptive power, and its walls are kept at a constant temperature. Any ray, say a in the figure, entering through the opening undergoes a multiple reflection before it can emerge again. At each reflection a proportion of the energy is absorbed, and consequently, the amount of energy leaving through the opening is extremely small. Hence the surface of the opening acts very nearly like that of an ideal black body. A hollow box of this type is sometimes called a "hohlraum" (German). Since the absorptivity of a black body is equal to unity, its emissivity, by the **Kirchhoff law**, is also unity, and it emits the maximum possible amount of radiation.

BLACK BODY RADIATION LAWS. See **Planck radiation formula**; **Wien displacement law**; **Stefan-Boltzmann law**; **Kirchhoff law**.

BLADE. An element of a turbine or turbo-compressor stage which effects a change in

the flow direction of the working fluid and which forms the channel for it. The part of the blade which is nearest the section at which it is fixed to the wheel is called its root, the other end is called its tip. Sometimes the tips of the blades are fixed in a shroud (see figure).

Blade details.

A two-dimensional arrangement of blade sections is called a *cascade*. The blade cross sections are made in the shape of airfoils.

BLADE EFFICIENCY. (Also known as diagram efficiency.) In a turbine or turbo-compressor stage, the ratio of the useful work per unit mass flow and time to the real **enthalpy drop** across the stage. (See **stage efficiency**.)

BLADE-SPEED RATIO. In a turbine or compressor **velocity diagram** the ratio u/V of peripheral velocity to absolute velocity at entry.

BLADE, TWISTED. In a turbine or turbo-compressor stage, the velocity diagram changes along the (finite) blade length. The angles of the flow can only coincide with the entry and exit angles of the blade at one section (usually at mid-length), at the *design diameter*. At all other sections, entry is oblique, and the degree of reaction changes along the blade length. These deviations from ideal flow are the source of losses in efficiency. In order to avoid them, the blade angles (see **velocity diagram**) may be continuously varied, and this causes the blades to be *twisted*.

The amount of twist can be calculated in two alternative ways: the *free vortex type* and the *constant reaction type*. In the free vortex type, the flow velocity in front of and behind the blade is made to vary inversely with the

radius (in an axial arrangement), in the same way as in a free vortex. In the constant reaction type the inlet and outlet blade angles are the same for the rotor and stator. The free vortex type has the advantage that there exists radial equilibrium between the pressure forces and the centrifugal forces. However, the amount of twist required is rather high, being somewhat smaller for the stator blades. The constant reaction type gives a radial increase in velocity, which is incompatible with a constant axial velocity. Equilibrium can only be established by increasing the axial velocity with decreasing radius, but the necessary twist is smaller and the same for rotor and stator blades.

BLASIUS EQUATION. (1) The differential equation

$$2f''' + ff'' = 0 \quad (a)$$

which describes the stream function

$$\psi = (\nu x U_\infty)^{1/2} f(\eta) \quad (b)$$

where

$$\eta = (U_\infty/\nu x)^{1/2}$$

in boundary layer flow past a flat plate at zero incidence (and, hence, zero pressure gradient along the flow). The function $f(\eta)$ determined by the above equation and the boundary conditions $f(0) = 0, f(\infty) = 1$, is called the *Blasius function*. Equation (a) must be integrated numerically and the Blasius function, together with its derivatives, is available in tabular form (see Schlichting, transl. Kestin, *Boundary Layer Theory*, McGraw-Hill, 1960).

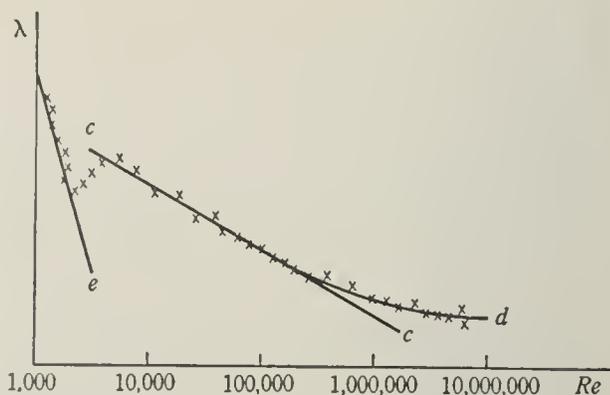

(2) The empirical formula

$$\lambda = 0.3164 Re^{-0.25} \quad (c)$$

which describes the relation between the pressure loss coefficient

$$\lambda = \frac{\Delta p}{\left(\frac{1}{2}\rho\bar{u}^2\right) \frac{l}{d}}$$

for fully developed turbulent flow in a pipe of diameter d and the Reynolds number $Re = \rho\bar{u}d/\mu$ (where Δp is the pressure loss over length l ; \bar{u} is the mean velocity; ρ is the (constant) density; μ is viscosity. The Blasius equation can be used in the range $2300 < Re < 100,000$. A comparison between the Blasius formula and experiment is shown in the figure.

Logarithmic graph of pressure loss coefficient (λ) of fluid flow in smooth pipes plotted against Reynolds number. The experimental results are denoted by the small crosses, the graph of the Blasius formula (c in accompanying article) is c, the graph of the Prandtl formula (d in accompanying article) is d, and the graph of the laminar flow formula (e in accompanying article) is e.

At higher Reynolds numbers, the loss coefficient is given by Prandtl's semi-theoretical formula

$$\frac{1}{\sqrt{\lambda}} = 2.0 \log_{10} (Re\sqrt{\lambda}) - 0.8 \quad (d)$$

and in laminar flow, the theoretical solution gives

$$\lambda = \frac{64}{Re} \quad (e)$$

All formulae are valid for smooth pipes only. (See **lift and moment on an airfoil, general formulae**.)

BLASIUS FORMULA. See Blasius equation.

BLAST LOADING. The forces applied to a structure by the pressure waves emanating from an explosion are called the blast loading. Both reflection and diffraction must be taken into account. The peak pressures may be several times those of the incident shock, but last only a short time. Drag or dynamic pressure loading behind the shock front may be more damaging.

BLEEDING. The action of extracting steam between the stages of a turbine, in particular for the purpose of feed-water heating. (See **carnotization**.)

BLOCH FUNCTION. It can be shown that the wave function of an electron in a periodic lattice has the form

$$\psi = u(\mathbf{r})e^{i\mathbf{k}\cdot\mathbf{r}}$$

where $u(\mathbf{r})$ has the periodicity of the lattice (i.e., is the same in every unit cell) and \mathbf{k} is the **wave vector** of the electron.

BLOCH THEOREM. (1) The lowest state of a quantum-mechanical system in the absence of a magnetic field can carry no current; an important result for the theory of **superconductivity**. (2) The statement that every electronic wave function in a periodic structure can be represented by a **Bloch function**. (Bloch's proof was general for solutions of the Schrödinger equation with a periodic potential.)

BLOCK. In computer practice, a group of words considered as a unit.

BLOCKAGE CORRECTION. See **wind tunnel interference**.

BLOCK RELAXATION. A variant of the method of **relaxation** for solving linear systems in which one solves two or more equations of the set simultaneously for the corresponding unknowns in terms of current approximations to the others. This generally speeds convergence if convergence occurs.

BLOW-DOWN. The sudden reduction in pressure inside a reciprocating engine cylinder following the opening of the exhaust valve or ports.

BLOWER. A device for supplying a stream of air at relatively low pressure in which compression is performed by a rotating member. Compression may be performed either by dynamic action, as in a **turbo-compressor**, or by positive displacement, as in a **Roots blower**.

BLUFF BODY, FLOW PAST. A bluff body may be defined, rather loosely, as a body on which the positive pressure gradient is large enough to cause separation of the boundary layer. This definition is a loose one, because in general the conditions for separation depend on the Reynolds number, and in particular on whether the boundary layer is laminar or turbulent. Nevertheless, the definition is convenient, serving to distinguish broadly between this class of body and the class of *streamline bodies* on which separation does not occur upstream of the trailing edge or tail.

The drag of a bluff body is relatively large, because the rise of pressure towards the rear of the body, which would occur in potential

flow, does not occur in a real fluid downstream of separation. Thus there is a relatively low pressure at the rear of the body and a large drag due to the distribution of normal pressure. The surface-friction drag is of the same order as for a streamline body and is usually almost negligible in comparison with the normal-pressure drag.

Because a turbulent boundary layer separates less readily than a laminar one, the position of separation on a bluff body is further downstream when the boundary layer is turbulent at separation than when it is laminar. Thus with a turbulent boundary layer the pressure at the rear of the body is higher, and the drag coefficient is lower, than with a laminar boundary layer. This leads to a considerable reduction of drag coefficient as the Reynolds number is increased through the *critical Reynolds number*, at which the boundary layer at separation changes from the laminar to the turbulent state. At Reynolds numbers a little below this critical value, slight roughening of the surface may cause the boundary layer to become turbulent before separation and hence lead to a large reduction of drag.

(See also **drag; separation of boundary layer**.)

BLUNDER. Any malfunction, human or otherwise, such as faulty arithmetic, use of an incorrect formula, etc., in a computation. The term blunder is also applied to the result of such a malfunction. (See **error**.)

BLUR CIRCLE. See **circle of least confusion**.

BODE DIAGRAM. See **frequency response representation**.

BODE LAW. In the latter part of the 18th century an empirical relationship was noticed between the mean distance of the various **planets** from the sun. This relationship was first published by Bode in 1772 and has since become known as Bode's law, in spite of the fact that there is certain evidence that it was known and used by Titius a number of years previous to the time of its announcement.

Bode's Law may be stated as follows: write down a series of 4's; to the first one add 0, to the second one add 3, to the third one add $6 = 3 \times 2$, to the fourth one, $12 = 6 \times 2$, to the fifth, $24 = 12 \times 2$, etc.; the resulting numbers divided by 10 will give the approximate

mean distances of the planets from the sun in **astronomical units**. The sequence is as follows:

Planet	Bode Distance	Mean Distance
Mercury.....	4 + 0 = 4	0.39
Venus.....	4 + 3 = 7	0.72
Earth.....	4 + 6 = 10	1.00
Mars.....	4 + 12 = 16	1.52
	4 + 24 = 28	
Jupiter.....	4 + 48 = 52	5.20
Saturn.....	4 + 96 = 100	9.53
Uranus.....	4 + 192 = 196	19.19
Neptune.....	4 + 384 = 388	30.07
Pluto.....	4 + 768 = 772	39.5

The value in the last column is the actual mean distance of the planet from the sun in astronomical units.

BODE RELATIONSHIP. See frequency response representation.

BODY FORCES. Forces on matter not resulting from inertia or contact with adjacent matter, e.g., gravitational or electromagnetic forces. They are usually assumed to be proportional to the mass to which they are applied.

BÖHMER INTEGRALS. See Cornu spiral.

BOHR FREQUENCY CONDITION. The assumption made by Bohr, in extension of Planck's quantum theory, that the frequency ν' (sec^{-1}) of radiation absorbed or emitted by an atom is proportional to the energy difference $E_1 - E_2$ between two quantum states, according to the relation

$$h\nu' = E_1 - E_2$$

where h stands for Planck's constant.

BOHR MAGNETON. The Bohr magneton (sometimes referred to as electronic Bohr magneton) is the unit used to measure the magnetic moment due to the orbital motion and the spin of the electron. The Bohr magneton is defined (in emu) as:

$$\mu_o = \frac{he}{4\pi mc} = 0.92731 \times 10^{-20} \text{erg gauss}^{-1}.$$

It is equal to the magnetic moment of an electric point charge moving in an orbit with angular momentum $h/2\pi$. Here e and m stand, respectively, for the electronic charge and mass, c for the velocity of light, and h for Planck's constant.

BOHR ORBITS. The orbits of the electron about the nucleus in Bohr's original model of the hydrogen atom. (See **electron orbits in an atom**.)

BOHR RADIUS. The radius of the innermost circular electron orbit (in non-rationalized c.g.s. units)

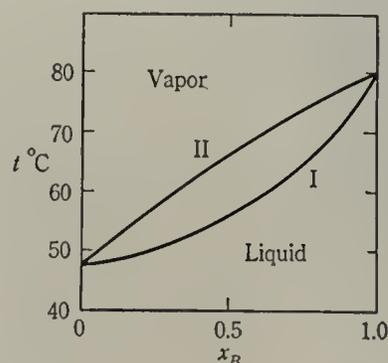

$$a_0 = \frac{h^2}{4\pi^2 m e^2} = (5.29172 \pm 0.00002) \times 10^{-9} \text{ cm}$$

in Bohr's model of the hydrogen atom, sometimes also referred to as first Bohr radius. Here h stands for Planck's constant, e and m respectively for charge and mass of the electron. The Bohr radius is often used as a unit of length in atomic physics.

BOILER. A device for the production of a flow of steam at high pressure and temperature for use in heating, in the production of power with the aid of a turbine, etc.

BOILING. The process of change of phase from liquid to gaseous states, also referred to as *evaporation*. The opposite process is called *liquefaction*. Sometimes a distinction is made between boiling, which involves the vigorous production of bubbles in the liquid, and evaporation which occurs mainly at the surface of the liquid and proceeds much more calmly.

BOILING CURVE AND CONDENSATION CURVE. Consider the phase diagram of a binary system forming a liquid and a vapor phase at constant pressure. Curve I is the boiling curve, which gives the coexistence temperature as a function of liquid composition; and curve II is the condensation curve, which gives the coexistent temperature as a function of the composition of the vapor phase. If the

Temperature-composition of a liquid-vapor system at constant pressure.

temperature is increased, vaporization begins when the boiling curve is crossed. Inversely, condensation begins when the temperature is decreased below the condensation curve.

BOILING POINT. The temperature at which boiling occurs for a given pressure. Sometimes the pressure is specified as that of 1 atmosphere. (See *phase change*.)

BOILING POINT CONSTANT. Consider a dilute solution in which all solute species may be regarded as non-volatile. The vapor in equilibrium with the solution is then formed from the solvent only. Call T° the boiling point of the pure solvent at the pressure concerned, and T the boiling point of the solution. For a dilute solution the difference

$$\theta = T - T^\circ \quad (1)$$

will be small compared with T° .

If the solution is also ideal one has

$$\theta = \frac{R(T^\circ)^2}{\Delta_e h^\circ} \frac{M_1}{1000} \sum_s m_s = \theta_e \sum_s m_s. \quad (2)$$

M_1 is the molar mass of the solvent, $\Delta_e h^\circ$ its latent heat of vaporization in kcal per mole at temperature T° , m_s the **molality** of solute s ; θ_e is called the *boiling point constant*, or *ebullioscopic constant*. It depends only on the properties of the solvent. For water

$$\theta_e = 0.51^\circ\text{C}.$$

BOLTZMANN CONSTANT. The multiplying constant, k , in the relation between **entropy** of a state and the logarithm of the probability of that state, or in the relation between the average kinetic energy and the absolute temperature. The Boltzmann constant is also equal to the ratio of the **gas constant** to the **Avogadro constant**. Its value is 1.3803×10^{-16} g cm² sec⁻² degree C⁻¹.

BOLTZMANN DISTRIBUTION. See *Maxwell-Boltzmann distribution*; *Boltzmann principle*, *distribution*.

BOLTZMANN EQUATION. See *transport equation*.

BOLTZMANN FACTOR. (1) The temperature-dependent **statistical weight** factor $e^{-\beta E}$ for a particle of energy E in a system at a temperature $1/k\beta$ (k is the Boltzmann constant). (See also *Maxwell-Boltzmann distribution*.) (2) A correction factor applied to

calculated line intensities in spectra due to thermal excitation.

BOLTZMANN FORMULA. See *Boltzmann principle*.

BOLTZMANN H-THEOREM. See *H-theorem*.

BOLTZMANN-PLANCK EQUATION. The relation between **entropy** S and number of **complexions** W ,

$$S = k \ln W,$$

where k is the **Boltzmann constant**.

BOLTZMANN PRINCIPLE (DISTRIBUTION). A somewhat general law relating to the statistical distribution of large numbers of minute particles subject to thermal agitation and acted upon by a magnetic, and electric, or a gravitational field, or by inertia. The number of particles, N , per unit volume in any region of the field, when the system is in statistical equilibrium, is given by the equation

$$N = N_0 e^{-\beta E}.$$

Here N_0 is the number of particles per unit volume in a region of the field where E , the potential energy of the particle, is zero, and where $e^{-\beta E}$ is the **Boltzmann factor**, which is temperature-dependent. (See *Maxwell-Boltzmann distribution*.)

BOLTZMANN STATISTICS. In the case of a system of independent particles, there will be $N!/n_1!n_2! \cdots$ different **microstates** corresponding to the same **macrostate** characterized by the numbers n_i of particles in the i -th single particle level, provided no symmetry considerations are taken into account. The macrostate characterized by a set of n_i will then have a weight proportional to $\Pi_j (n_j!)^{-1}$. This corresponds to Boltzmann statistics.

BOLTZMANN TRANSPORT EQUATION. See *transport equation*, *Boltzmann*.

BOLTZMANN TRANSPORT EQUATION FOR NEUTRONS. See *neutron transport theory*.

BOLTZMANN-VLASOV EQUATIONS. The basic equations which govern a high temperature plasma in which the collisional mean free path is much greater than all the characteristic lengths of the system, first used by Vlasov. They are

$$\frac{\partial f_j}{\partial t} + \mathbf{v} \cdot \nabla f_j + \frac{e_j}{m_j} \left[\mathbf{E} + \frac{\mathbf{v} \times \mathbf{B}}{c} \right] \cdot \nabla \mathbf{v} f_j = 0 \quad (1)$$

$$\nabla \times \mathbf{E} = -\frac{1}{c} \frac{\partial \mathbf{B}}{\partial t} \quad (2)$$

$$\nabla \times \mathbf{B} = \frac{4\pi}{c} \mathbf{j} + \frac{1}{c} \frac{\partial \mathbf{E}}{\partial t} \quad (3)$$

$$\nabla \cdot \mathbf{B} = 0 \quad (4)$$

$$\nabla \cdot \mathbf{E} = 4\pi\sigma \quad (5)$$

$$\mathbf{j} = \sum_j e_j \int f_j \mathbf{v} d^3\mathbf{v} \quad (6)$$

$$\sigma = \sum_j e_j \int f_j d^3\mathbf{v}. \quad (7)$$

Equation (1) is the usual Boltzmann equation for the one-particle distribution functions f_j of charge and mass e_j and m_j respectively. The electromagnetic fields \mathbf{E} and \mathbf{B} are determined by the usual Maxwell Equations (2)–(5). The current density \mathbf{j} and the charge density σ are given by Equations (6) and (7). The summations in (6) and (7) are over all particle species.

BOLZANO-WEIERSTRASS THEOREM. If A is a bounded set containing infinitely many points in a metric space S , then A has at least one limit point. This theorem is of fundamental importance in analysis, in the case, for example, that S is the set of real numbers.

BOND ANGLE. In a polyatomic molecule, the angle formed by the lines connecting one nucleus with two others, that is, the angle between two chemical bonds.

BOND CHARACTER. Empirical additive rules and tables of atomic radii have been used to predict the skeleton size of various molecules (see **atomic radius; bond length**). For the atoms which can form single, double or triple bonds, a different radius must be used for each kind of bond.

In some cases, the observed deviation from this additive rule can be attributed to a *change in bond character* caused by **resonance** with neighboring bonds. (For instance, the C—Me distance in toluene is smaller than the C—C distance in diamond.) The bond character can be estimated from the observed interatomic distance, and from a plot of bond length versus bond character for substances

whose bond character is unambiguous; examples are diamond, graphite, benzene, and ethylene, with respective double bond characters of 0, $\frac{1}{3}$, $\frac{1}{2}$, and 1.

BOND, CONJUGATED DOUBLE. The alternation of single and double bonds. By electron transfer the positions of the single and double bonds can be exchanged, leading to an exchange energy.

BOND, COORDINATE. See **coordinate bond**.

BOND, COVALENT. See **homopolar bond**.

BOND, ELECTROSTATIC. See **heteropolar bond**.

BOND, ELECTROVALENT. See **heteropolar bond**.

BOND ENERGIES. It has been suggested that ${}_a Q_f^\circ$, the heat of formation of a molecule from its constituent atoms (see **atomic heat of formation**), could be computed from a table of average bond energies, and the assumption of additivity:

$${}_a Q_f^\circ = \sum_{\substack{\text{all types} \\ \text{of bonds}}} n_{X_i-X_j} \cdot E_{X_i-X_j}$$

$n_{X_i-X_j}$ is the number of bonds between the two atomic species, X_i and X_j , in the molecule. $E_{X_i-X_j}$ is the average bond energy associated with each of these bonds. Fairly accurate predictions of the heats of formations of organic molecules can be made in this way, particularly for the *larger* hydrocarbons, alcohols and other aliphatic derivatives.

The differences between the observed heats of formation of *cis-trans* isomers and of branched and unbranched hydrocarbon chains show that the additivity rule is not strictly rigorous. Various improvements have been suggested.

It is only in the case of diatomic molecules that bond energies and dissociation energies (see **dissociation energies**) are equivalent. In the simple case of the H_2O molecule, the dissociation energies of the two successive steps $\text{H}_2\text{O} \rightarrow \text{H} + \text{OH} \rightarrow \text{H} + \text{H} + \text{O}$, differ by about 10%.

BOND ENERGY, ATOMIC. See **atomic bond energy**.

BOND, HETEROPOLAR. See **heteropolar bond**.

BOND, HOMOPOLAR. See **homopolar bond**.

BOND, HYBRID. See **hybridization of eigenfunctions**.

BONDING ORBITALS. In the molecular orbital theory (see **molecular orbital method**) of the chemical bond, when two atoms are brought together their electrons move into characteristic orbitals of the molecule. These electrons and orbitals are called either bonding or anti-bonding depending on whether they strengthen or weaken the resulting chemical bond. If their effect on the bond energy can be neglected, they are non-bonding orbitals or non-bonding electrons.

For example, the two electrons in the fundamental state of the H_2 molecule are bonding electrons. But when two H atoms with electrons of parallel spin are brought together, one electron only goes into a bonding orbital. The other moves into a strongly anti-bonding orbital, leading to an unstable molecule. The inner K orbitals in the Li_2 or Na_2 molecules are non-bonding. (See **bond types**.)

BOND, IONIC. See **heteropolar bond**.

BOND LENGTH. Distance between the nuclei of the two atoms participating in a bond. (See **atomic radius**; **bond character**; **mobile bond order**.)

BOND ORDER. See **mobile bond order**.

BOND, π - π . A covalent bond resulting from the interaction of two electrons having π -wave functions. The resulting wave function must be symmetrical with respect to an interchange of the two electrons, i.e., the wave functions of the two electrons must point in the same direction. This leads to a rigidity of the bond: the terminal groups of atoms are not free to rotate with respect to one another. A good example of this rigidity is the *cis-trans* isomerism for C=C double bonds.

BOND, σ - σ . A covalent bond resulting from the interaction of two electrons having σ -wave functions. In view of the symmetry character of these wave functions, the terminal groups of atoms should be free to rotate with respect to one another around the bond axis. (See, however, **hindered rotation**.)

BOND STRESS. The effectiveness of reinforcement, such as that of steel in concrete or

fibers in reinforced plastic, depends upon the transmission of load from the weaker material to the reinforcement. If this transfer takes place inside the member (as contrasted with post-stressing technique) it must be by shear on the surface of the reinforcement. This shear stress is called bond stress and often is the limiting feature. The smaller the diameter of the reinforcement for a given cross-sectional area of rod, wire or fiber, the lower the bond stress.

BOND TYPES. One may classify the various types of interatomic (and intermolecular) bonds occurring in nature into 4 broad categories:

(1) *Electrostatic bonds* resulting from Coulomb forces between positive and negative ions (ionic bonds) or between dipoles or multipoles. The forces are non-directional; the **coordination number** is high. (See **heteropolar bond**.)

(2) *Covalent bonds* in which the atoms share one or more electrons; in some cases, each atom provides valency electrons (*pure covalent bond*); in other cases, the valency electrons are provided by one of the atoms only (*coordinate bond*). The forces are directional and the coordination number usually low. (See **homopolar bond**.)

(3) *Metallic bonds*. The attractive forces result from the exchange interaction of the electron gas with the ionic lattice. The forces are non-directional, and the coordination number high.

(4) *Van der Waals bonds*. Van der Waals forces are important in molecular crystals. They result from London **dispersion forces**. They are non-directional, and have a high coordination number.

Perfect cases of the three first types are seldom encountered in nature, but bonds exhibiting virtually all degrees of transition between them exist. In most cases, however, one or the other of these limiting cases is a better first approximation for the calculation of the bond energy. The bond is said to be primarily electrostatic, covalent, or metallic in character.

(See also **atomic bond energy**; **valence forces**, **subsidiary**; **valency**, **directed**.)

BOOLEAN ALGEBRA. A distributive lattice which has universal bounds and has complements. (A lattice is distributive if $a(b + c)$

$= ab + ac$ and $a \times bc = (a \times b)(a \times c)$, has universal bounds if it contains elements O and I with $0 \leq a \leq I$ for all a , and has complements if for every a there exists an a' such that $aa' = O$ and $a + a' = I$.) Boolean algebra can be characterized in many other, equivalent ways. The subsets a, b, \dots of a set of objects S form a Boolean algebra if ab denotes the intersection and $a + b$ the union of a and b . The algebra of statements $a, b, c \dots$ with connectives "and," "or," "not" form a Boolean algebra if $a + b$ means a or b (including the possibility of both), while ab means a and b . Boolean algebras are important in the design of computing machines.

BORE. See hydraulic jump.

BORN AND VON KÁRMÁN THEORY. This theory followed the Debye theory of specific heats, in which a solid is treated as a continuous medium with a characteristic maximum frequency ν_{max} . In the Born and von Kármán theory, the solid is treated as an infinitely extended vibrating atomic lattice in which the vibrations of any given particle influence only immediately adjacent particles. This results in an energy equation of the form

$$E = \sum_p^{1,2,3} \iiint_0^{2\pi} \frac{N}{2\pi^3} f(\nu_p) d\phi d\psi d\chi$$

where

$$f(\nu_p) = h\nu / [\exp(h\nu/kT) - 1]$$

and ϕ, ψ, χ , are phase differences in the vibrations of neighboring points at a given instant, N is the number of atoms in the lattice, and k is the Boltzmann constant. There are three sums for the three types of vibration (one longitudinal and two transverse).

BORN APPROXIMATION. A quantum mechanical approximation method used particularly for the computation of cross sections in scattering problems. This approximation can be used when the relative kinetic energy of two particles is large compared to their interaction energy. The approximation consists of the assumption that the wave function of the system is made up of an incident plane wave, e^{ikz} , plus a spherical scattered wave, $v(\mathbf{r})$, with $|v(r)| \ll 1$. Qualitatively, this approximation is based on the idea that the large size of the relative kinetic energy compared to the interaction energy insures that the distortion of the incoming plane wave by the potential

can be neglected and that the weak potential will scatter a very small part of the incident wave.

BORN-HABER CYCLE. A thermodynamic cycle of operations used to obtain the electron affinities of certain atoms. It may be illustrated by consideration of the metal halides, when the cycle includes:

(1) A break-up of the crystal into ions, with attendant energy change U , the lattice energy. (See **Born-Mayer equation**.)

(2) Change of the ions formed into atoms, with energy changes of I , the ionization energy for the positive ion; and E , the electron affinity, for the negative ion.

(3) Condensation of the gaseous atoms into (a) a metallic solid, involving an energy change S , where S is the heat of sublimation per gram-mole, and (b) a halogen molecule, with energy change $\frac{1}{2}D$, where D is the dissociation energy.

(4) Reaction of metal and halogen to form the metal halide, the heat of reaction being Q . Then

$$E = Q + S + \frac{1}{2}D - U.$$

BORN-INFELD THEORY. A non-linear modification of Maxwell's equations. The Maxwell equations themselves remain unchanged, but ϵ and μ are related by the equations

$$\mu = \frac{1}{\epsilon} = \sqrt{1 + \frac{\mathbf{B}^2 - \mathbf{E}^2}{b^2}}.$$

(In a later modification

$$\mu = \frac{1}{\epsilon} = \sqrt{1 + \frac{\mathbf{B}^2 - \mathbf{E}^2}{b^2} + \frac{(\mathbf{E} \cdot \mathbf{B})^2}{b^4}})$$

b is a new universal constant, viz., the absolute electrostatic field at the center of a point electron. The electrostatic field of a point electron of charge e at a distance r is

$$\mathbf{E} = \frac{e}{\sqrt{r^4 + \frac{e^2}{b^2}}}.$$

The total electrostatic energy W is finite, viz.,

$$W = 1.2361 \left(\frac{e^2}{a} \right)$$

where

$$a = \sqrt{\frac{e}{b}} \text{ ("electronic radius").}$$

The theory is not unique and does not lead to new results which may be compared with those of experiment.

BORN-MAYER EQUATION. An equation which expresses the lattice energies of crystals in the form of the equation

$$U = \frac{Z^2 e^2 N A}{r} - b \exp(-rp) + \frac{c}{r^6} + \epsilon_0$$

where r is the interatomic distance. The first term represents the **Coulomb energy**, where Ze is the ionic charge, $2N$ is the number of ions in the crystal, and A , the **Madelung constant**, which varies with crystal structure. The second term allows for repulsive forces, the factor p being calculated from results of measurement of the compressibility of the material. The third term accounts for the **van der Waals forces**, while the final term ϵ_0 represents the **zero-point energy**.

BORN-OPPENHEIMER METHOD. An argument for calculating the **force constants** between atoms in a molecule or solid, based on the observation that the motion of the electrons is so rapid compared with that of the heavier nuclei that it can be assumed that the electrons follow the motion of the nuclei adiabatically. That is, one calculates the eigenvalues of energy for the electrons with the nuclei in fixed positions; the variation of this electronic energy with the configuration of the nuclei may then be treated as a contribution to the potential energy of the interatomic forces.

BORN REPULSION. The interaction of the electron shells of two atoms leads to a strong repulsion at sufficiently short range (**Pauli exclusion principle**). This effect, which is difficult to calculate, was represented empirically by Born by an additive term c/r^n in the potential energy of interaction for his ionic lattice model. (See **Born-Mayer equation**.) A similar term was used by Lennard-Jones to represent the intermolecular repulsion at close range. (See **Lennard-Jones potential**; **index of repulsion**.)

BOSANQUET LAW. A relationship in magnetism analogous to the **Ohm law** in electricity. It is of the form

$$\text{Flux} = \frac{\text{magnetomotive force}}{\text{reluctance}}; \quad \phi = \mathfrak{F}/\mathcal{R}.$$

Ignoring frequency, the reluctance of an air gap of length l and cross-sectional area A is

$$\mathcal{R}_g = \frac{l}{\mu_v A}$$

while that of the core of length L is

$$\mathcal{R}_c = \frac{L}{\mu_s \mu_v A}$$

making the total: $\mathcal{R} = \mathcal{R}_g + \mathcal{R}_c$. The magnetomotive force, in rationalized units, is $\mathfrak{F} = NI$. Using mksa units, l is in meters, A in square meters, I in amperes, \mathfrak{F} in ampere-turns, and the flux (ϕ) in webers.

BOSE-EINSTEIN DISTRIBUTION. (1) In a gas composed of a fixed number of particles that obey **Bose-Einstein quantum statistics**, the number of particles, n_i , in a state of energy, E_i , is given by

$$n_i = 1/[Ae^{E_i/kT} - 1],$$

where A is a constant that depends on the total number of particles present. Gases composed of particles with integral spin, such as helium of mass number 4, obey this distribution law.

(2) In applying the Bose-Einstein statistics to photons, the assumption of a fixed number of photons cannot be made. This fact leads to a slightly different distribution function than the one above, namely the constant A is unity, i.e.,

$$n_i = 1/[e^{E_i/kT} - 1].$$

This distribution law leads to the **Planck radiation formula** for black bodies.

BOSE-EINSTEIN GAS. Systems of non-interacting or only weakly interacting **bosons**. A perfect Bose-Einstein gas shows the phenomenon of **Einstein condensation**. A system of weakly interacting bosons can represent **helium gas**. Of special interest in that connection is the so-called **hard sphere boson gas** which shows a transition similar to the **lambda transition** of helium.

BOSE-EINSTEIN LIQUID. Liquid whose constituent particles are **bosons**. The best known example is ordinary **liquid helium**.

BOSE-EINSTEIN STATISTICS. In the case where the particles in a system of independent particles are described by a symmetrical wave function, there will be only one possible **macrostate** characterized by a set of numbers n_i of particles in the i -th single particle level, namely, the one corresponding to a symmetric superposition of all possible **microstates**. This means that in Bose-Einstein statistics every macrostate will have the same weight. (See also **quantum statistics**.)

BOSON. The generic name for the elementary particles obeying **Bose-Einstein statistics**. The connection of spin with statistics establishes that all bosons have integral spin or zero spin.

BOSONS, COMMUTATIVE RULES FOR. See **commutative rules for bosons**.

BOUGUER LAW. The law discovered by Bouguer in 1729, that the absorption of light in homogeneous materials depends on thickness according to the exponential expression given under **absorption coefficient**. The law was rediscovered by Lambert and is often referred to as the Lambert law of absorption. It is also related to the Beer law, which is obtained by setting the absorption coefficient $a = ac$. When the law is expressed in terms of common logarithms:

$$I = I_0 10^{-kx},$$

k is known as the *extinction coefficient*.

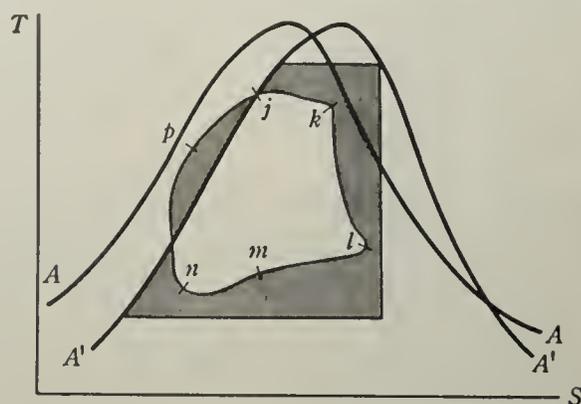

These laws may be applied to a narrow band of wavelengths, giving the *specular coefficient of absorption* or the *specular extinction coefficient* according to the form of the equation used. They do not hold for broad spectral bands if the coefficients depend appreciably on the wavelength.

BOULVIN DIAGRAM. The sequence of processes in a reciprocating steam engine cannot be drawn on a T,S diagram because the mass of steam contained in the engine cylinder varies during one cycle. It is much smaller during compression than during expansion, and varies continuously during admission and exhaust. The difficulty can be circumvented if certain more or less arbitrary assumptions, suggested by Boulvin, are made. It is assumed

that the cylinder is filled with a mass $m + m_r$ (m is the mass of steam admitted; m_r is the mass of residual steam) during the whole of the cycle, and that the processes in the boiler and condenser take place in the cylinder. It is imagined that there is no exhaust, but that the steam condenses in the cylinder, the heat of condensation being rejected through the walls, and the volume of steam being reduced practically to zero. Similarly, it is imagined that there is no admission but that the condensate evaporates in the cylinder. In this way an imaginary cycle with constant mass $m + m_r$ is assumed to be performed.

The mass of steam m admitted is calculated from the measured steam consumption, and the mass of residual steam, m_r , is calculated under the assumption that it is dry saturated at the beginning of compression.

A Boulvin diagram is shown in the figure. In it, $jklmnp$ represents the indicator diagram

Boulvin diagram.

cross-plotted from a p,V diagram. Line A is the boundary curve for mass m , and line A' is the boundary curve for mass $m + m_r$. The shaded areas represent the quantities of heat exchanged with the cylinder walls.

The Boulvin diagram illustrates the nature of the exchanges of heat which takes place in the engine cylinder. Its importance is primarily historical, owing to the fact that reciprocating steam engines are at present confined to marginal applications only.

BOUND. Let S be a set of real numbers, e.g., a sequence, the values of a function, etc. A number M , if it exists, which is greater than or equal to any member of S , is an upper bound for S , and the least such upper bound if it exists is called the *least upper bound* (l.u.b.) of S , and similarly for lower bounds.

BOUNDARY CIRCLES. In impedance matching, circles of constant standing-wave ratio which represent the boundaries of all transformation circles which may be transformed to the definition circle.

BOUNDARY CONDITION. A specified requirement for the solution of a given differential equation or set of equations at a given set of values of the independent variables.

BOUNDARY CONDITION, KINEMATIC. See kinematic boundary condition.

BOUNDARY CONDITIONS, MARK. In the analysis of the Milne problem in transport theory by means of the spherical harmonics method, the (vacuum) boundary condition—in the n^{th} order approximation—which states that the angular flux vanishes at $\frac{1}{2}(n+1)$ positive values μ_i . The μ_i are given by the positive roots of $P_{n+1}(\mu) = 0$, where $P_n(\mu)$ is the n^{th} Legendre polynomial. These conditions were first propounded by C. Mark.

BOUNDARY CONDITIONS, MARSHAK. In the analysis of the Milne problem in transport theory by means of the spherical harmonics method, the (vacuum) boundary condition—in the n^{th} order approximation—which states that the first $\frac{1}{2}(n+1)$ odd moments of the returning flux vanish. These conditions were first propounded by R. E. Marshak.

BOUNDARY CONDITIONS, NEUTRON DIFFUSION THEORY. Across an interface between two media, the neutron current, as given by Fick's Law, and the neutron flux are assumed continuous. At an outer boundary the neutron flux does not vanish; it is assumed to vanish at a point, the extrapolated end-point (z_0), lying outside the boundary. Alternatively, one may say that the magnitude of the logarithmic derivative of the flux, evaluated at the boundary, is equal to the reciprocal of a length, the linear extrapolation length, l . In general $l \neq z_0$.

BOUNDARY CONDITIONS, NEUTRON TRANSPORT THEORY. In moving across an interface between two media in direct contact, a packet of neutrons suffers no change. More precisely $N(\mathbf{r} + R\hat{\Omega}, E, \hat{\Omega})$ is a continuous function of R for $\mathbf{r} + R\hat{\Omega}$ at the interface. At an outer boundary of a geometrically simple medium $N(\mathbf{r}, E, \hat{\Omega}) = 0$ for all $\hat{\Omega}$ directed into the medium, and r on the surface.

BOUNDARY CONDITIONS ON THE ELECTROMAGNETIC FIELD VECTORS.

(1) At an uncharged boundary between two media the normal components of the magnetic flux density \mathbf{B} , and of the electric displacement \mathbf{D} are continuous. If the boundary carries a surface charge, then the difference in the normal components of \mathbf{D} is equal to the surface charge density. (2) Also the tangential component of the electric field intensity \mathbf{E} is continuous at a boundary, and the tangential component of the magnetic field intensity \mathbf{H} is continuous if the boundary carries no surface current. If there is a surface current, the difference in the tangential components of \mathbf{H} on the two sides of the boundary is the surface current per unit length flowing along the boundary.

BOUNDARY CONDITION, STANDARD. When applied to the Schrödinger equation of quantum mechanics, this condition requires that the wave function and its derivative vanish at infinity.

BOUNDARY CURVE. See saturation curve.

BOUNDARY LAYER. The Navier-Stokes equations for flow of a viscous fluid are non-linear, and solutions can only be obtained for a few special cases. For this reason, much theoretical work in fluid dynamics has been concerned with a hypothetical *ideal fluid*, which differs from real fluids in two important respects. The ideal fluid is assumed to have zero viscosity, so that there can be no shear stresses, and in addition it is assumed that it can have a non-zero velocity at a solid boundary, i.e., that it can slip at the boundary. Real fluids have viscosity, so that shear stresses are developed, and they must have zero velocity of slip at a solid boundary (except for gases at very low densities).

With a fluid of zero viscosity the condition of no slip at a boundary can only be satisfied by introducing a vortex sheet at the boundary. In a real fluid, with viscosity, there is an outward diffusion of vorticity from the boundary into the fluid. At high Reynolds numbers, however, the rate of outward diffusion of vorticity is small compared with the rate of convection with the stream, so that the vorticity is confined to a layer, the boundary layer, whose thickness is small compared with the length of the body. Thus, in the important

case of a body in a uniform stream, the flow outside the boundary layer is irrotational and may be calculated by neglecting viscosity. Effects of viscosity are confined to the boundary layer, and *if this does not separate* its only effect on the irrotational flow is equivalent to a small change in the shape of the body. If the boundary layer separates there are important effects on the irrotational flow which will be discussed later.

A boundary layer may be either *laminar* or *turbulent*, or in a state of transition between these two conditions. In a laminar boundary layer the shear stresses are caused directly by viscosity, while over the greater part of a turbulent layer the shear stresses are due mainly to the *Reynolds stresses* associated with the turbulence, the viscous stresses being comparatively small.

At low Reynolds numbers, and when the pressure gradient in the stream direction is strongly negative, laminar boundary layers are stable. Instability of a laminar boundary layer, followed by transition to turbulent flow, occurs more readily as the Reynolds number or the positive pressure gradient is increased.

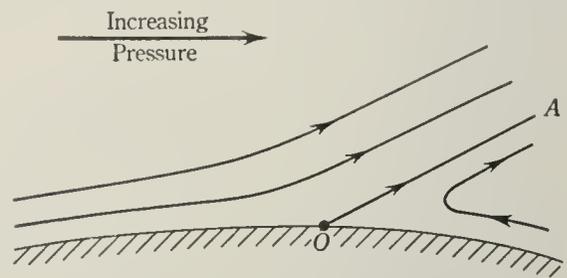

For a laminar boundary layer it can be shown that δ/l , v/u and $\tau_o/\rho U^2$ are all $O(R^{-1/2})$, where δ is the thickness of the layer, l is the length of the body, v and u are velocity components normal and tangential to the surface, τ_o is the shear stress at the boundary, and $R = \frac{\rho U l}{\mu}$ is

the Reynolds number based on the stream velocity U . Thus at high Reynolds numbers $\delta \ll l$ and $v \ll u$. As a consequence the Navier-Stokes equations can be simplified by omitting certain terms; in particular the variation of pressure across the boundary layer can be neglected. Approximate solutions of the resulting *boundary-layer equations* can be obtained by various methods.

The flow in a turbulent boundary layer is inherently much more complicated than that in a laminar layer, because in the former case there is no simple relation between the shear stress and the distribution of mean velocity. The methods available at present for calculating turbulent boundary layers rely on empirical data to a considerable extent.

Separation of a boundary layer can only occur when the pressure gradient in the stream direction is positive. Because the kinetic energy of the fluid in the boundary layer is

reduced by the action of viscosity, the pressure gradient may cause the fluid near the boundary to be brought to rest. In the figure

Separation of boundary layer.

this occurs at the point O , and the flow further downstream is reversed in direction. The limiting streamline at the boundary (of zero velocity) diverges from the boundary along OA , and the other streamlines are also deflected outward. There is a considerable effect on the irrotational flow outside the boundary layer, leading to a change of pressure distribution which in turn affects the flow in the boundary layer. Thus the final flow pattern, and in particular the position of the separation point O , depend on an interaction between the flow inside the boundary layer and the external flow.

When separation does not occur, the observed pressure distribution at high Reynolds numbers usually agrees well with the results of ideal fluid theory, because the boundary layer is thin and has only a small effect on the irrotational flow. When separation occurs, however, the separated boundary layer may cause large changes in the boundary conditions for the irrotational flow, so that the pressure distribution on the body differs considerably from that calculated for an ideal fluid. (See also **laminar boundary-layer equations; separation of boundary layer; turbulent boundary layer.**)

BOUNDARY LAYER, CALCULATION OF DEVELOPMENT. See **transition of turbulent flow in a boundary layer.**

BOUNDARY-LAYER CONTROL. Boundary-layer control is applied in two forms. In one of these, fluid is sucked into a porous or perforated wall to increase the stability of a laminar **boundary layer**, thus preventing or delaying transition to turbulent flow and reducing the drag due to surface friction. The volume flow required per unit area of surface

is of order $U \times 10^{-4}$ at Reynolds numbers of 10^6 to 10^7 , where U is the free-stream velocity.

The other form of boundary-layer control is applied to prevent separation of a boundary layer, either laminar or turbulent. This form of control may be applied by sucking fluid into the surface, by blowing fluid tangentially along the surface in the direction of the stream or, for a turbulent boundary layer, by various devices such as vortex generators which promote more rapid mixing in the layer.

BOUNDARY LAYER DISPLACEMENT THICKNESS. See displacement thickness of boundary layer.

BOUNDARY LAYER ENERGY EQUATION. See energy equation for boundary layer.

BOUNDARY LAYER, ENERGY THICKNESS OF. See energy thickness of boundary layer.

BOUNDARY LAYER, FORM PARAMETER FOR TURBULENT. See form parameter for turbulent boundary layer.

BOUNDARY LAYER IN A COMPRESSIBLE FLUID. When a compressible fluid flows past an insulated body at a high Mach number, the temperature at the body is greater than that in the free stream. At high Reynolds numbers the change of temperature occurs across a thin layer adjacent to the body, the *thermal boundary layer*. For all gases the Prandtl number is of order 1, and as a consequence the thickness of the thermal boundary layer is of the same order as that of the ordinary (velocity) boundary layer.

In general, calculation of boundary-layer flow in a compressible fluid is difficult, because of the interaction between the thermal and velocity boundary layers and because of the variation of viscosity with temperature. Non-dimensional quantities such as the skin-friction coefficient depend not only on the Reynolds number, external pressure distribution and surface roughness (as for an incompressible fluid), but also on (i) the Mach number, (ii) the Prandtl number, (iii) the functional relation between viscosity and temperature, (iv) the conditions of heat transfer at the boundary.

For either a laminar or a turbulent boundary layer at a given Reynolds number, the skin friction coefficient decreases with increas-

ing Mach number. With zero heat transfer, increasing Mach number reduces the stability of a laminar **boundary layer**, but heat transfer from the fluid to the body leads to a considerable increase of stability.

BOUNDARY LAYER IN UNSTEADY FLOW. When the flow in a boundary layer

is unsteady, an additional term $\frac{\partial u}{\partial t}$ appears in the equations. Thus for a laminar **boundary layer** the equations are

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = -\frac{1}{\rho} \frac{\partial p}{\partial x} + \nu \frac{\partial^2 u}{\partial y^2} \quad (1)$$

and the **equation of continuity**. The boundary conditions are the same as for steady flow, except that the velocity in the potential flow is now $U(x,t)$. The pressure gradient $\frac{\partial p}{\partial x}$ is determined by the potential flow, in accordance with the equation

$$-\frac{1}{\rho} \frac{\partial p}{\partial x} = \frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} \quad (2)$$

The equations can be solved by a process of successive approximation. Neglecting the terms in $\frac{\partial u}{\partial x}$, $\frac{\partial u}{\partial y}$ and $\frac{\partial U}{\partial x}$ in Equations (1) and (2), a first approximation to $u(x,y,t)$ is obtained from the equation

$$\frac{\partial u}{\partial t} - \nu \frac{\partial^2 u}{\partial y^2} = \frac{\partial U}{\partial t} \quad (3)$$

This first approximation is then used to calculate approximately the neglected terms and hence obtain a second approximation to $u(x,y,t)$, and so on.

The method outlined above can be used for a laminar boundary layer that is either started from rest or in periodic motion. For a **turbulent boundary layer** in unsteady flow there is no satisfactory theoretical approach and very few experiments have been made. (See also **laminar boundary-layer equations**.)

BOUNDARY LAYER, LAMINAR. See laminar boundary layer equations.

BOUNDARY LAYER, MOMENTUM EQUATION FOR. See momentum equation for boundary layer.

BOUNDARY LAYER, MOMENTUM THICKNESS OF. See momentum thickness of boundary layer.

BOUNDARY LAYER ON A FLAT PLATE, LAMINAR. For a thin flat plate at zero incidence, in a steady uniform stream of incompressible fluid, the pressure is uniform and the laminar boundary-layer equations reduce to

$$u \frac{\partial u}{\partial x} + \nu \frac{\partial u}{\partial y} = \nu \frac{\partial^2 u}{\partial y^2} \quad (1)$$

and

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0. \quad (2)$$

Taking the x -axis along the plate, with the origin at the leading edge, the boundary conditions are $u = v = 0$ at $y = 0$ and $u = U$ at $y = \infty$, where U is the velocity of the free stream.

The velocity profiles at different values of x are all similar, so that if u and y are expressed in suitable nondimensional terms all the velocity profiles are given by a single function. A stream function ψ is introduced, so that

$$u = \frac{\partial \psi}{\partial y} \quad \text{and} \quad v = \frac{\partial \psi}{\partial x}.$$

Then, putting

$$\eta = y \left(\frac{U}{\nu x} \right)^{1/2} \quad \text{and} \quad \psi = (\nu U x)^{1/2} f(\eta),$$

Equation (1) reduces to

$$ff'' + 2f''' = 0, \quad (3)$$

where the primes denote differentiations with respect to η . Equation (3) has been solved numerically, with the appropriate boundary conditions, by expressing f as a series in powers of η . A few points from the numerical solution are given in the following table.

η	0	1	2	3	4	5	6
f	0	0.1656	0.6500	1.3968	2.3058	3.2833	4.2796
$f' = \frac{u}{U}$	0	0.3298	0.6298	0.8460	0.9555	0.9915	0.9990

The shear stress at the wall is $\tau_0 = \mu \left(\frac{\partial u}{\partial y} \right)_{y=0}$.

Hence it can be shown that the skin friction coefficient is

$$C_f = \frac{\tau_0}{\frac{1}{2}\rho U^2} = 0.664 \left(\frac{\nu}{Ux} \right)^{1/2}.$$

If D is the drag per unit breadth of a plate of length l , wetted on both sides, integration of the expression for C_f shows that the drag coefficient is

$$C_D = \frac{D}{\frac{1}{2}\rho U^2 l} = 2.656 \left(\frac{\nu}{Ul} \right)^{1/2}.$$

Experiments with laminar boundary layers on flat plates agree well with these results, provided the Reynolds number $\frac{Ux}{\nu}$ is not less than about 10^4 . In a stream of very low turbulence the boundary layer may remain laminar for values of $\frac{Ux}{\nu}$ up to about 3×10^6 .

BOUNDARY LAYER, REATTACHMENT AFTER SEPARATION. See reattachment of boundary layer after separation.

BOUNDARY LAYER, SEPARATION OF. See separation of the boundary layer.

BOUNDARY-LAYER SHOCK-WAVE INTERACTION. See shock-wave boundary-layer interaction.

BOUNDARY LAYER, TRANSITION OF TURBULENT FLOW IN. See transition of turbulent flow in a boundary layer.

BOUNDARY LAYER, TURBULENT. See turbulent boundary layer.

BOUNDARY VALUE PROBLEM. A type of problem encountered in the solution of a differential equation or a system of differential equations which must meet given requirements for the value(s) of the independent variable, called the *boundary points*. For **ordinary differential equations** the usual numerical method of solution is to approximate the derivatives by finite differences and solve the resulting difference equations. This leads to **matrix inversion**, and the solution of linear equations, and possibly to the need for finding **eigenvalues and eigenvectors**. (See also **partial differential equations**.)

The *Dirichlet problem*, often called the *first*

boundary value problem, can be stated in the form: Assume a function of f continuous over a boundary surface S , with R the region bounded. The boundary problem is to find a solution of the **Laplace equation** $\nabla^2\phi = 0$ that is regular in R , continuous in $R + S$ and satisfies the equation $\phi = f$ at the boundary. This solution can be expressed in terms of **Green's function**.

The *Neumann problem*, often called the *second boundary value problem*, can be stated in the form: Assume a function of f continuous over a boundary S , with R the region bounded. The boundary value problem here is also (as in the Dirichlet problem above) to find the solution of the Laplace equation, with the conditions specified above, but with the added

conditions that the surface integral $\iint_S f dS$ vanishes, and also that the normal derivative is equal to f on the boundary surface. The solution can be expressed in terms of **Neumann's function**.

The *Robin problem*, often called the *third boundary value problem*, is subject to conditions specified above for the Neumann problem, but the equation it must satisfy is

$$g\partial\phi/\partial n + \psi\phi = f,$$

where g and ψ , as well as f , are functions that are continuous on S . The solution can be expressed in terms of **Robin's function**.

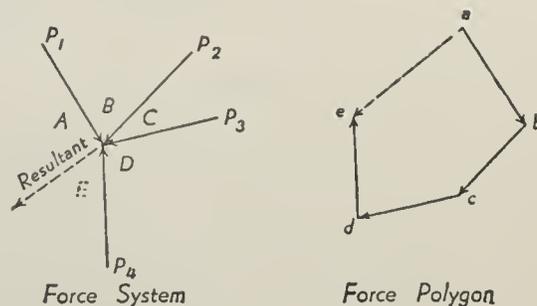

BOUNDED. A function $f(z)$ is said to be bounded if there exists a constant M such that $|f(z)| < M$ for all z in the domain of definition of f . A sequence of numbers a_1, a_2, \dots is bounded if $|a_n| < M$ for all n . A set of points is bounded if their distances from any one of them is bounded. (See also **variation**, **bounded**.)

BOUND PARTICLE. A particle surrounded by a potential barrier, and having insufficient kinetic energy to pass over the top of the barrier. In quantum mechanics, a particle which is classically bound may penetrate through a barrier. (See **penetration probability**.)

BOUSSINESQ PROBLEM. See **problem of Boussinesq and Cerruti**.

BOW NOTATION. Bow's notation is a standard method of representing, by letters of the alphabet, forces and stresses in graph-

ical analysis. This analysis may consist of such problems as the graphical solution of stresses in simple framed structures or the determination of the **resultant** of an independent system of unbalanced forces lying in the same plane and having a common point of application. The accompanying figure illustrates the method of applying Bow's nota-

tion to the latter system. Let P_1, P_2, P_3 and P_4 be a system of unbalanced forces lying in the same plane and having a common point of application. Denote the space between the line of action of each force by the letters A, B, C and D . Next construct a figure called a force polygon. This is accomplished by drawing a line parallel to P_1 and laying off its magnitude to a definite scale denoting the ends of the line by the letters a and b . From point b lay off bc equal in magnitude and parallel to P_2 . Repeat the operation for the other forces. Upon completion of this graphical figure it will be found, in general, that the line representing P_4 will not pass through point a . The distance from point a to end of this line, which will be lettered e , represents the value of the resultant of P_1, P_2, P_3 and P_4 according to the scale used. The direction of ae determines the line of action of the resultant. Thus, in Bow's notation a force in space is designated by the space letters on either side of it, whereas the forces as part of the force polygon are named by the letters at their extremities. This notation is further illustrated in the accompanying figure.

BOYLE-CHARLES LAW. The **Boyle law** expresses the variation of pressure and volume of a body of ideal gas at constant temperature; the **Charles law** expresses the proportionality of pressure to absolute temperature (at constant volume), while the **Gay-Lussac law** states the proportionality of volume to absolute temperature (at constant pressure).

A single statement covering all these relationships is the Boyle-Charles law, which leads

to, or is a form of, the ideal gas law. Its mathematical expression may be written:

$$pv = p_0v_0(1 + at),$$

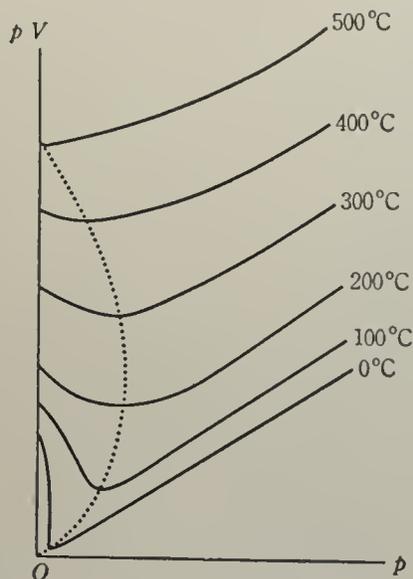

in which p_0v_0 is the value of pv at temperature $t = 0$, and a is the volume coefficient of expansion for the gas in question. If the centigrade scale is used, a is for all gases approximately equal to $\frac{1}{273}$ or 0.003663 per centigrade degree.

BOYLE CURVE. See Boyle temperature.

BOYLE LAW. (Mariotte law, law of Boyle-Mariotte.) At constant temperature the volume of a gas varies inversely as the pressure, and the pressure varies inversely as the volume. In other words, the product of the pressure and volume of a gas is constant at a given temperature. This law holds only for the ideal or **perfect gas**; all real gases depart from it to a greater or lesser extent.

BOYLE-MARIOTTE, LAW OF. See Boyle law.

BOYLE TEMPERATURE. The temperature, different for each gas, at which the **perfect gas** law is obeyed for a wide range of pressures from zero upwards. The figure represents an **Amagat diagram** for carbon dioxide. It is seen

Amagat diagram for carbon dioxide. The Boyle curve is the dotted line, while the Boyle temperature is the intersection of that line with the pV -axis.

that the isotherms in the gaseous phase pass through flat horizontal minima. If carbon dioxide obeyed the perfect gas law $pV = RT$, its isotherms would be straight horizontal lines.

The real gas behaves most nearly like a perfect gas in the neighborhood of the above minima. Their locus, shown by a dotted line, is called the *Boyle curve*. The isotherm (500°C for carbon dioxide) which corresponds to the intersection of the Boyle curve with the axis $p = 0$, possesses a large range of pressures from zero upwards in which the gas behaves very nearly like a perfect one. Hence the temperature which corresponds to the isotherm passing through the intersection of the Boyle curve with the axis $p = 0$ is called the Boyle temperature of a gas.

For a gas obeying the van der Waals equation, the equation of the Boyle curve in reduced coordinates is the parabola

$$(p_r V_r)^2 - 9(p_r V_r) + 6p_r = 0.$$

Hence the reduced Boyle temperature corresponds to

$$p_r V_r = 9 \quad \text{or} \quad T_r = \frac{27}{8} = 3.375.$$

The table below gives Boyle temperatures for several gases:

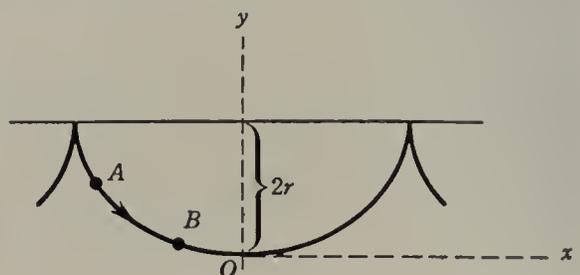

Gas	Boyle Temperature
He	-249°C
H_2	-166°C
N_2	$+51^\circ\text{C}$

If the **virial equation** is used, it is seen that the Boyle temperature corresponds to that temperature for which the second virial coefficient vanishes, or $B = 0$.

The general equation of the Boyle curve is

$$\left\{ \frac{\partial(pV)}{\partial p} \right\}_T = V + p \left(\frac{\partial V}{\partial p} \right)_T = 0.$$

BRACHISTOCHRONE (CURVE OF SHORTEST DESCENT). The curve along which a particle will fall from one point to another in the shortest time, under the in-

fluence of gravity only. (See **calculus of variations**.) In the illustration, a brachistochrone is the curve connecting two points *A* and *B* in the same vertical plane such that a mass sliding frictionless under the sole influence of gravitation will reach *B* in the shortest possible time after leaving *A*. The curve is a cycloid. Its equation is

$$x = r(\theta + \sin \theta)$$

$$y = r(1 - \cos \theta).$$

(See also **tautochrone** and **Huygen's pendulum**.) The line of descent is

$$t = \sqrt{\frac{r}{g}} \Delta\theta.$$

BRACKETT SERIES. Line series in the spectra of the hydrogen and the hydrogen-like ions He^+ , Li^{++} , etc. The wave numbers

$$\nu_n = \frac{1}{\lambda_n}$$

are given by the formula

$$\nu_n = RZ^2 \left[\frac{1}{4^2} - \frac{1}{n^2} \right], \quad (n = 5, 6, \dots),$$

where *R* stands for the **Rydberg constant** and *Z* for the **atomic number**.

BRAGG LAW. The law expressing the condition under which a crystal will reflect a beam of x-rays with maximum distinctness, at the same time giving the angle at which the reflection takes place. This law is also valid for the reflection of de Broglie waves associated with electrons, protons, neutrons, etc. For x-ray reflection it is customary to use the complement of the angle of incidence and reflection, that is, the angle which the incident or the reflected beam makes with the crystal planes, rather than with the normal. Let this "Bragg angle" be θ . If the planes or layers of atoms are spaced at a distance *d* apart, and if λ is the wavelength of the x-rays, Bragg's law is expressed by the equation

$$\sin \theta = \frac{n\lambda}{2d}.$$

The condition for an intensity maximum is that *n* must be a whole number. For example if the planes of rock salt parallel to the natural cubical

faces are spaced at $d = 2.814 \times 10^{-8}$ cm or 2814 x-units, and if the incident rays have a component of wavelength $\lambda = 714$ x-units, the above equation gives $\sin \theta = 0.1269n$. Then if the crystal is rotated slowly, there will be a distinct reflection when θ reaches $7^\circ 17'$ ($n = 1$), again at $14^\circ 42'$ ($n = 2$), also at $22^\circ 23'$ ($n = 3$), etc.

BRAGG RULE. An empirical relationship whereby the mass **stopping power** of an element for α -particles is inversely proportional to the one-half power of the atomic weight. This relationship is also stated in the form that the atomic stopping power is directly proportional to the one-half power of the atomic weight. The wide usefulness of the Bragg rule is due to the fact that it leads to relations between the stopping powers of different elements for α -particles. It also applies to other heavy charged particles as well as α -particles, and to the same degree of approximation.

BRAKE HORSEPOWER. The power output measured at the driving shaft of an engine. In the case of a prime mover it represents the net power delivered.

BRAKE MEAN EFFECTIVE PRESSURE. The ratio of the (indicated) **mean effective pressure** *P* to the mechanical efficiency η_m :

$$P_b = \frac{P}{\eta_m}.$$

Hence the **brake horsepower** of a reciprocating engine is given by

$$\text{IP}_b = \frac{P_b n V_s}{k}.$$

(For explanation of symbols see **mean effective pressure**.)

BRAKE THERMAL EFFICIENCY. (Also known as overall efficiency.) Ratio of brake horsepower of a prime mover to the energy supplied in producing it. The energy is usually supplied in the fuel, and in each particular case it is necessary to specify whether the brake thermal efficiency is based on its higher or lower calorific value. Standards of different countries differ on this point. The specific fuel consumption or the specific steam consumption are, in effect, reciprocals of the brake thermal efficiency.

BRANCH. (1) See **branch point**. (2) In topology, an **element** of a **tree**.

BRANCH CUT. See **branch point**.

BRANCHING FRACTION. In a radio-nuclide undergoing disintegration by more than one mode, the ratio of the number of atoms disintegrating by a particular mode to the total number of atoms disintegrating (per unit time), is the branching fraction for the particular mode of disintegration.

BRANCH POINT. If $f(z)$ is a multivalued function of the complex variable z and there exists a single-valued analytic function $g(z)$ such that at each z for which $f(z)$ is defined, the value of $g(z)$ coincides with one of the values of $f(z)$, then $g(z)$ is called a *branch* of $f(z)$. A curve in the domain of definition of $f(z)$ such that, if the points on this curve are removed, the remainder of the domain of definition is an open set for which there exists a branch of $f(z)$, is called a *branch cut*. A point at which a branch cut originates is called a branch point. Thus, if $f(z) = z^{1/2}$, the negative real axis, including the origin, is an example of a branch cut, while the origin itself is a branch point. (See also **Riemann surface**.)

BRAVAIS-MILLER INDICES. A modification of the **Miller indices** suitable for describing hexagonal crystals. In this system, three axes are taken, perpendicular to the **hexagonal axis** and at angles of 120° to one another. The symbols then consist of the reciprocal intercepts on these axes, followed by the reciprocal intercept on the hexagonal axis, all reduced to integers, e.g., (0001). The first three indices are not independent but must add to zero.

BRAVAIS POINTS. In **Gaussian optics**, the self-conjugate points of an optical system. A system thus has either zero, one, or two Bravais points.

BRA VECTOR. A vector in **Hilbert space**, contragradient to a **ket vector**, denoted by the symbol $\langle B|$. The scalar product of a bra and ket vector forms a scalar, the **Dirac bracket** expression $\langle B|A\rangle$. On the other hand, $|A\rangle\langle B|$ is an operator.

BRAYTON CYCLE. See **Joule cycle**.

BREAK-FREQUENCY. See **frequency response representation**.

BRETT FORMULAS. In the analysis of the torsion of thin-walled closed sections, it may be assumed that the shear stress is uniform across the thickness of the tube wall. Brett formula is a name given to a specific result obtained, as for example,

$$\tau = T/2At$$

where τ is the shear stress, T , the twisting moment and A , the area enclosed by the midline of the closed tube of local thickness t . (See **Batho's formula**.)

BREEDING GAIN. In nuclear reactor theory, the **breeding ratio** minus one.

BREEDING RATIO. In nuclear reactor theory, the number of fissionable nuclei produced, via neutron capture, per fissionable nucleus destroyed.

BREIT-WIGNER FORMULA. A formula relating the cross section σ of a particular nuclear reaction to the energy E of the incident particle, when E lies close to the energy E_0 required to form a discrete resonance level of the compound nucleus. If the spin of the incident particle is i and of the target nucleus I , and if J is the spin of the compound state, then the cross section for a reaction in which particle a is absorbed and particle b emitted is given by

$$\sigma_{(a,b)} = \frac{(2J + 1)\pi\lambda^2}{(2i + 1)(2I + 1)} \frac{\Gamma_a\Gamma_b}{(E - E_0)^2 + \frac{1}{4}\Gamma^2}$$

Here Γ_a/Γ is the probability that the compound state, once formed, will disintegrate by the re-emission of the incident particle without loss of energy, while Γ_b/Γ is the probability that particle b will be emitted from the compound state; Γ is the width of the level; and $2\pi\lambda$ is the de Broglie wavelength of the incident particle. In the case of the radiative capture of slow neutrons, for example, Γ_n is proportional to the incident neutron velocity, while Γ_γ is approximately independent of neutron energy, but much larger than Γ_n . If there is no competing process other than elastic scattering of the neutrons, we then have $\Gamma = \Gamma_n + \Gamma_\gamma \approx \Gamma_\gamma = \text{constant}$. The term λ^2 is inversely proportional to the square of the incident neutron velocity, hence $\sigma(n,\gamma) \propto E^{-1/2}/\{(E - E_0)^2 + \frac{1}{4}\Gamma^2\}$ approximately. The energy dependence is in general more complicated than this, but the main effect in the immediate neighborhood

of the resonance is produced by the Lorentz denominator.

BREWSTER ANGLE. The Brewster angle or polarizing angle (see **polarized light**) of a dielectric is that angle of incidence i for which a wave polarized parallel to the plane of incidence is wholly transmitted (no reflection). Thus $\tan i = n/n'$ where n and n' are the indices of refraction in the media before and after refraction. An unpolarized wave of intensity I_0 incident at this angle is resolved into a transmitted partly polarized component and a reflected component of intensity I which is now 100% polarized with its electric vector perpendicular to the plane of incidence and where

$$I = \frac{1}{2}I_0 \sin^2 (i - r) = \frac{1}{2}I_0 \left(\frac{n'^2 - n^2}{n'^2 + n^2} \right)^2.$$

If, on the other hand, the incident light were already 100% polarized at Brewster's angle,

$$I = I_0 \left(\frac{n'^2 - n^2}{n'^2 + n^2} \right)^2.$$

(See **Brewster law**.)

BREWSTER LAW. A simple relationship, for any dielectric reflector, between the polarizing angle (see **polarized light**) for the reflected light of a particular wavelength and the relative index of refraction of the substance for the same wavelength. The relationship is that the tangent of the polarizing angle is equal to the relative refractive index.

BRIGGS LOGARITHMS. See **logarithm**.

BRILLOUIN EFFECT. Upon the scattering of monochromatic radiation by certain liquids, a doublet is produced, in which the frequency of each of the two lines differs from the frequency of the original line by the same amount, one line having a higher frequency, and the other a lower frequency.

BRILLOUIN FUNCTION. In the quantum theory of paramagnetism, a quantum-mechanical analog of the Langevin equation (see **Weiss theory; Langevin function**) was developed by Brillouin, with the following result:

$$\frac{I_s}{I_0} = \frac{2J + 1}{2J} \operatorname{ctnh} \frac{(2J + 1)a}{2J} - \frac{1}{2J} \operatorname{ctnh} a/2J$$

where $a = Jg\beta(H + NI_s)/kT$, β is the Bohr magneton, $eh/4\pi mc$, J is the momentum quantum number, and

$$g = \frac{2mc}{e} = \frac{\text{magnetic moment}}{\text{angular momentum}};$$

(g is 1 for orbital motion alone; 2, when the moment is due entirely to spin).

BRILLOUIN ZONE. An electron moving within an ionic crystal moves in a potential field which may be approximated to as that of a constant potential within the crystal (as in the elementary Drude-Lorentz theory), modified by a varying potential which varies as the periodicity of the lattice. The allowed solutions of the wave equation for such a system are those for which the energy lies in a series of bands, the wave vector \mathbf{k} of the electron being imaginary at other values. The values of \mathbf{k} at which discontinuities occur lie at the surfaces of polyhedra in \mathbf{k} -space called Brillouin zones. The Brillouin zones may be calculated for a given lattice structure.

BRITISH THERMAL UNIT (ABBREVIATED B.T.H.U. OR BTU). The unit of heat in the English system of units. Originally defined as $\frac{1}{150}$ part of the quantity of heat required to raise 1 lbm of water from its freezing point to its boiling point at a pressure of one atmosphere. Nowadays the unit is defined by the equation

$$1 \text{ kcal}_{\text{IT}}/\text{kg} = 1.8 \text{ Btu}/\text{lb}$$

exactly. Here 1 kcal_{IT} denotes the international steam tables kilocalorie. (See **thermal units**.)

$$\begin{aligned} 1 \text{ BTU} &= 1055.056 \text{ J} = 1075.857 \text{ kpm} \\ &= 0.252074 \text{ kcal}_{15^\circ} = 0.251996 \text{ kcal}_{\text{IT}} \\ &= 2.93071 \times 10^{-4} \text{ kw.hr}_{\text{int}}. \end{aligned}$$

BRITTLE FRACTURE. Some structural materials at normal operating temperature fail in a brittle manner. Cast iron, unreinforced concrete, glass and some plastics are common examples. Far more troublesome is the brittle fracture of metals, especially structural steel, which normally exhibit great ductility. For each type of test for brittle behavior (notched bar impact, notched bar tension or slow bend, etc.), there is a transition temperature or range below which the material behaves in a brittle

manner and above which failure is truly ductile. Evidence is accumulating that the prior strain history of the material is of great importance in the effective exhaustion of ductility.

BROADENING OF SPECTRAL LINES. A spectral line emitted by an atomic or nuclear system does not consist of a single frequency, but rather of a continuous group of frequencies, which may be very narrow in its extent. The inherent width of a line is known as its **natural width**. A spectral line may be additionally broadened by **Doppler broadening** and by collision, or **pressure broadening**. In the latter case, the lifetime τ of an excited state may be reduced during a collision, which in turn increases the energy level width, Γ , of the excited state through the relation, $\Gamma = \hbar/\tau$. Since the change in energy ΔE in the transition and the frequency of emitted radiation are related by $\Delta E = h\nu$, any broadening of the energy change results in a broadening of the frequency spectrum.

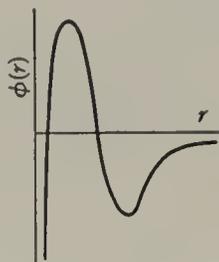

BRØNSTED AND LEWIS TREATMENT OF ACIDS. See acids and bases, definitions of Brønsted and Lewis.

BROUWER FIXED POINT THEOREM. The theorem that any continuous transformation of a circle (circumference and interior) into itself must have at least one fixed point. The analogue in **Hilbert space** is often useful for proving the existence of a solution of a differential problem. There are numerous generalizations.

BUCKINGHAM POTENTIAL. The intermolecular potential

$$\phi(r) = b \exp[-ar] - cr^{-6} - dr^{-8} \quad (1)$$

has an exponential repulsive part and an attractive part which is the sum of two power laws. It contains four parameters a , b , c , d . The choice of the exponents -6 and -8 in

Buckingham potential.

the attractive part is made for theoretical reasons (see **intermolecular forces**); the exponential form of the repulsive part is somewhat arbitrary. This potential becomes unrealistic for very small distances (see figure).

BUCKLING. (1) The abrupt change from one equilibrium geometric configuration to a neighboring or a distant configuration. The simplest example is provided by a perfectly straight column under perfectly axial compression. As the axial load increases the straight configuration is always permissible from the point of view of equilibrium. Above the **Euler buckling load** for an elastic column or the **tangent modulus load** for an elastic-plastic one, a bent configuration also is permissible. The actual behavior depends upon the unavoidable initial imperfections of geometry or loading. In practice, therefore, if a neighboring buckled configuration exists the structure will buckle. If a distant one exists, as in many problems of shells and most problems of buckling in the plastic range, the eigenvalue problem associated with the buckling of perfect structures may have little practical relevance. It is necessary to follow the detailed history of the deflection and stress in an initially imperfect structure as the load is increased from zero. (2) In nuclear reactor theory, the distribution of thermal neutron flux far from boundaries and sources is assumed to satisfy the equation

$$(\nabla^2 + B^2)\Phi(\mathbf{r}) = 0.$$

B^2 , the buckling, when expressed in terms of material properties is an intensive quantity, called the *material buckling*. When the differential equation is assumed to hold throughout an unreflected system (see **first fundamental theorem**) and to describe a critical chain reaction, the lowest **eigenvalue**, B^2 , dictated now by the shape of the system, is called the *geometrical buckling*.

BUCKLING, IMPACT. At high rates of loading, mass acceleration terms become important and higher transient axial loads can be carried than the axial loads which would cause static **buckling**.

BUCKLING LAG. The difference in load carrying capacity between a buckled sheet and a fully effective sheet may be described as due to buckling lag.

BUCKLING, LATERAL. See lateral buckling.

BUCKLING, LOCAL. The load carrying capacity of a structure is often limited by local buckling or crippling. A column or frame may have sufficient strength if it acts as a unit but the flange or some other structural element may buckle over a short length, precipitating collapse of the entire structure.

BUCKLING, TORSIONAL OR TWIST. A column of open or profile section is relatively flexible and weak in torsion. If buckling about the weak axis is prevented, the column will tend to fail by twisting or torsional buckling. The lateral buckling of beams is an allied phenomenon.

BUDAN THEOREM. Given any polynomial $P(x)$ in the single variable x , let P and its derivatives be evaluated at $x = r$, for any r . Ignoring vanishing derivatives, let V_r represent the number of variations in sign in the sequence P, P', P'', \dots . Then the number of roots of $P(x) = 0$ exceeding r is $V_r + 2r$, where r is an integer ≥ 0 . **Descartes's rule of signs** is a particular case with $r = 0$, where V_0 is the same as the variations in sign in the coefficients. Any r for which $V_r = 0$, all $P^{(i)}$ having the same sign, is an upper bound for the roots of $P(x) = 0$. In case $V_r - V_s = 1$, there must be exactly one root on the interval from r to s . All roots are counted according to multiplicity, e.g., a double root is counted twice.

BUILDING-UP PRINCIPLE. The method of deriving the different electronic terms of an atom or molecule by the hypothetical bringing together of their components. In the case of an atom this means successive addition to the nucleus of electrons in quantum states permitted by the **Pauli principle**. In the case of a molecule there are various alternatives. One is a procedure analogous to that used in the case of an atom, that is, successive addition of electrons to the nuclei with fixed internuclear distances, corresponding to those in the completed molecule. Another is the bringing together of the whole component atoms, a third the drawing apart of the component atoms from an assumed position of zero separation ("splitting the united atom").

BUILD-UP FACTOR. In the study of the penetration of radiation through matter, the

point kernel (see **kernel, point**) representing the flux at one point due to unit source at another, will deviate from the first-flight or transport kernel, $(4\pi R^2)^{-1} \exp(-\Sigma R)$. The deviation, due to multiple scattering, is expressed by multiplying the transport kernel (see **kernel, transport**) by the factor $B(R)$, called the build-up factor.

BULK COMPLIANCE. See **compliance, bulk**.

BULK MODULUS (MODULUS OF VOLUME ELASTICITY). The isothermal or isentropic bulk moduli are reciprocals of the isothermal or isentropic **coefficients of compressibility**. Hence

$$B_T = -V \left(\frac{\partial p}{\partial V} \right)_T$$

$$B_S = -V \left(\frac{\partial p}{\partial V} \right)_S$$

In older publications the isentropic bulk modulus is called the adiabatic bulk modulus.

BULK TEMPERATURE. In heat transfer, the temperature of the bulk of the fluid. More precisely, in internal flow, the weighted mean temperature of the fluid in a cross section; in external flow, the temperature of the fluid at a large distance from the body, or the so-called free-stream temperature.

BURGER-DORGELO-ORNSTEIN SUM RULE FOR ATOMIC SPECTRA. See **multiplet intensity rules**.

BURGERS MATERIAL. Material represented by four-element model. (See **viscoelastic models**.)

BURGERS VECTOR. A vector which defines the direction and magnitude of the slip produced by a **dislocation**.

BURNETT EQUATIONS. The Enskog-Chapman method for the solution of the Boltzmann equation presents the distribution function as a series of successive approximations (see **Enskog series**). The first order approximation leads to the **Navier Stokes equations** of hydrodynamics, in which the **flux vectors** are linear functions of the first order in the gradients of the macroscopic quantities (density, velocity, temperature). It is only valid when these gradients are small.

The second approximation leads to the

Burnett equations, where the flux vectors then depend on the *second derivative* of these macroscopic quantities, and on the *square of the gradients*. There is some doubt as to the rapidity of the convergence of the Enskog series, and attempts to apply the Burnett equations to such phenomena as shock waves and the transmission of sound waves in rarefied gases have led to disappointing results.

BURNING RATE. For solid propellant fuels, the rate of burning (r) is the linear measure (normal to the burning surface) of the propellant grain which is consumed in unit time, usually expressed in inches per second.

BURNING RATE, EROSIVE. The increase in burning rate over normal conditions, which is incident to the sweep of hot gases over a burning propellant surface.

BURNING RATE, LINEAR. The rate at which a solid propellant burns normal to its surface under design combustion chamber pressure. The burning rate is in accordance with the Muraour relationship. It is given by the equation:

$$r_0 = a_2 p_c^n = \frac{dw/dt}{A_p \gamma_p},$$

where r_0 is the linear burning rate, a_2 is an experimental constant, p_c is the chamber pressure, n is a variable exponent, dw/dt is the rate of flow of propellant by weight, A_p is the burning surface and γ_p is the specific weight of propellant.

BURNT CASES. Gases resulting from the combustion of a fuel with air in an internal combustion engine or other appliance (e.g., a boiler). The composition of the burnt gases is determined by the fuel composition, the air

ratio, and the completeness of the combustion process.

BUSEMANN SECOND-ORDER THEORY. A second-order theory, applicable to two-dimensional airfoils in supersonic flow. At a point on an airfoil where the surface is inclined at an angle θ to the stream, the pressure coefficient is

$$C'_p = \frac{2\theta}{\sqrt{M^2 - 1}} + \left[\frac{(M^2 - 2)^2 + \gamma M^4}{2(M^2 - 1)^2} \right] \theta^2, \quad (1)$$

where M is the Mach number of the stream. The sign of θ is the same as for the **Ackeret theory**, and if the term in θ^2 in Equation (1) is neglected the Ackeret formula is obtained.

When Equation (1) was first derived by Busemann, a term in θ^3 was also obtained, but this third-order term is affected by entropy changes in shock waves and is not included in the usual form of the theory.

In the expression for the lift coefficient of an airfoil the second-order terms cancel, so that the lift given by Equation (1) is the same as that given by the Ackeret theory. Also, for an airfoil which is symmetrical about the chord line and about the normal to the chord line through its center, the second-order terms in the expression for the drag cancel, so that again Equation (1) gives the same result as the Ackeret theory. In general, however, the second-order term in Equation (1) does affect the drag. It also affects the pitching moment, usually moving the center of pressure of a symmetrical airfoil *ahead* of the half-chord position given by the linear theory of Ackeret.

BY-PASS ENGINE. A type of **jet-propulsion** engine in which a fan driven by the gas-turbine engine provides an additional flow of air in the jet.

C

C. In **neutron scattering** and **transport theory**, the average number of neutrons appearing as the result of the collision of a neutron with an atomic nucleus.

CABLE. The word cable often implies the idealization of a tension member which has no flexural strength or rigidity.

CALCULATOR. In current usage the term is used interchangeably with **computer** as either one who or that which calculates or computes. Since the term "computer" more often designates a machine in current literature, it is suggested here that "calculator" be applied only to the human being, and "computer" only to the machine.

CALCULUS. The word comes from the Latin *calculus*, a stone or pebble used in reckoning. The unqualified word is usually taken to mean differential and integral calculus. For other kinds of calculus (e.g., calculus of **finite differences**, calculus of **variations**) see the respective headings.

CALCULUS OF VARIATIONS. See **variations**, **calculus of**.

CALCULUS, SPINOR. See **spinor calculus**.

CALENDAR EQUATION. An empirical (thermal) equation of state for steam:

$$v = 47 \frac{T}{p} + 0.001 - 0.075 \left(\frac{273}{T} \right)^{1/3}$$

where v , the specific volume, is expressed in m^3/kg , T in $^\circ\text{K}$, and p in kp/cm^2 . It is sufficiently accurate for pressures up to 20 kp/cm^2 (about 300 lb/in^2) and for temperatures below 500°C (932°F). The equation is not dimensionally correct; it is a modified form of the Clausius equation. (See also **steam tables**.)

CALLIER COEFFICIENT. The density of photographic negatives measured by parallel light is greater than if measured by diffused

light. This effect is caused by scattering. Callier defined a coefficient as

$$Q = \frac{\text{density measured by parallel light}}{\text{density measured by diffused light}}$$

The average value of Q is about 1.4 ± 0.2 .

CALORESCENCE. The transformation of infrared radiant energy into visible radiation.

CALORIC EQUATION OF STATE. Often a distinction is made between the various types of equations of state. The relation between pressure, volume and temperature, the so-called p, V, T , relation, is then called the *thermal equation of state*. Equations involving a caloric parameter, such as **enthalpy**, **internal energy**, **entropy**, etc., are then called caloric equations of state.

CALORIE. See **thermal units**.

CALORIFIC VALUE. The number of units of heat obtained by the complete combustion of a unit mass of a substance, usually a fuel. In measuring the calorific value, it is stipulated that the products of combustion are cooled to the initial temperature of the fuel, and it is necessary to specify whether combustion has taken place at constant volume or constant pressure. (See also **combustion**.)

CALORIMETRIC COEFFICIENT. One of the following six coefficients, used to express the rate of absorption of heat during reversible changes of pressure, volume, and temperature:

(1) Heat of compression at constant volume, $(\partial q/\partial p)_v$.

(2) Heat of expansion at constant pressure, $(\partial q/\partial v)_p$.

(3) Specific heat at constant volume, $(\partial q/\partial T)_v$.

(4) Specific heat at constant pressure, $(\partial q/\partial T)_p$.

(5) Latent heat of change of pressure, $(\partial q/\partial p)_T$.

(6) Latent heat of change of volume, $(\partial q/\partial v)_T$.

In these expressions, q is the quantity of heat, p , the pressure, v , the volume and T , the absolute temperature.

CANDELA. The unit of luminous intensity. The magnitude of the candela is such that the luminance of a full radiator at the temperature of solidification of platinum is 60 candelas per square centimeter. Definition adopted by the 9th General Conference on Weights and Measures (1948).

CANDELA PER SQUARE METER. A metric unit of luminance, recommended by the C.I.E.

CANDLE. A common synonym for the unit of luminous intensity, the **candela**.

CANONICAL. Of standard form, especially if the form is simple. For example, a canonical matrix of a certain kind has non-zero elements only on the main diagonal.

CANONICAL COORDINATES. The canonical coordinates of a particle are its coordinates q_i and its conjugate momenta $p_i = \frac{\partial L}{\partial \dot{q}_i}$; $\left(\dot{q}_i = \frac{dq_i}{dt}\right)$. L is the **Lagrangian** of the system. The definition of L is $L(q_i, \dot{q}_i, t) = T(q_i, \dot{q}_i, t) - V(q_i, t)$. T is the kinetic energy and V the potential energy of the system.

By means of the defining equation for p_i , the velocities \dot{q}_i can be replaced in terms of the p_i in the Lagrangian, and the Lagrangian $L^*(q_i, p_i, t)$ results.

$$L^*(q_i, p_i, t) = L(q_i, \dot{q}_i, t)$$

$$\text{i.e., } T^*(q_i, p_i, t) - V^*(q_i, t) = T(q_i, \dot{q}_i, t) - V(q_i, t)$$

$$\text{But } V^*(q_i, t) \equiv V(q_i, t)$$

Therefore

$$L^*(q_i, p_i, t) = T^*(q_i, p_i, t) - V(q_i, t)$$

$$\text{and } T^*(q_i, p_i, t) = T(q_i, \dot{q}_i, t).$$

where the dots denote the derivative with respect to time.

CANONICAL CORRELATION. Suppose there is a p -variate population with variates x_1, x_2, \dots, x_p , and a q -variate population with variates y_1, y_2, \dots, y_q , and suppose for definite-

ness that $p \geq q$. Then it is possible to find p linear combinations of the x 's, u_1, u_2, \dots, u_p and q linear combinations of the y 's, v_1, v_2, \dots, v_q all with zero mean and unit variance, such that

$$i \quad \text{cov}(u_i u_j) = 0 \quad i \neq j$$

$$ii \quad \text{cov}(v_i v_j) = 0 \quad i \neq j$$

$$iii \quad \text{cov}(u_i v_j) = 0 \quad i \neq j$$

where $\text{cov}()$ denotes **covariance**. The correlation between u_i and v_i is called a canonical correlation; at most q of these correlations are non-zero. If u and v are the linear combinations corresponding to the largest canonical correlation, then v is the linear combination of the y 's which can be predicted from the x 's by linear regression with least residual variance (the most predictable criterion), and u is the appropriate predictor.

CANONICAL ENSEMBLE. An ensemble with a density ρ given by the equation

$$\rho = e^{\beta(\psi - \epsilon)}$$

where $\beta = 1/kT$ (k , Boltzmann's constant; T , absolute temperature), ψ , a normalizing constant and ϵ , the energy of the system.

CANONICAL EQUATIONS OF MOTION. For the k th set of generalized coordinates and conjugate momenta in a conservative dynamical system, there can be written a pair of first-order partial differential equations:

$$\frac{\partial H}{\partial p_k} = \frac{dq_k}{dt}$$

$$\frac{\partial H}{\partial q_k} = -\frac{dp_k}{dt}$$

where H is the **Hamiltonian function** for the system and p_k and q_k are generalized momenta and coordinates, respectively. They are said to be *canonically conjugate variables*. These equations are called the canonical equations of motion. (See also **canonical coordinates; coordinates and momenta (generalized)**.)

CANONICAL EQUATIONS OF OPTICS. The optical paths $x = x(z)$, $y = y(z)$ in a medium of refractive index $n = n(x, y, z)$ are the solutions of the canonical equations.

$$\frac{dx}{dz} = \frac{\partial H}{\partial p}, \quad \frac{dy}{dz} = \frac{\partial H}{\partial q},$$

$$\frac{dp}{dz} = -\frac{\partial H}{\partial x}, \quad \frac{dq}{dz} = -\frac{\partial H}{\partial y},$$

where

$$H = -r = -\sqrt{n^2 - p^2 - q^2}$$

is the **Hamiltonian function** of optics and (p, q, r) is a tangent vector, to the optical path, of length n . The canonical equations are the **Euler equations** of the **canonical form of the Fermat principle**.

CANONICAL FORM OF THE FERMAT PRINCIPLE. The optical paths joining the points P_0, P_1 in a medium with refractive index $n = n(x, y, z)$ are the extremum of

$$V = \int_{P_0}^{P_1} (pdx + qdy + rdz)$$

where (p, q, r) is a tangent vector, to the optical path, of length n . The **Euler equations** of this variational problem are the **canonical equations of optics**.

CANONICAL TRANSFORMATION. A transformation from one set of generalized coordinates and momenta to a new set such that the form of the **canonical equations of motion** is preserved. This usually involves finding a transformation function S which is a continuous and differentiable function of the old and new generalized coordinates and the time. The transformation can be defined by

$$L(q, \dot{q}) = L'(Q, \dot{Q}) + \frac{dS}{dt}$$

$$S = S(q, Q, t)$$

$$p_k = \frac{\partial S}{\partial q_k}; \quad P_k = -\frac{\partial S}{\partial Q_k};$$

$$H = \bar{H} - \frac{\partial S}{\partial t}$$

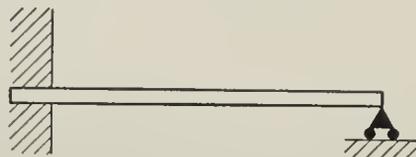

where L is the **Lagrangian function** in the original set of coordinates, and L' is the Lagrangian function in the transformed set of coordinates. H is the **Hamiltonian function** in terms of p, q, t , and \bar{H} is the Hamiltonian function in terms of P, Q, t .

CANONICAL VARIABLES. See **Lagrangian formalism**.

CANTILEVER. Pertaining to overhang or projection beyond supports. (See **beam, cantilever** and **beam, overhanging**.)

CANTILEVER BEAM. See **beam, cantilever**.

CANTILEVER, PROPPED. A beam fixed at one end and propped or simply supported at the other.

Propped cantilever.

CAPACITANCE. (1) Electrical capacitance is the ratio of the **electric charge** given a body to the resultant change of **potential**. It is usually expressed in **coulombs** of charge per volt of potential change, that is, in terms of the farad, or its submultiples; the cgs electromagnetic unit is the abfarad. If a conductor is completely isolated, that is, far removed from other conductors, including the earth, and is surrounded by a homogeneous, perfectly insulating dielectric, its capacitance depends only upon the size and shape of its external surface, and upon the **dielectric constant** of the surrounding medium. The capacitance of a circuit, whether "distributed" or intentionally introduced by means of capacitors, acts as a capacitor in parallel with the conductor, and may have marked effect upon alternating or variable currents traversing it.

(2) For acoustical capacitance, see **compliance, acoustic**.

CAPACITANCE, ACOUSTIC(AL). See **compliance, acoustic**.

CAPACITANCE, GEOMETRIC. The **capacitance** of an isolated conductor *in vacuo*. For a sphere of radius a ,

$$V = \frac{Q}{a}, \quad \text{hence } C = Q/V = a$$

where electrostatic units are used. For a hemisphere of radius a , $C = 0.845a$. For many other bodies C is approximated by $\sqrt{S/4\pi}$, where S is the surface area.

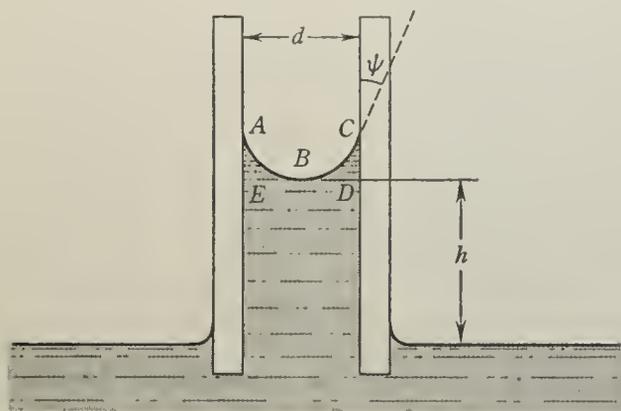

CAPACITANCE, SPECIFIC ACOUSTIC.

That coefficient which, when multiplied by 2π times the frequency, is the reciprocal negative imaginary part of the specific acoustic impedance. (See **impedance, specific acoustic**.) The dimensions of specific acoustic capacitance are cm^5/dyne .

CAPACITOR. A device whose primary purpose is to introduce **capacitance** into an electric circuit or network.

CAPACITY, CARRYING. See **carrying capacity**.

CAPILLARITY. For convenience in analyzing the phenomena of capillarity it is usual to assume that there is a **surface tension** at every surface separating a liquid from a gas,

Capillarity.

or from a solid, or from another liquid. The surface tension T is defined as the tensile force acting across any line in the surface, per unit length of line. The potential energy per unit area of surface, due to the surface tension, is also equal to T .

The surface tension of any liquid in contact with a gas *decreases* with increasing temperature. For an unassociated liquid the surface tension is zero at the critical temperature.

As a consequence of surface tension there is a difference of pressure across a curved surface, the pressure being greater on the concave side. For a spherical surface of radius R the pressure difference is $2T/R$.

It can be shown that surface tension causes a cylindrical liquid surface to become unstable when the wavelength of a disturbance imposed on it exceeds the circumference. This is one of the principal causes of the breaking-up of liquid jets into small drops.

When a liquid surface meets a solid, the angle between the surface of the liquid and

that of the solid, at any point on the line of contact, is known as the *angle of contact* of that particular liquid and solid.

If a cylindrical tube of small internal diameter, open at both ends, is held vertically with one end immersed in a liquid, surface tension will cause the liquid to rise in the tube as in the figure, provided the angle of contact for the liquid and the tube is less than 90° . If the diameter of the tube d is very small, so that the weight of liquid in the region $ABCDE$ is negligible, the height h to which the liquid rises in the tube is

$$\frac{4T \cos \psi}{\rho g d},$$

where ρ is the density of the liquid and ψ is the angle of contact at the wall of the tube. In many cases the liquid "wets" the tube, so that ψ is small and $\cos \psi = 1$. For a few cases, such as mercury in glass, ψ is greater than 90° so that h is negative.

CAPILLARY WAVES. Waves on a liquid surface in which the surface tension T provides an appreciable force. The pressure under the surface is increased by amount $T \nabla^2 \zeta$, where ∇^2 is the two-dimensional Laplacian operator and ζ is the displacement from a plane, assumed small. In such cases gravity, which produces a pressure increment $g\rho\zeta$ is, in effect, replaced by $[g + \frac{T}{\rho} \nabla^2]$.

Two-dimensional waves on deep water, of length $2\pi/k$, then have speed c given by

$$c^2 = \frac{g}{k} + \frac{Tk}{\rho}$$

which has a minimum value when $k^2 = g\rho/T$. For waves with shorter length the velocity increases as wavelength decreases, so that the group velocity exceeds the phase velocity. These particular waves are called *ripples*. On water ripples have a wavelength less than about 1–2 cm (the value depending largely on T , which varies with temperature).

CARATHÉODORY PRINCIPLE. An independent formulation of the second law of **thermodynamics**. It is best stated in two parts:

Part 1. In the neighborhood of any thermodynamic state of any system there exist states which are inaccessible from it along any *reversible adiabatic* (i.e., isentropic) path.

Part 2. In the neighborhood of any thermodynamic state of any system there exist states which are inaccessible from it as a result of any (reversible or irreversible) **adiabatic process**.

Carathéodory's principle constitutes a generalization of known experimental facts. The two parts of it are sufficient for the formulation of the second law and for derivation of its most essential corollaries. (See **thermodynamics, second law of**.)

CARATHÉODORY (MATHEMATICAL) THEOREM. A theorem which relates the property of integrability of **Pfaffian expressions** (linear differential forms) to the existence of inaccessible points.

Given a Pfaffian

$$dy = \sum X_i dx_i \quad (a)$$

where the X_i s are functions of the x_i in an n -dimensional space \mathfrak{X}_i , two neighboring points x_i, x'_i are called *accessible* if they lie on an element of a curve satisfying the Pfaffian differential equation

$$\sum X_i dx_i = 0. \quad (b)$$

Otherwise they are called *inaccessible*.

The Pfaffian Equation (a) is called integrable if a function $\lambda(x_i)$ of the x_i s exists, such that

$$dy = \lambda(x_i) d\phi(x_i) \quad (c)$$

where $\phi(x_i)$ is also a function of the n independent variables x_i . The function λ is then called an *integrating factor* of the Pfaffian.

It may be noted that: (1) a Pfaffian in two independent variables x_1, x_2 always possesses an integrating factor, but that for $n \geq 3$ this is no longer the case; (2) if one integrating factor exists, there are infinitely many, because $\lambda' = \lambda d\psi/d\phi$ is also an integrating factor if $\psi(\phi)$ is any given function of ϕ ; (3) the curves which satisfy Equation (b) in the case of an integrable Pfaffian, also satisfy the condition $\phi(x_i) = \text{const}$. Here, and above, the symbols $X_i(x_i), \phi(x_i)$, etc., denote functions of all the n variables x_i .

Carathéodory's mathematical theorem asserts that if the Pfaffian Equation (a) is integrable, then in the neighborhood of any given point $A(x_i)$, however small, there exist points which are inaccessible from it.

The converse theorem is also true. In other words, if the Pfaffian Equation (a) possesses the property that in every arbitrarily-close neighborhood of a given point $A(x_i)$ there exist

inaccessible points, then the Pfaffian is integrable.

Both theorems can be summarized in the statement that the existence of inaccessible points in the neighborhood of a given point is both necessary and sufficient for the integrability of a Pfaffian expression.

The converse theorem plays an important part in Carathéodory's formulation of the second law of **thermodynamics**.

CARATHÉODORY THEOREM (IN OPTICS). Two surface elements can be imaged by a continuous manifold of rays tangential to both elements only if the optical magnitudes of the elements are equal, i.e., $|ndS| = |n'dS'|$.

CARDINAL NUMBER. It is difficult to give a satisfactory definition of a cardinal number, but this difficulty is not of great importance, since it is clear under what condition two sets contain the same cardinal number of objects, namely that they can be put into one-to-one correspondence with each other. This cardinal number is called the *power* of the set. An **infinite set** that can be put into one-to-one correspondence with the set of positive integers is said to be countable (or denumerable, or enumerable). A cardinal number which is not finite is called transfinite.

CARDINAL POINTS OF AN OPTICAL SYSTEM. The **focal points**, the **principal points** and the **nodal points** constitute the cardinal points of an optical system.

CARDINAL STIMULI. Four standard stimuli by means of which the three **reference stimuli** and the basic stimulus of any **trichromatic system** may be defined. Light of wavelengths 700, 546.1 and 435.8 millimicrons and illuminant B have been adopted by the C.I.E.

CARLSON METHOD. See S_N method in neutron transport theory.

CARNOT CYCLE. The hypothetical cycle in the diagram of Figure 1. The cycle consists of the following *reversible* processes: 1–2, iso-

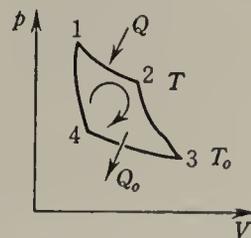

Fig. 1. Carnot cycle— p, V diagram.

thermal expansion during which a quantity of heat Q is transferred to the working fluid; 2-3, isentropic expansion; 3-4, isothermal compression during which a quantity of heat Q_o is rejected by the working fluid; 4-1, isentropic compression to the initial state 1. If the working fluid is a perfect gas, then

$$V_1V_3 = V_2V_4. \quad (a)$$

The efficiency of a Carnot cycle

$$\eta = \frac{\oint dW}{Q} = \frac{Q - |Q_o|}{Q} = \frac{T - T_o}{T}. \quad (b)$$

Also

$$\frac{Q}{T} = \frac{|Q_o|}{T_o}$$

so that

$$\frac{Q}{T} + \frac{Q_o}{T_o} = 0.$$

(Here Q_o is negative according to the sign convention: see **heat**.)

The efficiency of a Carnot cycle is independent of the physical properties of the working fluid, and, as shown by Equation (b), is a function of the two thermodynamic temperatures T and T_o only. If the two constant temperatures T and T_o are not measured on the thermodynamic temperature scale, but on an arbitrary empirical temperature scale, so that

T corresponds to θ and

T_o corresponds to θ_o ,

we have

$$\eta = 1 - \frac{f(\theta)}{f(\theta_o)} \quad (c)$$

where $f(\theta)$ is a universal function depending only on the properties of the empirical temperature scale. Its representation, Figure 2, in a

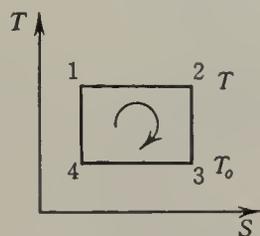

Fig. 2. Carnot cycle— T,S diagram.

T,S diagram is particularly simple. Since a reversible Carnot cycle has the highest efficiency of all cycles, reversible or irreversible, operating between a highest temperature T and a lowest temperature T_o , it can be used as a

standard of comparison for real cycles. It also represents the ideal arrangement for the conversion of heat into work.

The properties of Carnot cycles can be used for an elementary mathematical formulation of the second law of **thermodynamics** and the concept of **entropy**.

The forward Carnot cycle (as discussed above), can, in principle, be used for the production of power (conversion of heat into work). When the cycle is operated in *reverse*, it can be used in principle as a refrigerator or heat pump. When the temperature, T , is equal to that of an available cooling source (atmosphere), the cycle rejects heat Q to it and absorbs heat Q_o at a lower temperature T_o . It can thus serve as a *refrigerator* maintaining the temperature of a body at $T_o < T$ by removing a heat leak Q_o into it at the expense of the work,

$$W = Q - |Q_o|.$$

When the temperature T_o is equal to that of an available source (surrounding atmosphere), the cycle can extract heat Q_o from it and maintain a body at a temperature $T > T_o$ by supplying heat Q to it to cover its heat leaks at the expense of work W (*heat pump*). In either case, the Carnot cycle represents the minimum amount of work W required for the purpose under given conditions (determined by T and T_o).

The performance of a refrigerator is expressed by the coefficient of performance

$$e = \frac{|Q_o|}{W} = \frac{|Q_o|}{|Q| - |Q_o|} = \frac{T_o}{T - T_o}$$

and the quantity of heat $|Q_o|$ extracted from the cooling chamber is called the *refrigerating effect*.

There exists no agreed coefficient to express the operation of a heat pump, but the ratio

$$\frac{Q}{W} = \frac{T}{T - T_o}$$

can serve the purpose.

It should be noted that the efficiency of the forward cycle is highest when T is as high as possible. Since, in practice, T_o will always be fixed by the temperature of the surrounding atmosphere, a high efficiency corresponds to a large difference $T - T_o$. In contrast, a high coefficient of performance, or a high effectiveness of a heat pump corresponds to a small difference $T - T_o$.

It would appear that decreasing T_o for a

power cycle below that of the surrounding atmosphere is advantageous in that the efficiency η is increased. However, it must be realized that this can only be achieved at the expense of work in operating a refrigerator, and no advantage is gained.

CARNOTIZATION. A process of feed-water heating by bleeding steam in a steam plant, usually steam-turbine plant, in order to increase its thermal efficiency. Since the ideal limit of efficiency is that of a **Carnot cycle**, the process of increasing the efficiency of the cycle is called "carnotization."

The plant is drawn schematically in Figure 1. The feed-water from the condenser is supplied by the feed pump, and pre-heated in the 3 feedwater heaters with the aid of steam from the multi-stage turbine. The condensate passes through throttling valves from each pre-heater to the next one with a lower pressure and partly evaporates, the steam being utilized for pre-heating in the next stage. From the last pre-heater the condensate passes through the counter-flow heat exchanger in which it transfers its sensible heat, and finally reaches the inlet duct of the feed pump through the throttling valve.

The process is illustrated in the T,S diagram of Figure 2. There it has been assumed that steam at three different pressures is bled from the plant and is used to heat the feed-water in stages. The quantity of steam bled from the turbine is so adjusted that, for example at pressure p_3 , its heat of condensation (the rectangle bounded by the line cd , the abscissas

from c and d to the S -axis and the S -axis itself) is equal to the sensible heat of the feed water between the temperatures corresponding to pressures p_3 and p_2 (the figure bounded by the line ab , the abscissas from a and b to the

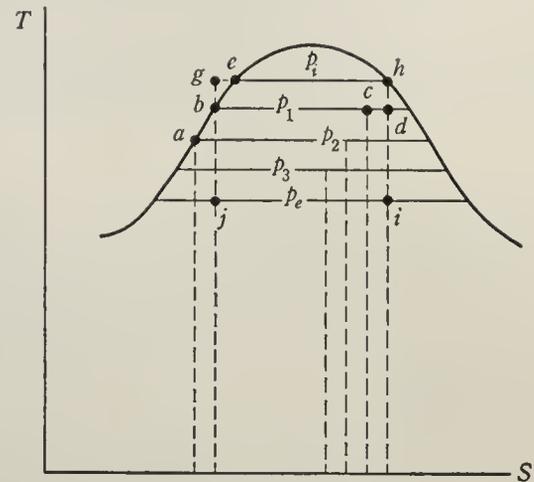

Fig. 2. T,S diagram of Carnotization process.

S -axis and the S -axis itself). By relating similarly the heat of condensation of the steam for the other pressure intervals to the sensible heat of the feed water for the corresponding temperature differences, and summing heats of condensation and sensible heat, it is found that the ideal work of the modified cycle differs from that of an equivalent Carnot cycle $ghij$ only by the small triangle geb ; hence the efficiency is almost equal to that of a Carnot cycle. As the number of stages is increased, the approximation to a Carnot cycle becomes closer. The above cycle is also known as the regenerative (steam) cycle, and it is said that

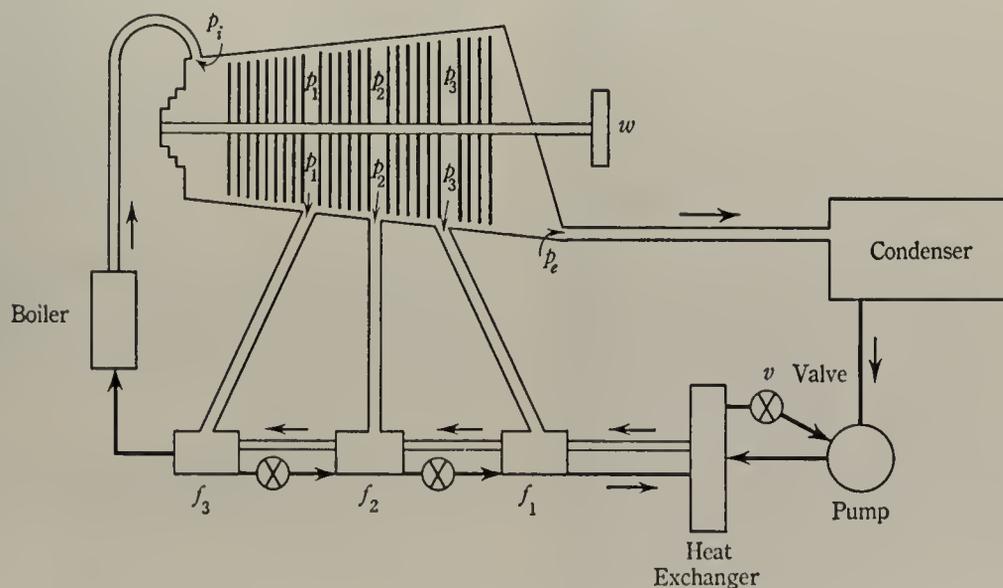

Fig. 1. Steam power plant with interstage bleeding, illustrating Carnotization. (Certain auxiliary equipment, e.g., superheater, economizer, etc., not shown.)

heat is being "regenerated" in the heat exchangers.

CARNOT THEOREM. The most essential corollary of the second law of **thermodynamics**. It can be stated in the following way: For any system there exist two properties, its thermodynamic temperature T and its entropy S such that in any infinitesimal reversible process, the quantity of heat exchanged is given by

$$dQ = TdS.$$

Furthermore, the thermodynamic temperature T is a positive function of the empirical temperature θ measured on an arbitrary empirical temperature scale. The Carnot theorem is a direct consequence of Part 1 of the **Carathéodory principle**.

Some authors prefer to reserve the designation of Carnot's theorem to the following corollary of the second law of thermodynamics: No engine operating between two reservoirs of fixed temperatures T and T_o ($T > T_o$) can have a higher efficiency η than that of a reversible Carnot cycle operating between the same sources, thus,

$$\eta < \eta_c$$

$$\text{where } \eta_c = 1 - \frac{T_o}{T}.$$

CARRIER DENSITY. In thermal equilibrium, the density, n , of electrons, and p , of holes in a non-degenerate semiconductor are related by the equation

$$np = N_c N_v \exp(-E_G/kT)$$

where E_G is the width of the **energy gap** between the **valence band** and the **conduction band**, and N_v , N_c are the effective densities of states in these bands, i.e.,

$$N_c = N_v = 2(2\pi mkT/h^2)^{3/2}.$$

CARRIER EQUATION. See **adiabatic saturation**.

CARRY. (1) A signal, or expression, produced as a result of an arithmetic operation on one digit place of two or more numbers expressed in positional notation and transferred to the next higher place for processing there. (2) Usually a signal or expression as defined in (1) above which arises in adding, when the sum of two digits in the same digit place equals or exceeds the base of the number system in use. If a carry into a digit place will result

in a carry out of the same digit place, and if the normal adding circuit is bypassed when generating this new carry, it is called a *high-speed carry*, or *standing-on-nines carry*. If the normal adding circuit is used in such a case, the carry is called a *cascaded carry*. If a carry resulting from the addition of carries is not allowed to propagate (e.g., when forming the partial product in one step of a multiplication process), the process is called a *partial carry*. If it is allowed to propagate, the process is called a *complete carry*. If a carry generated in the most significant digit place is sent directly to the least significant place (e.g., when adding two negative numbers using nines complements) that carry is called an *end-around carry*. (3) In direct subtraction, a signal or expression as defined in (1) above which arises when the difference between the digits is less than zero. Such a carry is frequently called a *borrow*. (4) The action of forwarding a carry. (5) The command directing a carry to be forwarded.

CARRYING CAPACITY (LOAD). The load-carrying capacity of a structure is the maximum load which can be applied prior to complete collapse or is the maximum load which can be applied without causing clearly excessive deflection or danger of **brittle fracture**. (See **limit load**.)

CARRYOVER FACTOR. When elastic continuous (rigid) frames are analyzed by the **moment distribution** technique, moments are balanced or distributed at each joint and part of the distributed moments are carried over to neighboring joints. The fraction carried over is called the carryover factor. When individual beams and columns are of uniform cross section the carryover factor is one half. No moment is carried over to a hinged end, however.

CARRY, SELF-INSTRUCTED. A system of executing the **carry** process in which **information** is allowed to propagate to succeeding places as it is generated and without receipt of a specific signal.

CARRY, SEPARATELY-INSTRUCTED. A system of executing the **carry** process in which **carry information** is allowed to propagate to succeeding places only on receipt of a specific signal.

CARTESIAN COORDINATES. See *coordinate*.

CARTESIAN OVAL. See *Cartesian surfaces*.

CARTESIAN SURFACES. The aplanatic surfaces of revolution are the Cartesian surfaces generated by revolving the *Cartesian oval*

$$n_0 \sqrt{x^2 + y^2} \pm n_1 \sqrt{(x - a)^2 + y^2} = c$$

about the x -axis. The Cartesian oval is a fourth degree algebraic curve. In certain cases, when the surface is aplanatic under reflection, or in the case of refraction if one of the conjugate points is at infinity, then the Cartesian oval degenerates to a conic section. When both conjugate points are at infinity, the Cartesian oval degenerates to a line.

Descartes' investigation of the aplanatic properties of the conics is evidence that he anticipated Snell's discovery of the laws of refraction.

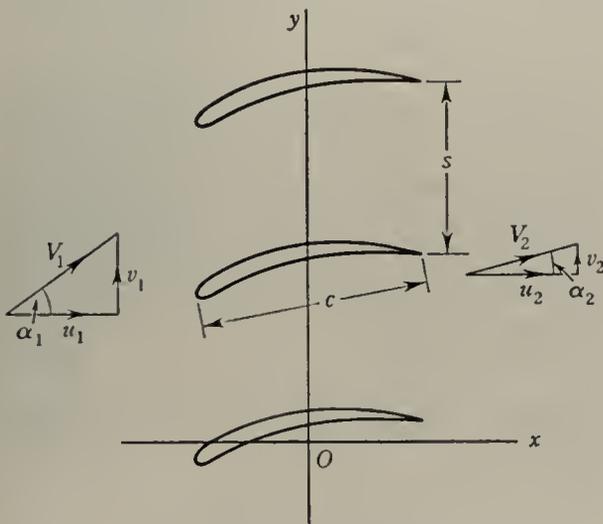

CARTESIAN TENSOR. See *tensor field, Cartesian*.

CARTESIAN TENSOR FIELD. See *tensor field, Cartesian*.

CARTESIAN VECTOR FIELD. See *vector field, Cartesian*.

CASCADED CARRY. See *carry*.

CASCADE OF AIRFOILS. An infinite set of similar airfoils, all placed at the same incidence and equally spaced. In the figure, only three of the airfoils are shown, but the set is assumed to extend to $y = \pm \infty$. The velocities

Cascade of airfoils.

at $x = -\infty$ and $x = +\infty$ are assumed to be uniform and equal to V_1 and V_2 respectively, with components u_1, v_1, u_2 and v_2 as shown. The equation of continuity then shows that $u_1 = u_2$. From the equation of momentum it can be shown that the **Kutta-Joukowski law**, relating lift to circulation, applies to a cascade if the stream velocity is taken to be the vector mean velocity

$$V = \frac{1}{2}(V_1 + V_2).$$

Thus for each airfoil, if Γ is the circulation, the lift is $\rho V \Gamma$ acting in a direction normal to V . The lift coefficient C_L , defined in terms of the vector mean velocity V , is

$$C_L = 2 \frac{s}{c} (\tan \alpha_1 - \tan \alpha_2) \cos \alpha_m,$$

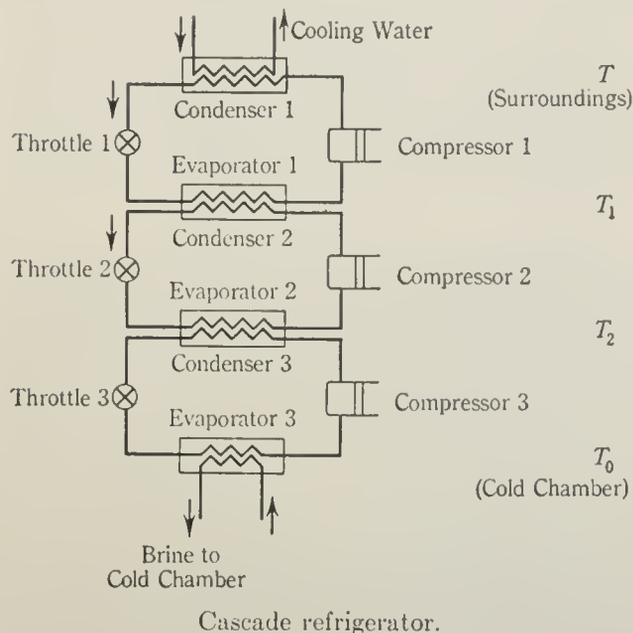

where $\tan \alpha_m = \frac{1}{2}(\tan \alpha_1 + \tan \alpha_2)$.

The flow through a cascade of airfoils can be calculated in various ways by the use of conformal transformations. For the simple case of a cascade of thin flat plates, the cascade in the ζ -plane can be transformed into a circle in the z -plane. In the general case, when the airfoils have thickness and camber, the cascade in the ζ -plane can be transformed into an oval in the z -plane. If the airfoils are thin and of small camber, this oval in the z -plane approximates to a circle and can be transformed into a true circle in the z' -plane by a method analogous to Theodorsen's method (see **airfoil theory**) for a single airfoil.

The cascades that are of practical importance usually consist of airfoils of large camber. The solution by conformal transformation is then very lengthy and complicated, and an alternative method is often used, in which each airfoil of the cascade is represented by a distribution of vorticity along the center line. This implies that the thickness of the airfoil is neglected, i.e., the method is analogous to thin-airfoil theory as applied to a single airfoil. (See A. Robinson and J. A. Laurmann, *Wing Theory*, Cambridge, 1956.)

CASCADE REFRIGERATOR. An arrangement of refrigerators, each filled with a different working fluid, operating in series, the evaporator of one serving as the condenser for the next. In this manner low refrigeration temperatures can be achieved with reasonable coefficients of performance. In addition, the properties of the refrigerants can be suited to

the respective temperature ranges. Cascade refrigerators have been used to liquefy gases in the last stage.

CASTIGLIANO FIRST THEOREM. Within the framework of classical elasticity theory, we consider a body to be subjected to concentrated forces with components $P_i^{(\alpha)}$ ($i = 1, 2, 3$; $\alpha = 1, 2, \dots$) in a rectangular Cartesian coordinate system x . The components $u_i^{(\alpha)}$ in the system x of the displacement undergone in the deformation, by the particle of the body at which the force $P_i^{(\alpha)}$ is applied, are given by $u_i^{(\alpha)} = \frac{\partial U}{\partial P_i^{(\alpha)}}$, where U is the strain energy for the deformations produced by the system of forces $P_i^{(\alpha)}$ ($\alpha = 1, 2, \dots$).

When the boundary displacements are zero wherever they are specified and the stress-strain relation is elastic, the complement of the strain energy is a minimum. For a linearly elastic system, the complement of the strain energy equals the strain energy, so that the strain energy is also a minimum. The derivative of the strain energy with respect to any applied force P_i is then the displacement of the point of application of the force in the direction of the force:

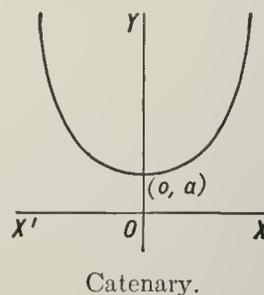

$$\frac{\partial U}{\partial P_i} = \delta_i.$$

CATACAUSTIC. A caustic produced by reflection.

CATENARY. The locus of the transcendental equation

$$y = \frac{a}{2} (e^{x/a} + e^{-x/a}) = a \cosh \frac{x}{a}$$

The curve can be generated by the focus of a parabola rolling along a straight line and its shape is that taken by a uniform, heavy flexible cable freely suspended from its ends. The involute of the catenary is called the *tractrix*.

CATENARY CURVE OR CABLE. A homogeneous flexible cable, when suspended from two fixed points and allowed to hang freely, assumes the form of a **catenary** curve. The equation for a catenary cable with a linear mass density ρ is

$$y = \frac{A}{\rho g} \cosh \frac{\rho g x}{A}$$

where g is the acceleration of gravity and A is a constant equal to ρg times the perpendicular distance from the x -axis to the lowest point of the catenary.

CATION. See **electroncutrality**.

CATOPTICS. That part of optics dealing with reflection, especially spectral reflection. Formally called *anacamptics*, though "*Catoptics*" was the title of Euclid's book on reflection. (See **dioptrics**.)

CATOPTRIC SYSTEM. (1) If an optical system is convergent, it is called catoptric if the object space focal length is positive and the image space focal length is negative. If a lens system is divergent, it is called catoptric if the object space focal length is negative and the image space focal length is positive. (2) Any mirror system.

CAUCHY (INTEGRAL) CONVERGENCE TEST. If

$$\lim_{n \rightarrow \infty} |a_n|^{1/n} < 1,$$

then the infinite series

$$\sum_{n=1}^{\infty} a_n$$

converges absolutely. A corollary, known as the *Cauchy ratio test*, or sometimes as *d'Alembert's test*, involves

$$\lim_{n \rightarrow \infty} |a_{n+1}/a_n| = r.$$

If $r > 1$, the series converges; if $r < 1$, it diverges; if $r = 1$, the test fails and the series may either converge or diverge.

CAUCHY DISTRIBUTION. A statistical distribution of the form

$$dF = \frac{dx}{\pi(1+x^2)}, \quad -\infty \leq x \leq \infty.$$

CAUCHY-EULER EQUATION. Synonym of Euler-Lagrange equation; see **variations, calculus of**.

CAUCHY FORMULA FOR REFRACTIVE INDEX. There is no simple formula expressing the index of refraction of a medium as a function of wavelength. A number of semi-empirical formulas have been used. One of these is *Sellmeier's equation*.

$$n^2 = 1 + \frac{A_1 \lambda^2}{\lambda^2 - \lambda_1^2}$$

where A_1 is a constant characteristic of the material and λ_1 is an idealized absorption wavelength of the medium. When $\lambda_1 \ll \lambda$ this reduces to

$$n^2 = 1 + A_1 + \frac{A_1 \lambda_1^2}{\lambda^2}.$$

Cauchy suggested that the Laurent expansion

$$n = \sum a_n \lambda^{-2n}$$

would be more satisfactory. **Herzberger's dispersion formula** is the best currently available for most optical material.

CAUCHY INTEGRAL FORMULA. The formula

$$f(z) = \frac{1}{2\pi i} \int_C \frac{f(\zeta)}{\zeta - z} d\zeta,$$

where the path of integration C consists of a finite number of simple closed rectifiable

curves in the complex plane bounding a region D in which $f(z)$ is analytic.

CAUCHY INTEGRAL THEOREM. If $f(z)$ is an analytic function of a complex variable z which has no singular point within or on a given closed curve C , then

$$\int_C f(z) dz = 0,$$

where the **integral** is extended over the entire contour C . (See also **Morera theorem**.)

CAUCHY NUMBER. A non-dimensional number arising in the study of the elastic properties of a fluid. It may be written $U^2 \rho / e$, where U is a characteristic velocity, ρ the density, and e the modulus of elasticity of the fluid. It is the square of the **Mach number**.

CAUCHY PROBLEM FOR PARTIAL DIFFERENTIAL EQUATIONS. The Cauchy problem for a set of partial differential equations can be stated, in general form, as follows:

Let t, x_1, x_2, \dots, x_n denote independent variables, while u_1, u_2, \dots, u_m are the dependent variables. Let there be given m equations of the form

$$\frac{\partial^{k_i} u_i}{\partial t^{k_i}} = F_i, \quad i = 1, 2, \dots, m$$

where F_i is a function of the independent and dependent variables and of partial derivatives of the latter of order not higher than k_i . In physical applications, t is usually the time and x_1, x_2, \dots, x_n are space coordinates.

For a fixed $t = t_0$, let the following conditions (the initial or Cauchy data) be prescribed

$$\frac{\partial^k u_i}{\partial t^k} = \phi_{ik}(x_1, x_2, \dots, x_n), \quad k = 0, 1, \dots, k_i - 1,$$

where the functions ϕ_{ik} are given over some region of the space (x_1, x_2, \dots, x_n) .

For example, for a vibrating membrane ($n = 2, m = 1, k_1 = 2$) there is one hyperbolic partial differential equation

$$\frac{\partial^2 u}{\partial t^2} = \frac{\partial^2 u}{\partial x_1^2} + \frac{\partial^2 u}{\partial x_2^2}$$

and the Cauchy conditions are

$$u(t_0, x_1, x_2) = \phi(x_1, x_2),$$

and

$$\dot{u}(t_0, x_1, x_2) = \psi(x_1, x_2,$$

representing the initial position and velocity, respectively. (See also **Riemann method**.)

CAUCHY RELATIONS (IN CRYSTAL STRUCTURE). If it is assumed that the forces between the atoms of a crystal lattice are central forces (i.e., that they act along the lines joining the centers of the atoms), and if it is also assumed that each atom is at a center of symmetry (i.e., that if \mathbf{r}_{jk} is the vector joining two atoms, replacing \mathbf{r}_{jk} by \mathbf{r}_{kj} does not change the structure), certain relations can be established between the elastic constants of the unstrained crystal.

Thus, if the relations between the six components of the stress tensor p_{ij} and the six components of the strain tensor s_{ij} are written in the usual way, we have

$$p_i = \Sigma c_{ij}s_j.$$

There are thus 36 elastic constants c_{ij} but the relation $c_{ij} = c_{ji}$ necessary for the existence of a strain energy function reduces this number to 21. The Cauchy relations state that in addition

$$c_{12} = c_{66}, \quad c_{23} = c_{44}, \quad c_{31} = c_{55}$$

$$c_{14} = c_{65}, \quad c_{25} = c_{46}, \quad c_{36} = c_{54}.$$

Thus, if these relations were true, there could be no more than 15 independent elastic constants for a crystal.

Ionic crystals are found to satisfy the Cauchy relations reasonably well, but metals do not, because the interatomic forces are not central.

Poisson showed that, for an isotropic solid, the assumption of central forces led to a single elastic constant, the value of **Poisson's ratio** being always 0.25.

CAUCHY RELATIONS IN ELASTICITY THEORY. Relations between the elastic constants in the **generalized Hooke's law**, which result from the assumption that the material consists of particles, between each pair of which a force acts along the line joining them, the magnitude of this force depending on the distance between the pair of particles.

CAUCHY-RIEMANN EQUATIONS. For functions $u = u(x,y)$ and $v = v(x,y)$ the Cauchy-Riemann equations are

$$\frac{\partial u}{\partial v} = \frac{\partial v}{\partial y}, \quad \frac{\partial u}{\partial y} = -\frac{\partial v}{\partial x}.$$

These equations are satisfied by the real and imaginary parts of an analytic function $f(z) = u(x,y) + i(v,y)$ of the complex variable z .

CAUCHY SEQUENCE. A sequence a_1, a_2, \dots of elements of a metric space is called a Cauchy sequence if, for every $\epsilon > 0$, there exists an integer N such that $|a_m - a_n| < \epsilon$ for all $m, n > N$.

CAUSALITY, MICROSCOPIC. See **causality principle (2)**.

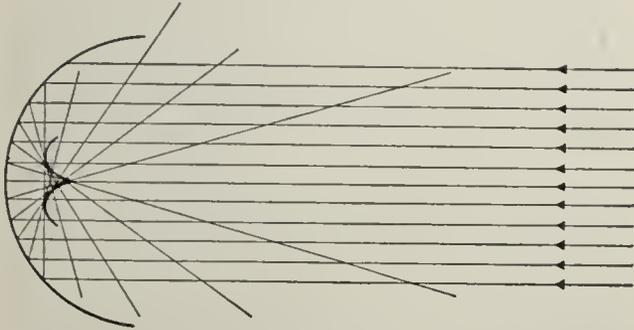

CAUSALITY PRINCIPLE. (1) The hypothesis that a precisely determined set of conditions will always produce precisely the same effects at a later time. Classical physics was based on the idea that the precise determination of the initial conditions was possible in principle. Quantum mechanics is based rather on the **Heisenberg uncertainty principle**, which indicates that such precise determination is impossible. (2) The principle of microscopic causality is the statement that signals never propagate with a velocity faster than that of light, no matter how short the distance involved. In the language of local quantum field theory, it is expressed by the statement that the commutator of two observable (Hermitian) Heisenberg field operators, taken at different space-time points, vanishes if the separation between these points is space-like. If $A(x)$ and $B(y)$ are two such Heisenberg operators, causality asserts that

$$[A(x), B(y)] = 0 \quad \text{for } (x - y)^2 < 0.$$

The arguments which lead to this formulation are as follows: in quantum theory the lack of commutativity of two observable operators implies that these cannot be measured simultaneously with arbitrary accuracy. However, measurements at points which are separated by space-like distances can never perturb one another, since relativity demands that signals (energy) cannot be propagated with a velocity greater than that of light. Hence the commutator of observables with space-like connections must vanish.

CAUSTIC. One of the earliest discoveries in optics (F. Maurolycus, 1575) was that the rays of a normal congruence are tangent to a surface, called the *caustic surface*, and that the

general ray is tangent to the caustic surface in two points. For example, the caustic of a parabolic mirror due to an incident beam of rays parallel to the axis of symmetry is a semi-cubic paraboloid of revolution. Gaviola's caustic test for parabolic mirrors is based on the caustic being the locus of centers of curvature of the parabolic sections.

Caustic of a parabolic mirror.

The most instructive definition characterizes the caustic surface as a set of caustic curves. A *caustic curve* is the edge of regression of the polar developable of a line of curvature on a **wave front**. This means that the set of normal planes of a line of curvature of a wave front are the tangent planes of a **developable surface**, the *polar developable*. The characteristic lines, or rulings, of the polar developable are the tangent lines of the edge of regression or caustic curve. This shows that the caustic surface consists of two sheets, whose points are the centers of curvature of the wave front, or the **tangential** and **sagittal foci** of the rays.

CAVITATION. In a flowing liquid, if the motion causes the absolute pressure at any point to fall below the vapor pressure p_v , bubbles of vapor are usually formed. Usually, at some point further downstream, the pressure rises again to some value above p_v ; the bubbles of vapor then collapse rapidly and often a loud noise is emitted and the high pressures generated locally cause pitting and corrosion of solid objects.

Since any pressure variations in the vapor cavity are very small compared with those in the liquid, the boundary of the vapor cavity may be considered to be one of constant pressure. This has sometimes been applied as a method of determining the shape of a solid boundary to give constant pressure on the boundary.

The *cavitation number* of a stream of liquid pressure p_1 and velocity v is defined as

$$\lambda = \frac{p_1 - p_v}{1/2\rho v^2}.$$

This number is a measure of the tendency for cavitation to occur when the stream is disturbed by the introduction of a solid body. If C_p is the pressure coefficient at any point on the body, cavitation may be expected to occur wherever $-C_p > \lambda$. Thus a small value of λ means that the body must introduce only small disturbances if cavitation is to be avoided.

Cavitation is of great practical importance in connection with water turbines and ships' propellers. In both these cases it is desirable to use the highest possible blade speed, but the speed that can be used is restricted by the necessity for avoiding cavitation, with its associated loss of efficiency and corrosive damage to the solid surface.

It has been shown that in water from which all dissolved air has been carefully removed it is possible for the pressure to fall considerably below p_v without the formation of any bubbles of vapor. It is even possible for the absolute pressure in the water to become negative.

CAVITATION NUMBER. See **cavitation**.

CAVITY FIELD IN A DIELECTRIC. The cavity field is the electrical field inside a spherical cavity of dielectric constant ϵ_2 , which is included in a medium of dielectric constant ϵ_1 , when the dipole moment of the sphere is 0 (i.e., when the spherical cavity is not polarized, see **polarization**). If the static field inside the dielectric ϵ_1 has, at a sufficiently large distance from the cavity, the value E_∞ , the cavity field G has the value

$$G = \frac{3\epsilon_1}{2\epsilon_1 + \epsilon_2} E_\infty.$$

For an empty sphere $\epsilon_2 = 1$, and

$$G = \frac{3\epsilon_1}{2\epsilon_1 + 1}.$$

(See also **reaction field**.)

CAYLEY-KLEIN PARAMETER. One of a set of four quantities used to describe the orientation of a rigid body. They are not linearly independent but may be expressed in terms of the **Euler angles**. When combined into matrix

equations they are related to the Pauli spin matrices which occur in quantum mechanics. (See also **Euler-Rodrigues parameters**.)

C-CIRCUIT. An alternate term for **fundamental circuit**.

ČEBYŠEV. See **Chebyshev**.

CELESTIAL SPHERE. An imaginary sphere of infinite radius upon which the celestial bodies are assumed to be fixed. The celestial sphere is used as a convenience in solving problems in celestial mechanics, navigation, and related fields. Points on the celestial sphere are determined by their celestial altitude and celestial azimuth. Since the celestial sphere is infinite in size, the earth's radius is not significant in comparison, and calculations are based upon the assumption that terrestrial observations are made from the center of the earth rather than the surface.

CELL, BINARY. In computers, an elementary unit of storage which can be placed in either of two stable states.

CELL EMF (FORMULA FOR). Since the electrical work done by a reversible cell equals the decrease of Gibbs free energy (**Gibbs function**) in the cell reaction

$$-\Delta G = W = EIt = Eq = EnF.$$

It follows that

$$E = -\frac{\Delta G}{nF}$$

where ΔG is the free energy change, n , the number of faradays passing through the cell, and F is the faraday (96,500 coulombs).

CELL MODEL OF THE LIQUID STATE. For densities as high as those in the liquid state far below the critical temperature, one may expect a certain order in the mutual distribution of the molecules. Intermolecular distances between first neighbors smaller than the molecular diameter are prohibited by the strong repulsive forces (see **intermolecular forces**) while distances much larger than the mean intermolecular distances are statistically very unlikely.

This more or less regular structure forms the basis of the cell models. In its simplest form, it assumes that each molecule is confined to its own cell (Eyring, Eyring and Hirschfelder, Lennard-Jones and Devonshire).

The field acting on each molecule in its cell is rapidly fluctuating, and may be replaced by an *average field* of spherical symmetry. If the lifetime of a molecule in its cell is sufficiently long, the exchange of places may be neglected in the evaluation of the thermodynamic properties (but of course not in the evaluation of the transport properties).

Denote by Ψ the **partition function** corresponding to a molecule in its cell referred to the energy of the particle at the center of the cell, and denote by $\omega(r)$, the mean energy of interaction. Then the *cell partition function* is

$$\Psi = 4\pi \int_{cell} \exp \left\{ \frac{1}{kT} [-(\omega(r) - \omega(0))] \right\} \cdot r^2 dr \quad (1)$$

where $\omega(0)$ is the value of $\omega(r)$ at the center of the cell. The configurational partition function of the liquid may be written

$$Q = \Psi^N \exp \left[-\frac{1}{2kT} N\omega(0) \right] \quad (2)$$

where $\frac{1}{2} N\omega(0)$ is the energy of the system when all particles are at the centers of their cells.

Using an explicit expression for $\omega(r)$, all thermodynamic properties may be deduced from (2).

The cell model gives a reasonable semi-quantitative description of the thermodynamic properties of a liquid. It suffers, however, from the basic weakness of a one-particle model. **Correlations** between molecules are not properly taken into account and the **entropy** is underestimated. The cell model has also been used for solutions (Prigogine).

CELSIUS TEMPERATURE SCALE. See **temperature**.

CENSORING. In the theory of sampling, a sample is said to be censored when the values of some of the members are unknown or deliberately ignored. If values exceeding (or falling short of) a fixed variate-value are unknown or discarded the sample is sometimes said to be *truncated*. The distinction between censoring and truncation is sometimes blurred and usage is not uniform.

CENTER, INSTANTANEOUS. The point about which a body having general motion may be considered to be in pure rotation (i.e., without **translation**) for any instant. The in-

stantaneous center is not necessarily on the body; in fact, it can be, in the case of rectilinear motion, infinitely distant.

CENTER OF A GROUP. The set (also called the central) of those elements of the **group** which commute with every element of the group. The center always includes the unit element.

CENTER OF AREA. See **centroid** (of a geometrical figure).

CENTER OF A SET OF VALUES. In statistics, the center of a set of values is the point midway between the two extreme values.

CENTER OF COLLINEATION. In **Gaussian optics**, the center of collineation is the point common to all rays joining **conjugate points** of (1) a spherical refracting surface, or (2) a thin lens. In case (1) it is the center of the sphere, in (2) it is the **optical center**.

CENTER OF CURVATURE. See **curvature**.

CENTER OF CURVE. See **centroid** (of a geometrical figure).

CENTER OF GRAVITY. The point through which the resultant of the gravitational forces on a body acts for every position of the body. This point exists when the dimensions of the body are negligible compared with its distance from the center of the earth. Designating the total weight of the body by W , the weight per unit of volume V , by ρ , the position vector of any point by \mathbf{r} , and the position vector of the center of gravity by \mathbf{r}_g .

$$W\mathbf{r}_g = \int_V \rho \mathbf{r} dV.$$

CENTER OF INVERSION. (1) For geometrical meaning, see **inverse surfaces**. (2) A **symmetry element** possessed by certain crystals, whereby the crystal can be brought into self-coincidence by the operation $\mathbf{r} \rightarrow -\mathbf{r}$, where \mathbf{r} is the vector position of a point in the crystal referred to the center of inversion.

CENTER OF MASS. That point in a body about which the sum of the moments of all the individual masses constituting the body is zero. If the individual (point) masses be called m_j and the vector position of m_j from some fixed origin be called \mathbf{r}_j , the center of mass is located \mathbf{r} from the origin, where

$$\mathbf{r}\Sigma m_j = \Sigma m_j \mathbf{r}_j$$

the summation being extended over all of the masses constituting the body. For a body whose mass is continuously distributed over its volume, the coordinates of the center of mass are:

$$x_c = \frac{\int x\rho dx}{M}, \quad y_c = \frac{\int y\rho dy}{M}, \quad z_c = \frac{\int z\rho dz}{M},$$

where M is the total mass of the body and $\rho = f(x, y, z)$ is the density as a function of position. If the density is constant throughout, the center of mass coincides with the center of volume. (See **centroid of a geometrical figure**.)

CENTER-OF-MASS (COORDINATE) SYSTEM. In general, any frame of reference moving with the center of mass of a system. Calculations in the center of mass system are often simpler than in other coordinate systems because the total **momentum** in the former is always zero. (See **L-system** and **C-system**.)

CENTER OF MOMENTS. The point about which moments are computed. Symbolizing moment as $\mathbf{r} \times \mathbf{F}$, the center of moments is the origin from which the position vector \mathbf{r} to any point on the line of action of the force \mathbf{F} is measured.

CENTER OF OSCILLATION. The frequency of oscillation of a physical pendulum is given by

$$f = \frac{1}{2\pi} \sqrt{\frac{gl}{k^2 + l^2}},$$

where l is the distance from the point of suspension to the center of mass, and k is the **radius of gyration**. A simple pendulum having the same frequency will be of length

$$l_1 = \frac{k^2 + l^2}{l}.$$

The point which lies at a distance l_1 from the point of suspension on the line through the point of suspension and center of mass is called the center of oscillation. If the physical pendulum were to be suspended from this point, its frequency would be the same as for the original point of suspension. (See also **pendulum, physical**; **pendulum, simple**.)

CENTER OF PERCUSSION. See *percussion, center of*.

CENTER OF PRESSURE. The point on an area of a submerged body at which the resultant of the pressure force on the area acts.

CENTER OF SHEAR. See *shear center*.

CENTER OF SUSPENSION. See *center of oscillation*.

CENTER OF SYMMETRY. See *symmetry, center of*.

CENTER OF TWIST. See *shear center*.

CENTER OF VOLUME. See *centroid (of a geometrical figure)*.

CENTIGRADE HEAT UNIT (ABBREVIATED C.H.U. OR CHU). Originally defined as $\frac{1}{100}$ part of the quantity of heat required to raise 1 lbm of water from its freezing to its boiling point at atmospheric pressure. This unit was used in engineering calculations based on the British system of units together with the Celsius (Centigrade) temperature scale. Now largely obsolete. (See *thermal units*.)

CENTIGRADE TEMPERATURE SCALE. See *temperature*.

CENTRAL DIFFERENCE OPERATOR. See *difference operators*.

CENTRAL FORCE. See *force, central*.

CENTRAL LIMIT THEOREM. An important theorem in probability to the general effect that the sum of n independent random variables with finite *variances*, suitably standardized, tends to the *normal (Gaussian) distribution* as n tends to infinity. There are various forms of the theorem; a necessary and sufficient condition is that no variate dominates the others. More general theorems concerning random variables which do not possess finite variances, or are not independent, are possible and are also known as central limit theorems.

CENTRAL MEAN OPERATOR. See *difference operators*.

CENTRAL POINT OF A GENERATOR. See *ruled surface*.

CENTRAL QUADRIC. A quadric which has a center, e.g., an ellipsoid or hyperboloid. By

a suitable choice of the rectangular Cartesian reference system x, y, z , the equation of any central quadric may be written in the form

$$\frac{x^2}{a} + \frac{y^2}{b} + \frac{z^2}{c} = 1,$$

where a, b and c are real constants. The origin of the coordinate system is then the center of the quadric and the directions of the axes x, y, z are the *principal axes of the quadric*. If a, b and c are all positive, the quadric is an *ellipsoid*. If $a > b > c$ and c is negative, while a and b are positive, the quadric is a *hyperboloid of one sheet*. If a is positive and b and c are both negative, it is a *hyperboloid of two sheets*.

CENTRIFUGAL. Moving outward or directed outward, in the sense of away from a center.

CENTRIFUGAL COMPRESSOR. See *axial-flow compressor*.

CENTRIFUGAL FORCE. A radially outward force experienced by an observer in a reference frame which is rotating at an *angular velocity* ω with respect to an *inertial frame*. The centrifugal force is an *inertial force* and may be considered as the reaction to the *centripetal force* necessary to hold the observer at a fixed point in the rotating frame, and thus has a magnitude equal to and a direction opposite to the centripetal force.

CENTRIPETAL ACCELERATION. The acceleration toward the center of curvature to which any particle moving in a curved path is subject. It is equal to v^2/r where v is the speed of the particle and r is the radius of curvature of the path (see *centripetal force*). An equivalent term is *normal acceleration*.

CENTRIPETAL FORCE. The radially inward force mv^2/r required for motion of a particle of mass m , traveling at speed v in a curved path of radius of curvature r . When the motion is circular with angular velocity ω , the *centripetal acceleration* v^2/r may be written as $r\omega^2$.

CENTRODE. The path of the instantaneous center of a plane figure having plane motion, that is, motion resulting when all points in the figure move in parallel fixed planes. Any plane body having plane motion which is neither entirely rectilinear nor entirely rota-

tive, but a combination of the two, may be considered at any instant as having rotary motion about a moving point called the *instantaneous center of rotation*.

CENTROIDAL AXIS. An axis through the centroid of a cross section, therefore a possible neutral axes for bending.

CENTROID (OF A GEOMETRICAL FIGURE). The centroid of a given geometrical figure (curve arc, portion of a plane or curved surface, or solid) is the point whose **coordinates** are the **mean values** of the coordinates of the points of the given figure; it is independent of the choice of axes. The centroid of a geometrical figure corresponds to the **center of gravity** (or **center of mass**) of a homogeneous material body of similar form.

For a plane curve arc, the centroid is given by formulae:

$$\bar{x} = \frac{\int_a^b x ds}{L}, \quad \bar{y} = \frac{\int_a^b y ds}{L},$$

$$ds = \sqrt{1 + \left(\frac{dy}{dx}\right)^2} \cdot dx = \sqrt{1 + \left(\frac{dx}{dy}\right)^2} \cdot dy,$$

where L is the length of the arc, and ds is the length of an infinitesimal portion of the curve.

For a plane area, the centroid is given by:

$$\bar{x} = \frac{\iint_A x dS}{A}, \quad \bar{y} = \frac{\iint_A y dS}{A},$$

where A is the area of the given region, and dS is the area of an infinitesimal portion of the surface.

For a solid, the centroid is given by:

$$\bar{x} = \frac{\iiint_V x dV}{V}, \quad \bar{y} = \frac{\iiint_V y dV}{V}, \quad \bar{z} = \frac{\iiint_V z dV}{V},$$

where V is the volume of the given region, and dV is the volume of an infinitesimal portion of the solid.

CENTROID OF MASS. See **center of mass**.

CEPHEID VARIABLES. See **variable stars**.

CERENKOV RADIATION. A charged particle moving with uniform velocity v through a medium in which the velocity of light is less

than v will produce radiation which is sharply peaked along a cone in the forward direction. This cone is defined by the angle $\theta = \cos^{-1}(c/nv)$, where c is the velocity of light *in vacuo* and n is the **index of refraction** of the medium. This phenomenon is roughly analogous to the formation of shock waves in a fluid medium.

CETANE NUMBER. (Correctly cetene number.) The use of the term cetane number is becoming widespread in (misplaced) analogy with octane number. (See **knocking**.)

CHAIN RULE OF DIFFERENTIATION.

Let $w(u_1, u_2, \dots, u_m)$ be a function of m variables u_j , each of which is a function $u_j(x_1, x_2, \dots, x_n)$ of n variables x_i . Then w is a (composite) function of the variables x_i and, under mild conditions of continuity on w and u_j , the partial derivative $\partial w/\partial x_i$ of w with respect to x_i is given by the chain rule:

$$\frac{\partial w}{\partial x_i} = \frac{\partial w}{\partial u_1} \cdot \frac{\partial u_1}{\partial x_i} + \frac{\partial w}{\partial u_2} \cdot \frac{\partial u_2}{\partial x_i} + \dots + \frac{\partial w}{\partial u_m} \cdot \frac{\partial u_m}{\partial x_i}.$$

Many similar chain rules can be formulated for derivatives of higher order.

CHANNEL. (1) A combination of transmission media and equipment capable of receiving signals at one point and delivering related signals at another point. (2) In electronic computers, that portion of a storage medium which is accessible to a given reading station. (See also **track**.) (3) A **bar** having a section in the shape of a rectangle lacking one side. (4) A closed or partly-closed duct through which fluid flows.

CHANNEL CAPACITY. The maximum possible **information rate** through a **channel** subject to the constraints of that channel; channel capacity may be either per second or per symbol.

CHANNEL, ENERGY LENGTH OF. See **energy length for pipe or channel**.

CHANNEL STORAGE. The water volume within a specified portion of a stream channel.

CHANNEL, TRANSITION TO TURBULENT FLOW IN. See **transition to turbulent flow in a pipe or channel**.

CHANNEL, TWO-DIMENSIONAL, LAMINAR FLOW IN. For two-dimensional laminar flow, in a straight channel formed by paral-

lel walls at a distance $2b$ apart, the velocity distribution is given by

$$u = \frac{p'}{2\mu} (b^2 - y^2), \tag{1}$$

where u is the velocity at a distance y from the center, p' is the longitudinal pressure gradient and μ is the viscosity.

If τ_o is the shear stress at the wall, the skin friction coefficient is

$$C_f = \frac{\tau_o}{\frac{1}{2}\rho V^2} = \frac{12}{R}, \tag{2}$$

where V is the mean velocity and R is the Reynolds number based on this velocity and the channel width $2b$. This type of flow is often known as *plane Poiseuille flow*.

CHANNEL UTILIZATION INDEX. The ratio of the information rate (per second) through a channel to the channel capacity (per second).

CHAPMAN-JOUGET CONDITION. In steady-state detonation the lowest possible shock wave velocity is given by

$$v = \frac{1}{\rho_1} \left(\frac{P_2 - P_1}{\frac{1}{\rho_1} - \frac{1}{\rho_2}} \right)^{1/2}$$

where ρ_1 and ρ_2 are the densities in front of and behind the incident shock, respectively, and P_1 and P_2 are the corresponding pressures.

CHARACTER. (1) The trace (sum of the diagonal elements) of a matrix representation of a group. The character of all elements in a given class of the group is the same. (2) One of a set of elementary symbols (marks or events) which may be arranged in ordered aggregates to express information. A group of characters in one context, may be considered as a single character in another, as in the binary-coded-decimal system.

CHARACTERISTIC. (1) A synonym for eigen-, as in **eigenfunction** and **eigenvalue**. (2) For a first-order partial differential equation of the form

$$f(x,y) \frac{\partial z}{\partial x} + g(x,y) \frac{\partial z}{\partial y} = h(x,y),$$

any curve given in parametric form by $x = x(t)$, $y = y(t)$, $z = z(t)$ such that

$$\frac{dx}{dt} = f(x,y), \quad \frac{dy}{dt} = g(x,y), \quad \frac{dz}{dt} = h(x,y)$$

is called a characteristic. The importance of these characteristics is due to the fact that every integral surface $z = z(x,y)$ for the given partial differential equation is generated by a one-parameter family of characteristics; that is, every characteristic having a point in common with the surface lies entirely on it. In general, boundary conditions may be assigned at will along any non-characteristic curve. The concept can be generalized for equations of higher order in a greater number of variables. (See **characteristics, method of**.) (3) See **characteristic equation of a matrix**. (4) See **equation of state**.

CHARACTERISTIC EQUATION (OF GEOMETRICAL OPTICS). The differential equation of geometrical optics

$$V_x^2 + V_y^2 + V_z^2 = n^2$$

is referred to as the characteristic equation or *eikonal equation*. The solutions are **Hamilton's characteristic** (eikonal) of the optical system with index of refraction $n = n(x, y, z)$.

CHARACTERISTIC EQUATION OF A GAS. See **equation of state**.

CHARACTERISTIC EQUATION OF A MATRIX. The characteristic equation of a square matrix $\mathbf{A} = \{a_{ij}\}$, $i, j = 1, 2, \dots, n$, is $\det \{\mathbf{A} - \lambda \mathbf{I}\} = 0$ regarded as an algebraic equation in λ , where \mathbf{I} is the identity matrix and \det denotes determinant, so that in expanded form the equation is

$$\begin{vmatrix} a_{11} - \lambda & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} - \lambda & \cdots & a_{2n} \\ \vdots & \vdots & \cdots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} - \lambda \end{vmatrix} = 0.$$

This determinant is called the *secular determinant*, and this equation is often called the *secular equation* because of their application to the study of secular perturbations of the planets. (See also **matrix**.)

CHARACTERISTIC EQUATION OF A SYSTEM. The equation which determines the

normal modes and hence the degree of **stability** of a system.

If the system is envisaged as comprising n physical quantities $q_1(t), \dots, q_n(t)$, whose Laplace transforms $Q_1(s), \dots, Q_n(s)$ are related by the n equations

$$a_{1m}(s)Q_1(s) + a_{2m}(s)Q_2(s) + \dots + a_{nm}(s)Q_n(s) = f_m(s), \quad (m = 1, 2, \dots, n)$$

in which $f_m(s)$ is a function of s depending on initial conditions or external inputs or both, then the equation

$$\Delta(s) \equiv \begin{vmatrix} a_{11} & a_{21} & \dots & a_{n1} \\ a_{12} & a_{22} & \dots & a_{n2} \\ \vdots & \vdots & \ddots & \vdots \\ a_{1n} & a_{2n} & \dots & a_{nn} \end{vmatrix} = 0$$

is the characteristic equation of the system. As a particular case, for a control system in which

$$\begin{aligned} \theta_o(s) - G(s)\theta_e(s) &= 0 \\ \theta_o(s) + \theta_e(s) &= \theta_i(s) \end{aligned}$$

in which $\theta_i, \theta_o, \theta_e$, are the **Laplace transforms** of the input, the output and the error respectively and $G(s)$ is the output to error **transfer function** the characteristic equation is

$$1 + G(s) = 0.$$

CHARACTERISTIC FUNCTION. If $F(x)$ is a **probability distribution function**, its characteristic function is given by the **Fourier transform**

$$\phi(t) = \int_{-\infty}^{\infty} e^{itx} dF(x).$$

The characteristic function is a **moment generating function**,

$$\phi(t) = \sum \mu'_r (it)^r / r!$$

where μ'_r is the r th **moment** of $F(x)$ about the origin. The characteristic function uniquely determines the distribution function by the formula

$$F(x) - F(0) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \phi(t) \frac{1 - e^{-ixt}}{it} dt.$$

If the frequency function (probability density function), $f(x)$, exists this is equivalent to

$$f(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-ixt} \phi(t) dt.$$

Likewise the characteristic function of a function $g(x_1, x_2, \dots, x_n)$ of variates x_1, x_2, \dots, x_n distributed with function $F(x_1, x_2, \dots, x_n)$ is

$$\int \exp\{itg\} dF(x_1, x_2, \dots, x_n).$$

If the variates are independent the characteristic function of their sum is the product of their individual characteristic functions, a fact which gives the characteristic function a fundamental role in sampling theory.

The logarithm of the characteristic function is called the **cumulant** generating function.

CHARACTERISTIC FUNCTION OF A SET. The function whose value is unity for points of the **set** and zero elsewhere.

CHARACTERISTIC FUNCTION OF OPTICS. See **Hamilton's characteristic** and **eikonal**.

CHARACTERISTIC FUNCTIONS IN THERMODYNAMICS. See **thermodynamics, characteristic functions in**.

CHARACTERISTIC IMPEDANCE. See **impedance, characteristic**.

CHARACTERISTIC LENGTH. In propulsion, the ratio of the volume of a combustion chamber to its nozzle throat area. It is a measure of the length of travel available for the combustion of propellants. To obtain the best performance possible, the chemical reaction should be completed before the gaseous combustion products reach the entrance to the exhaust nozzle. The objective is to minimize the characteristic length without introducing any significant reduction in the measured value of **characteristic velocity** due to incomplete reaction of propellants. The relationship is:

$$L^* = \frac{V_c}{A_t}$$

where L^* is the characteristic length, V_c is the chamber volume, and A_t is the nozzle throat area.

CHARACTERISTIC OF A LOGARITHM. See **logarithm**.

CHARACTERISTIC OF A SURFACE. See **surface characteristic**.

CHARACTERISTIC POINTS (FOR A TWO-PARAMETER FAMILY OF SURFACES).

The points defined by

$$\begin{aligned} f(x,y,z,a,b) &= 0, \\ \partial f(x,y,z,a,b)/\partial a &= 0, \\ \partial f(x,y,z,a,b)/\partial b &= 0, \end{aligned}$$

for particular values of the parameters a and b , where $f(x,y,z,a,b) = 0$ is a two-parameter family of surfaces. The *envelope of the two-parameter family of surfaces* is the surface whose equation is obtained by eliminating a and b from these equations. It is the locus of the characteristic points.

CHARACTERISTIC POLYNOMIAL OF A MATRIX. See *matrix*.

CHARACTERISTICS, METHOD OF. (See also *characteristic*.) A method of calculating, for instance, supersonic flow fields for an inviscid gas. In its usual form, as considered here, the method applies only to irrotational flow, but it has also been extended to rotational flow. The method can be used for steady flow, either in two dimensions or with axial symmetry, or for unsteady one-dimensional flow.

In steady supersonic flow the **Mach lines** are characteristics, in the sense used in the theory of hyperbolic equations. In the method of characteristics the network formed by the two families of Mach lines is computed numerically, step-by-step, the **Mach angle** and flow direction being found for each intersection point as the computation proceeds. It is usually necessary to start the computation at a line on which the properties of the flow are known.

In steady two-dimensional flow the conditions that must be satisfied along the Mach lines are

$$\nu + \theta = \text{constant for } a + \text{ Mach line}$$

and

$$\nu - \theta = \text{constant for } a - \text{ Mach line,}$$

where θ is the inclination of the velocity vector to the axis. ν is the Prandtl-Meyer function given by

$$\nu = \mu - \frac{\pi}{2} + \lambda^{-1} \tan^{-1} (\lambda \cot \mu),$$

where μ is the **Mach angle** and

$$\lambda^2 = \frac{\gamma - 1}{\gamma + 1}.$$

The method of characteristics has been much used for computing the shapes of supersonic nozzles to give regions of uniform flow. (See also **Prandtl-Meyer expansion**.) (See H. W. Liepmann and A. Roshko, *Elements of Gas-dynamics*, Wiley, New York, 1957.) It is quite generally employed in the solution of problems governed by **hyperbolic partial differential equations**; for instance, in the theory of plasticity.

CHARACTERISTIC TEMPERATURE. See **Debye temperature**.

CHARACTERISTIC VALUE OF TENSOR. See **eigenvalue equation**.

CHARACTERISTIC VECTOR OF A MATRIX. See **matrix**; **principal vector**; and **eigenvalues and eigenvectors of matrices**.

CHARACTERISTIC VELOCITY. See **velocity, characteristic**.

CHARACTERISTIC WAVELENGTH OF A MEDIUM. The characteristic velocity (see **velocity, characteristic**) divided by the frequency:

$$1/f\sqrt{\mu\epsilon}.$$

CHARACTERISTIC X-RAY SPECTRUM. See **x-ray spectrum, characteristic**.

CHARGE, BOUND. An electric charge which appears at the surface of a **dielectric** by virtue of its **polarization**. The surface density of these charges is equal to the polarization within the dielectric. Such charges are bound in the sense that they result from the creation and reorientation of dipoles within the dielectric. The total amount of bound charge throughout the volume of any dielectric is zero. Bound charges are distinguished from free charges. (See **charge, free**.)

CHARGE CONJUGATION OPERATION. The operation which transforms any state containing n particles of type i , momenta \mathbf{p}_j , spin σ_j into a state of m anti-particles of type i , momenta \mathbf{p}_j , spin σ_j .

This operation is a unitary one and is usually denoted by **C**. The transformation laws of a charged spin 0, spin $\frac{1}{2}$ and spin 1 field under this operation is as follows:

$$\begin{aligned}
 \text{Spin } 0 \quad & C\phi(x)C^{-1} = \eta_0^C \phi^*(x) \\
 & C\phi(x)^*C^{-1} = \bar{\eta}_0^C \phi(x) \\
 \text{Spin } \frac{1}{2} \quad & C\psi(x)C^{-1} = \eta_{1/2}^C C\bar{\psi}^T(x) \\
 & C\bar{\psi}(x)C^{-1} = \bar{\eta}_{1/2}^C \psi^T(x)C^* \\
 \text{Spin } 1 \quad & C\phi_\mu(x)C^{-1} = \eta_1^C \phi_\mu^*(x) \\
 & C\phi_\mu^*(x)C^{-1} = \bar{\eta}_1^C \phi_\mu(x).
 \end{aligned}$$

For the spin $\frac{1}{2}$ case C is the matrix satisfying $C\gamma_\mu^T C = -\gamma_\mu$ ($\gamma_\mu\gamma_\nu + \gamma_\nu\gamma_\mu = 2g_{\mu\nu}$).

If the Hamiltonian for these field theories is invariant under the operation $C:HC^{-1}=H$, then C is a constant of the motion. The total charge of the system, however, anti-commutes with C . One can assume that $C^2 = 1$. It is known that the weak interactions violate C -invariance.

CHARGE CONSERVATION. See **gauge invariance**.

CHARGE-CURRENT DENSITY FOUR VECTOR. The four functions of position and time $j_\mu(r,t)$ where $j_1, j_2, j_3,$ are the components of electric current density, and $j_4 = ic\rho$, where ρ is the charge density. For a Dirac electron field,

$$j_\mu = ic\psi\gamma_\mu\bar{\psi}$$

where $\bar{\psi}$ is the **adjoint** wave-function.

CHARGE DENSITY. Electrostatics deals both with finite, point charges, and distributed charges. (1) A distributed charge can be described in terms of its density (coulombs per cubic meter) at each point of the region of interest. The density is a three-dimensional analog of a simple derivative. (See the **Poisson equation**.) (2) The term is also used to refer to the surface charge density, the charge per unit area.

CHARGE DENSITY OF NUCLEI. Experiments in which atomic nuclei are bombarded with high energy electrons have shown that the electric charge of the nucleus, which arises from the protons, is distributed consistently with the formula

$$\rho(r) = \rho_0[1 + e^{(r-R)/a}]^{-1}$$

where $R = r_0A^{1/3}$ is a measure of the nuclear radius, $r_0 \approx 1.1 \times 10^{-13}$ cm, $A =$ mass number, and $a \approx 0.6 \times 10^{-13}$ cm is a measure of the thickness of the nuclear surface; ρ_0 is a constant.

CHARGE, ELECTRIC. A quantity of **electricity**, measured in **coulombs** or related units. The flow of charge per unit time is the **electric current**. The elementary unit of charge is the charge on the **electron**. (See **electron**.)

CHARGE, FREE. An electric charge on the surface of a conductor or those charges on the surface of a dielectric that are not bound (cf. **charge, bound**). When free charges occur at the interface of dielectrics, there is a discontinuity in the normal component of the **electric displacement vector** at the interface, the magnitude of the change being equal to the surface density of free charges.

CHARGE INDEPENDENCE. The property whereby the nuclear forces between a pair of protons, a pair of neutrons, or a neutron and a proton, are the same in corresponding states of relative motion. Nuclear forces appear to possess this property to a high degree of accuracy. The result is that closely corresponding states can be found in nuclei of the same mass number A but possessing different numbers of neutrons and protons, and this has led to a considerable simplification in the description of the states of light nuclei. In heavier nuclei ($A > 40$) the electrostatic forces between protons (which are clearly not charge-independent) destroy this simplification. The term is also used in an extended sense to describe interactions between mesons and nucleons (neutrons and protons) which also appear to be charge-independent. (See **isotopic spin**.)

CHARGE IN SPACE, FIELD OF MOVING. See **field of moving charge in space**.

CHARGE INVARIANCE. Hypothesis that nucleon-nucleon **interactions** are invariant under rotations in isotopic spin space. One consequence of this is the charge independence of nuclear forces.

CHARGE-MASS RATIO. The ratio of the electric charge of a particle and its mass, important in the physics of electrons, ions, and other electrified bodies of molecular order.

CHARGE NUMBER. The charge number of an ion is the ratio of its charge to that of the proton H^+ . Thus Ba^{++} has the charge number $+2$; PO_4^{---} has the charge number -3 . (See **electroneutrality**.)

CHARGE RENORMALIZATION. In quantum electrodynamics a procedure which allows the removal of certain **divergences** connected with the vacuum fluctuations of the charged matter field. Every charged particle induces a vacuum polarization, i.e., a reordering of the charge distribution of the vacuum. More specifically, a charged particle of charge Q as a result of its interaction with the electron-positron field, surrounds itself with a cloud of (virtual) electrons and positrons. Some of these, with net charge δQ , of the same charge as Q , escape to infinity (due to the infinite range of the Coulomb field), leaving a net charge $-\delta Q$ in the part of the cloud which is closely bound to the test body (i.e., within a distance \hbar/mc). In the present formulation of quantum electrodynamics, δQ is infinite (the aforementioned divergence). The recognition that it is not Q but $Q - \delta Q$ which is the experimentally observed charge of the particle (as long as one only probes distances greater than \hbar/mc), and that it is this quantity which must be set equal to the observed charge, allows one to bypass the divergence difficulty. (See **S matrix, evaluation of.**)

CHARGE-TRANSFER SPECTRUM. See **spectrum, charge-transfer.**

CHARLES LAW. (Also known as the Gay-Lussac law.) Gases heated (or cooled) at constant pressure expand (or contract) by the same fraction of their volume for the same rise of temperature:

$$v = v_0(1 + \alpha t) \quad \text{at } p = \text{const.}$$

The law is found to be an asymptotic one for real gases being valid for $p \rightarrow 0$; $V \rightarrow \infty$ (**perfect gases**). It is contained in the perfect gas law $pv = RT$. Here t is measured on the Celsius or Fahrenheit temperature scales, whereas T is measured on the Kelvin or Rankine scales, respectively. Charles' law is now only of historical significance.

CHATELIER(LE)-BRAUN PRINCIPLE. Let us perturb a system which is initially in stable equilibrium (see **thermodynamic stability conditions**) to a neighboring non-equilibrium state. Since the initial equilibrium is supposed to be stable, the system will return to an equilibrium state.

Theorems governing the behavior of perturbed systems are often known as *theorems*

of constraint or theorems of moderation. The best known thermodynamic theorem of moderation is that of Le Chatelier-Braun (also called the Le Chatelier-Braun Principle) which in the form stated by Le Chatelier is:

"Any system in chemical equilibrium undergoes, as a result of a variation in one of the factors governing the equilibrium, a *compensating* change in a direction such that, had this change occurred alone it would have produced a variation of the factor considered in the *opposite direction*."

However this principle suffers from a number of important exceptions. It is therefore preferable to study the "inoderation" starting from the usual thermodynamic formalism without invoking a special principle. (See also **van't Hoff theorem; Chatelier theorem.**)

CHATELIER(LE) THEOREM. If a reaction is accompanied by an increase in volume, an increase in pressure leads to a reduction of the extent of reaction; correspondingly, if the reaction is accompanied by a decrease in volume, an increase in pressure advances the equilibrium value of the extent of reaction.

Quantitatively this theorem may be expressed by

$$\left(\frac{d\xi}{dp}\right)_T = \frac{V_{T,p}}{a_{T,p}} \quad (1)$$

where ξ is the **extent of reaction**, and

$$V_{T,p} = \left(\frac{\partial^2 V}{\partial \xi^2}\right)_{T,p} \quad a_{T,p} = -\left(\frac{\partial^2 G}{\partial \xi^2}\right)_{T,p} \quad (2)$$

where G is the Gibbs free energy (see **thermodynamics, characteristic functions**). The **chemical stability** condition is

$$a_{T,p} < 0 \quad (3)$$

This theorem is also closely related to the **Chatelier(Le)-Braun principle**.

CHEBYSHEV APPROXIMATION. See **minimax approximation**.

CHEBYSHEV EQUATION. A special case of the Gauss hypergeometric equation

$$(1 - x^2)y'' - xy' + n^2y = 0$$

where n is an integer. The name is often spelled differently, particularly *Tchebycheff*. (See **Chebyshev polynomials**.)

CHEBYSHEV EXPANSION. An expansion in Chebyshev polynomials. Since $T_n = x^n +$ terms of lower degree, $x^n = T_n +$ Chebyshev polynomials of lower degree. Let $f(x)$ have the expansion

$$f(x) = \alpha_0 + \alpha_1 x + \alpha_2 x^2 + \dots, \quad -1 \leq x \leq 1.$$

By expressing each x^n in terms of Chebyshev polynomials and collecting terms one has

$$f(x) = \beta_0 + \beta_1 T_1(x) + \beta_2 T_2(x) + \dots.$$

It generally happens that for a given degree of accuracy this Chebyshev expansion can be truncated much sooner than the power series expansion, hence for computing purposes is more effective. (See **minimax approximation**.)

(For more details see Zdenek Kopal, *Numerical Analysis*, John Wiley & Sons, Inc., 1955; Cornelius Lanczos, *Applied Analysis*, Prentice-Hall Company, 1956.)

CHEBYSHEV INEQUALITY. Let $g(x)$ be a non-negative function of a variate x . Then

$$P\{g(x) > k\} \leq \frac{E\{g(x)\}}{k}, \quad k > 0.$$

If $g(x) = (x - m)^2$ where m is the mean of x , and $k = t^2 \sigma^2$, where σ^2 is the variance, the inequality reduces to the **Bienaymé-Chebyshev inequality**.

CHEBYSHEV POLYNOMIALS. The class of special functions obtained by orthogonalizing over the interval $[-1, 1]$ the sequence of powers $1, x, x^2, \dots$ with the weighting function $w(x) = (1 - x^2)^{-1/2}$. They satisfy the differential equation

$$(1 - x^2)y'' - xy' + n^2y = 0, \quad n = 0, 1, 2, \dots.$$

They are given explicitly by:

$$T_0(x) = 1, \quad T_n(x) = 2^{1-n} \cos(n \cos^{-1} x),$$

so that

$$T_1(x) = x, \quad T_2(x) = x^2 - \frac{1}{2},$$

$$T_3(x) = x^3 - \frac{3}{4}x, \dots.$$

Their normalizing factor is $2^{n-1/2} \pi^{-1/2}$ and their generating function is $2^{-n}(1 - t^2)(1 - 2tx + t^2)$. They satisfy the recursion formula

$$T_{n+1}(x) - xT_n(x) + \frac{1}{4}T_{n-1}(x) = 0, \quad n > 1.$$

Their Rodrigues formula is:

$$T_n(x) = (1 - x^2)^{1/2} \frac{(-1)^n 2n!}{(2n)!} \frac{d^n}{dx^n} (1 - x^2)^{n-1/2}.$$

They have the minimum property, among all polynomials of degree n with unity for leading coefficient, of having the least deviation from the real axis; that is: $\max |T_n(x)| = \min$. This property makes the Chebyshev polynomials important, e.g., in arranging a physical process so that its oscillations, which after a certain time may become very great, are a minimum in some fixed interval.

By some authors the polynomials

$$P_n(x) = 2^{n-1} T_n(x) = \cos(n - \cos^{-1} x)$$

are called the Chebyshev polynomials. For these the recursion is

$$P_{n+1} = 2xP_n - P_{n-1}.$$

(See Zdenek Kopal, *Numerical Analysis*, John Wiley & Sons, Inc., 1955; Cornelius Lanczos, *Applied Analysis*, Prentice-Hall Company, 1956.)

CHEBYSHEV QUADRATURE FORMULA. A formula of the form

$$\int_a^b w(x)f(x)dx = \omega \sum_0^n f(x_i) + R_n,$$

where the points x_i are so chosen that the integration is exact when $f(x)$ is a polynomial of degree as high as possible. It turns out the x_i can be determined as roots of an algebraic equation of degree $n + 1$, but unless $n \leq 7$ or $n = 9$ they do not all lie on the interval of integration. The formula is advantageous in particular in cases where the $f(x_i)$ are experimentally measured, since in the formula they are equally weighted.

CHEBYSHEV SYSTEM (OF ORDER n). A set of functions

$$\phi_0(x), \phi_1(x), \dots, \phi_n(x),$$

linearly independent and continuous on an interval (a, b) with the property that if the linear combination

$$F_n(x) = \alpha_0 \phi_0(x) + \dots + \alpha_n \phi_n(x)$$

vanishes more than n times on the interval, then it vanishes identically, and hence $\alpha_0 = \alpha_1 = \dots = \alpha_n = 0$. Such a system is

$$\phi_0 = 1, \quad \phi_1 = x, \quad \dots, \quad \phi_n = x^n;$$

for the interval from 0 to 2π , the system

$$\begin{aligned} \phi_0 &= 1, & \phi_1 &= \sin x, & \phi_2 &= \cos x, & \dots, \\ \phi_{2n-1} &= \sin nx, & \phi_{2n} &= \cos nx \end{aligned}$$

is a Chebyshev system of order $2n$. Such systems are of importance in minimax approximation.

CHECK. A process of partial or complete testing of (1) the correctness of machine operations, (2) the existence of certain prescribed conditions within the computer, or (3) the correctness of the results produced by a routine. A check of any of these conditions may be made automatically by the equipment or may be programmed. (See also **marginal checking**; **verification**.)

CHECK, AUTOMATIC. A check performed by equipment built into the computer specifically for that purpose, and automatically accomplished each time the pertinent operation is performed. Sometimes referred to as a built-in check. Machine check can refer to an automatic check, or to programmed check of machine functions.

CHECK DIGITS. See **check, forbidden-combination**.

CHECK, FORBIDDEN-COMBINATION. A check (usually an automatic check) which tests for the occurrence of a nonpermissible code expression. A *self-checking code* (or *error-detecting code*) uses code expressions such that one or more errors in a code expression produces a forbidden combination. A *parity check* makes use of a self-checking code employing binary digits in which the total number of 1's (or 0's) in each permissible code expression is always even or always odd. A check may be made for either even parity or odd parity. A *redundancy check* employs a self-checking code which makes use of redundant digits called *check digits*.

CHECKING, MARGINAL. A preventive maintenance procedure in which certain operating conditions, e.g., supply voltage or frequency, are varied about their normal values in order to detect and locate incipient defective units. (See also **check**.)

CHECK, MACHINE. See **check, automatic**.

CHECK, MATHEMATICAL. See **check, programmed**.

CHECK, PARITY. See **check, forbidden-combination**.

CHECK POINT. See **point, way**.

CHECK PROBLEM. See **check, programmed**.

CHECK, PROGRAMMED. A check consisting of tests inserted into the program of the problem and accomplished by appropriate use of the machine's instructions. A *mathematical check* (or *control*) is a programmed check of a sequence of operations which makes use of the mathematical properties of that sequence.

CHECK, REDUNDANCY. See **check, forbidden-combination**.

CHECK ROUTINE OR CHECK PROBLEM. A routine or problem which is designed primarily to indicate whether a fault exists in a digital computer, without giving detailed information on the location of the fault. (See also **routine diagnostic**; **routine test**; **check, programmed**.)

CHECK, SELECTION. A check (usually an automatic check) in a digital computer to verify that the correct register, or other device, is selected in the performance of an instruction.

CHECK, TRANSFER. A check (usually an automatic check) on the accuracy of the transfer of a word.

CHEMICAL AFFINITY. The entropy production due to a chemical reaction has the form (see **thermodynamics, second law of**).

$$\frac{d_i S}{dt} = \frac{1}{T} A v \geq 0, \quad (1)$$

where A is the chemical affinity and v , the reaction rate (see **chemical reaction rate**); A is related to the characteristic functions U , H , A , G and to the chemical potentials μ by the relations (see **thermodynamics, characteristic functions of**; **chemical potentials**).

$$\left. \begin{aligned} A &= -\left(\frac{\partial U}{\partial \xi}\right)_{S,V} = -\left(\frac{\partial H}{\partial \xi}\right)_{S,p} \\ &= -\left(\frac{\partial A}{\partial \xi}\right)_{T,V} = -\left(\frac{\partial G}{\partial \xi}\right)_{T,p} \\ &= -\sum_i \nu_i \mu_i \end{aligned} \right\} \quad (2)$$

when ξ is the extent of reaction and ν_i the stoichiometric coefficient.

The basic properties of the affinity A are that it is always of the same sign as the re-

action rate, and that if the affinity is zero the reaction rate is also zero, i.e., the system is in equilibrium.

This definition of affinity is essentially due to De Donder and is called De Donder's fundamental inequality. In the notation used by G. N. Lewis and his school, it is supposed that ξ increases by unity, therefore the relations (2) are written in the form

$$\begin{aligned} A &= -(\Delta U)_{S,V} = -(\Delta H)_{S,p} = -(\Delta A)_{T,V} \\ &= -(\Delta G)_{T,p}. \end{aligned} \quad (3)$$

Note that in this entry, A is the affinity and A , the **Helmholtz function** (work function.)

CHEMICAL CONSTANT. A constant occurring in the **vapor pressure equation** and determined by the introduction of an absolute entropy. (See **thermodynamics, third law of.**)

CHEMICAL EQUILIBRIUM. A system is said to be in chemical equilibrium where the **chemical affinities** of all the possible chemical reactions are equal to 0. As long as one may neglect possible secondary interactions between the reactants one can use the formula for the equilibrium constant K (see **chemical equilibrium, calculation of**) which is related to change in the Gibbs free energy ΔG by the formula

$$\beta \Delta G = -N \ln K,$$

where $\beta = 1/kT$ (k is Boltzmann's constant, T is the absolute temperature). This relation as well as the relation between K and the concentrations of the reactants can be derived by the method of **grand ensembles**. The same method can also be used to evaluate corrections for the case of non-ideal gases.

CHEMICAL EQUILIBRIUM, CALCULATION OF. This can be performed by using the method of **grand ensembles**, from which one obtains a formula for the equilibrium constant K , which is the ratio

$$K = \frac{\Pi C_i}{\Pi C_j},$$

where the C_i are the concentrations of the reactants on the one side of the reaction equation and the C_j those on the other side. Another formula for K is

$$K = \frac{\Pi Z_i}{\Pi Z_j},$$

where the Z_i and Z_j are the **partition functions** of the reactants. (See also **Saha equilibrium formula** and **chemical equilibrium.**)

CHEMICAL INTERACTION. The understanding of the types of bonds has improved to such a point in the last fifty years that it has become extremely difficult to distinguish between what used to be called chemical and physical interactions. An accurate definition of either term is practically impossible now.

If one limits the definition of physical interactions to the van der Waals forces only, one must define the ionic and metallic lattices as "chemical molecules." Even in the crystals of dipolar molecules, electrostatic interactions are important. If, on the other hand, one includes the electrostatic forces in the definition of "physical interactions," a major part of the bond energy of many molecules (NaCl for example) must be attributed to so-called physical interactions.

Steric factors (intramolecular van der Waals forces) affect the molecular structure and bond energy of many molecules; on the other hand, it is the hydrogen bonds, which are quasi-covalent in character (see **coordinate bonds**) which are largely responsible for the cohesion of water, HF, organic acids and alcohols in the liquid and solid state.

The classification of some interactions as chemical or physical is thus mainly a matter of convenience and tradition; it is more accurate to speak of the interaction as being mainly covalent, electrostatic, metallic or van der Waals in type. (See **bond types.**)

CHEMICAL POTENTIAL, INFLUENCE OF CURVATURE ON. Consider a small spherical drop of curvature r . Its **chemical potential** μ_r is related to the chemical potential μ_0 of a bulk liquid phase at the same temperature (for the bulk phase $1/r = 0$) by the relation

$$\mu_r - \mu_0 = \frac{2\gamma}{r} V \quad (1)$$

where V is the molar volume of the liquid (supposed to be independent of pressure) and γ , the surface tension. We see that the chemical potential increases when the drop becomes smaller.

CHEMICAL POTENTIALS. Chemical potentials are defined in terms of the entropy by

the relationship (see **thermodynamics, characteristic functions of**)

$$\mu_i = -T \left(\frac{\partial S}{\partial n_i} \right)_{U,V} \quad (1)$$

Apart from the factor T (the **absolute temperature**) the chemical potential is equal to the change of the entropy dS due to the introduction of the mole number dn_i into the system, at constant total energy U and volume V .

Other sets of independent variables than U and V are often much more convenient. One has also (see **thermodynamics, characteristic functions of**),

$$\begin{aligned} \mu_i &= \left(\frac{\partial U}{\partial n_i} \right)_{S,V} = \left(\frac{\partial H}{\partial n_i} \right)_{S,p} \\ &= \left(\frac{\partial A}{\partial n_i} \right)_{T,V} = \left(\frac{\partial G}{\partial n_i} \right)_{T,p} \end{aligned} \quad (2)$$

The first and last members of Equation (2) show that μ_i is the **partial molar quantity** associated with the Gibbs free energy, G . **Euler's theorem** gives then

$$G = \sum_i n_i \mu_i \quad (3)$$

The relation to **chemical affinity** is also very direct

$$A = - \sum_i \nu_i \mu_i \quad (4)$$

It follows that the condition for chemical equilibrium is

$$\sum_i \nu_i \mu_i = 0 \quad (5)$$

where the ν_i are **stoichiometric coefficients**. This formula expresses the **law of mass action**. Similarly the condition for two phases α and β to be in equilibrium with respect to species i is

$$\mu_i^\alpha = \mu_i^\beta \quad (6)$$

The chemical potential has then the same value in the two phases. (See also **membrane equilibrium; Gibbs-Duhem equation; ideal systems; absolute activity; thermal potential**.)

CHEMICAL REACTION RATE. The quantity ν defined by the equation:

$$\nu = d\xi/dt.$$

where ξ is the **extent of reaction**, and t , the time. (See **conservation of mass; extent of**

reaction; absolute reaction rate theory; equilibrium theory in chemical kinetics; collision theory of chemical kinetics.)

CHEMICAL REACTIONS, ORDER OF. See **order of chemical reactions**.

CHEMICAL STABILITY CONDITION. (See **thermodynamic stability conditions**.) The chemical stability condition expresses the stability of the system with respect to perturbations of the **chemical equilibrium**. At constant pressure and temperature the stability is expressed by

$$\left(\frac{\partial^2 G}{\partial \xi^2} \right)_{p,T} > 0 \quad (1)$$

where G is the Gibbs free energy (see **thermodynamics, characteristic functions of**) and ξ , the extent of reaction. This condition shows that $G(\xi)$ is minimum when the chemical equilibrium is stable. (See also **Chatelier (Le) theorem**.)

CHIEF RAY. See **principal ray**.

CHILD-LANGMUIR-SCHOTTKY EQUATION. See **perveance**.

CHIÓ'S METHOD (FOR EVALUATING A DETERMINANT). A method identical in principle with Gaussian elimination for **matrix inversion** and the solution of linear equations. If the elements are α_{ij} and $\alpha_{11} \neq 0$, then from the i th row subtract the first multiplied by α_{i1}/α_{11} . The result is a determinant of equal value with a zero in position $(i, 1)$. After this has been done for each row other than the first, the determinant reduces to one of lower order.

CHI-SQUARE. If a sample of n values is drawn from a **normal distribution** with variance σ^2 , and if the **variance** is estimated as

$$s^2 = \Sigma(x - \bar{x})^2 / (n - 1),$$

then the ratio $(n - 1)s^2/\sigma^2$ is known as χ^2 , and has the **probability function**

$$P(\chi^2)d\chi^2 = \frac{1}{\Gamma(\frac{1}{2}\nu)} e^{-\frac{1}{2}\chi^2} \left(\frac{1}{2}\chi^2\right)^{\frac{\nu}{2}-2} d\left(\frac{1}{2}\chi^2\right),$$

$$0 \leq \chi^2 \leq \infty,$$

when $\nu = (n - 1)$ is the **degrees of freedom**. This is a special case of the Pearson Type III

function; the probability integral is an **incomplete gamma function**.

If an hypothesis completely specifies the frequencies f_t to be expected in n classes, the goodness of fit of a sample providing frequencies f_o can be tested by calculating

$$\chi^2 = \sum \frac{(f_o - f_t)^2}{f_t}$$

and entering a table of χ^2 with $(n - 1)$ degrees of freedom. This quantity closely approximates the above distribution provided that none of the f_t 's are too small—say, less than 5; to avoid this it is often necessary to combine two or more classes with small expectations. If the hypothesis specifies a probability distribution in which p parameters have to be estimated from the sample in order to compute the expected frequencies, the degrees of freedom are reduced to $(n - p - 1)$.

With **discrete variates**, χ^2 provides a sensitive test of departure from the **Poisson distribution**. If we put

$$\chi^2 = (n - 1)s^2/\bar{x}$$

where \bar{x} is the sample mean and n the number of observations the standard distribution is closely followed for a true mean ≥ 2 .

A similar test can be applied to the **binomial distribution**. In this form, χ^2 is sometimes referred to as the *index of dispersion*.

The χ^2 distribution tends to normality for large values of ν . The usual tables do not extend above $\nu = 30$; for larger values, it is ordinarily sufficient to take $\sqrt{(2\chi^2)}$ as *normally distributed* with mean $\sqrt{(2\nu - 1)}$ and unit standard deviation.

CHOKING. The condition wherein the mass of a compressible fluid flowing through a duct has reached its maximum value. It is always associated with the attainment of sonic velocity (local Mach number = 1) in some cross section of the duct.

CHOLESKI'S METHOD (FOR INVERTING A POSITIVE DEFINITE HERMITIAN MATRIX A). This method is to express the matrix first in the form

$$A = R^*R$$

where R is upper triangular and R^* its conjugate transpose, and thence to compute R^{-1} and multiply by its conjugate transpose. The

method is mathematically equivalent to the method of elimination, but requires the extraction of n square roots.

CHORD. (1) A segment of a straight line between two specified points of intersection of the line with a given curve or surface. (2) In topology, an **element** belonging to the complement of a **tree**. (See also **pitch**.)

CHORD METHOD. A method for the calculation of collision probabilities, introduced by P. A. M. Dirac. The principal result is:

$$1 - P_0 = \frac{1}{\Sigma R_{av}} \int (1 - e^{-\Sigma R}) \phi(R) dR.$$

Here, P_0 is the first flight collision probability in a body characterized by macroscopic cross-section Σ and chord distribution function $\phi(R)$.

CHORD OF AIRFOIL. The section of any airfoil may be formed by superposing a symmetrical *fairing* on a curved *mean line*. In the figure, the broken curved line is the mean line and the chord, or chord line, is the straight line AB joining the ends of the mean line.

The chord of an airfoil section has sometimes been defined as the straight line joining the centers of curvature of the leading and trailing edges. For the usual airfoils of small camber, the difference between the two definitions is small.

CHRISTOFFEL (3-INDEX) SYMBOLS. Let g_{ij} and g^{ij} be the components in the coordinate system x of the covariant and contravariant **metric tensors** respectively. The quantities

$$\frac{1}{2} \left(\frac{\partial g_{ik}}{\partial x^j} + \frac{\partial g_{kj}}{\partial x^i} - \frac{\partial g_{ij}}{\partial x^k} \right)$$

are called the *Christoffel (3-index) symbols of the first kind*, or *three-index symbols of the first kind*. They are usually denoted $\Gamma_{k;ij}$, or $[ij,k]$. The quantities

$$\frac{1}{2} g^{km} \left(\frac{\partial g_{im}}{\partial x^j} + \frac{\partial g_{mj}}{\partial x^i} - \frac{\partial g_{ij}}{\partial x^m} \right)$$

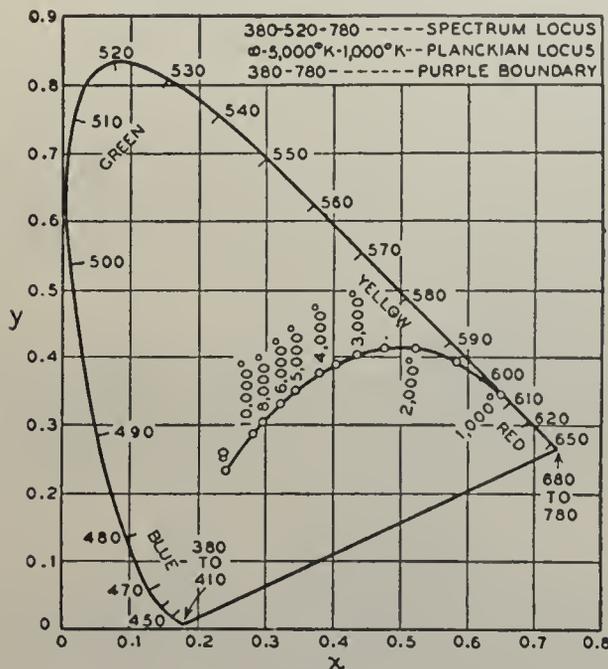

are called the *Christoffel (3-index) symbols of the second kind*, or *three-index symbols of the second kind*. They are usually denoted Γ_{ij}^k or $\{ij\}^k$.

CHROMATIC ABERRATION. The failure of all the light from one point of an object to form an image at a point because of the dispersion of the material of the lenses. The focal length of a lens is, in general, greater for red light (longer wavelength) than for blue light (shorter wavelength). Systems consisting entirely of reflection optics do not show chromatic aberration. Hence, reflection optics are used extensively in infrared instruments. With compound lenses a proper choice of kinds of glass and of lens curvatures can partially compensate for chromatic aberration over a not-too-large wavelength region.

CHROMATICITY. The color quality of a light definable by its **chromaticity coordinates**, or by its **dominant** (or **complementary**) **wavelength** and its **purity** taken together.

CHROMATICITY COORDINATES. The ratio of each of the three **tristimulus values** of a light to their sum.

CHROMATICITY DIAGRAM. A chromaticity diagram or color triangle is a plane diagram showing the results of mixing color

CIE (x,y) chromaticity diagram plotted in rectangular coordinates.

stimuli, every color being represented unambiguously by a single point on the diagram. The most common chromaticity diagram at present is the CIE (x,y) diagram, plotted in rectangular coordinates.

CHROMINANCE. The colorimetric difference between any color and a reference color of equal **luminance**, the reference color having a specified **chromaticity**. In three-dimensional color space, chrominance is a vector which lies in a plane of constant luminance. In that plane it may be resolved into components, called *chrominance components*.

CHRONOLOGICAL OPERATOR. The Dyson chronological operator P is defined as follows: Operating on a product of time-labeled operators, it rearranges them in the same order as the time sequence of their label, the latest one in time occurring first in the product

$$P(A_1(t_1) \cdots A_n(t_n)) = A_i(t_i)A_j(t_j) \cdots A_l(t_l) \quad t_i > t_j > \cdots > t_l. \quad (1)$$

The Wick chronological product T is defined in the same way as Dyson's chronological operator P , except that the T operator includes in its definition the sign of the permutation of fermion operator factors in going from the left to the right-hand side of (1), i.e.,

$$T(A_1(t_1) \cdots A_n(t_n)) = \delta_p A_i(t_i) \cdots A_l(t_l) \quad t_i > \cdots > t_l$$

δ_p is ± 1 according to whether the permutation is even or odd.

CIE-DISTRIBUTION COEFFICIENTS. The **tristimulus values** of the spectral components of an **equi-energy spectrum** in the CIE (XYZ) system. These coefficients $\bar{x}_\lambda, \bar{y}_\lambda, \bar{z}_\lambda$ are so chosen that the values of \bar{y}_λ are identical with the relative luminous efficiencies V_λ .

CIE (1931) STANDARD COLORIMETRIC OBSERVER. The receptor of radiation whose colorimetric characteristics correspond to the distribution coefficients $\bar{x}_\lambda, \bar{y}_\lambda, \bar{z}_\lambda$ adopted by the International Commission on Illumination in 1931.

CIE (1931) STANDARD COLORIMETRIC SYSTEM. A linear and single-valued colorimetric system for evaluating any spectral distribution of energy with the aid of three functions of wavelength, the distribution coefficients: $\bar{x}_\lambda, \bar{y}_\lambda, \bar{z}_\lambda$.

CIRCLE, GEODESIC. See **geodesic circle on a surface**.

CIRCLE OF CONFUSION. See **circle of least confusion**.

CIRCLE OF CONVERGENCE. See **convergence**.

CIRCLE OF CURVATURE. See **curvature**.

CIRCLE OF LEAST CONFUSION. Due to imperfect imagery and to the fact that the images of points at different object distances are commonly observed on a single image-plane (e.g., the film in a camera), the image of a **point object** is, in general, a small region approximately circular, the *circle of confusion*, or blur circle. The smallest blur circle as the image plane is varied is the circle of least confusion. In thin lens theory the center of the circle of least confusion is the midpoint of the **tangential** and **sagittal foci** on a ray. The **locus of centers** is the surface of least confusion. For a thin lens this surface is a sphere centered at the center of the lens.

CIRCLE, OSCULATING. See **curvature**.

CIRCLE POLYNOMIALS. The polynomials

$$R_n^m(x) = \sum_{k=0}^{\frac{1}{2}(n-m)} \frac{(-1)^k (n-k)! x^{n-2k}}{k! \{\frac{1}{2}(n+m) - k\}! \{\frac{1}{2}(n-m) - k\}!}$$

were used by F. Zernike in his classic paper (1934) on the knife-edge test and the phase-contrast method in optics. The R_n^m are orthogonal and are normalized upon multiplying by the factor $(2n+2)^{-1/2}$. Thus it follows that

$$R_n^m(r) \cos m\theta, \quad R_n^m(r) \sin m\theta,$$

for $n \geq m \geq 0$, $n - m$ even, is orthogonal over the unit circle. This set is also complete. The aberration function of an axially symmetrical optical system can be expanded in terms of the functions $R_n^m(r) \cos m\theta$. Using this expansion, small aberrations of the same generic type may be balanced against each other to obtain maximum **Strehl definition**. (See **Nijboer-Zernike aberration functions**.)

CIRCUIT. A **connected graph** or **subgraph** in which each **vertex** is of degree two. It can be shown that **loop** and **circuit** are equivalent concepts. Unfortunately the words **circuit** and **network** have been used interchangeably in the older electrical engineering literature and has been a constant source of confusion. The

above definition substitutes precision for vagueness, and at the same time retains the full intuitive flavor of the word. (See also entries under **network**.)

CIRCUIT, ALTERNATING CURRENT. See **alternating current circuit**.

CIRCUIT ELEMENT. See **element, circuit**.

CIRCUIT MATRIX. See **matrix, circuit**.

CIRCUIT, ORIENTED. The e elements of a **circuit** of a *finite graph* (see **graph, finite**) can be arranged in cyclic order either as $\epsilon_1, \epsilon_2, \dots, \epsilon_e, \epsilon_1$ or $\epsilon_e, \epsilon_{e-1}, \epsilon_{e-2}, \dots, \epsilon_1, \epsilon_e$ and these are, to within cyclic permutations, the only cyclic orders possible. If one of these two possible orientations is assigned to the circuit, the circuit is oriented accordingly.

CIRCUITS, FUNDAMENTAL. Let G be a connected graph containing v vertices and e edges and T a **tree** of G . The end points of each **chord** (with respect to T) are connected by a unique *tree path*. A chord together with its corresponding tree path forms a fundamental circuit. The number of fundamental circuits is equal to the number of chords or $e - v + 1$. If G is finite but not *connected* it consists of P maximal connected subgraphs, each of which possesses a **tree** and its associated fundamental circuits.

CIRCULAR APERTURE. For the **Fraunhofer diffraction** pattern of a circular aperture, see the discussion of the **Airy disc**.

CIRCULAR CURVATURE. See **curvature**.

CIRCULAR DICHROISM. The unequal absorption of the two circular components of plane-polarized light in an optically active medium.

CIRCULAR FUNCTION. A **trigonometric function**.

CIRCULAR MOTION, UNIFORM. See **uniform circular motion**.

CIRCULAR POINT (ON A SURFACE). A point at which the principal curvatures (see **curvature**) of the surface are equal.

CIRCULAR POLARIZATION. Polarization with a cycle that is a circle. (See **polarization cycle**.)

CIRCULATION. The circulation around a closed path of any vector field is the line integral of that vector around the path. The vector ordinarily considered is the fluid velocity, and the circulation is

$$\oint \mathbf{v} \cdot d\mathbf{s}$$

where \mathbf{v} is the fluid velocity, and $d\mathbf{s}$ is a vector element of the path. It is equal to the flux of vorticity through the circuit $\int \boldsymbol{\omega} \cdot d\mathbf{S}$ where $d\mathbf{S}$ is the element of any surface bounded by the circuit.

CIRCULATION THEOREM (BJERKNES).

A theorem stating that the rotation of a mass of horizontally moving air in the atmosphere is inversely proportional to the area of its projection on the equatorial plane. Application of this theorem is extremely limited because it assumes strictly horizontal motion, and when subsidence or upward motion occur much greater changes in rotation are produced than are due to changes in latitude as envisaged in the theorem. The theorem is, however, of some historical interest.

CIRCULATION THEOREM (KELVIN). In an inviscid fluid in which the density is uniquely determined by the pressure, and any body forces are conservative (and proportional to the mass to which they are applied), the **circulation** round a circuit always composed of the same fluid particles remains constant during the motion, i.e.,

$$\frac{D}{Dt} \oint \mathbf{v} \cdot d\mathbf{S} = 0.$$

In an inviscid fluid the resultant of conservative body forces (e.g., gravity) and inertia forces is seen from the equation of motion to be in the direction of the pressure gradient, which, in the above case, is parallel to the density gradient: these forces cannot therefore change the vorticity. The only means of changing the vorticity is by distorting the fluid; but if the circuit moves with the fluid the flux of vorticity remains constant because the vortex lines move with the fluid.

CIRCULATORY INTEGRAL. See **integral, circulatory.**

CIRCUMHOROPTER. See **Vieth-Müller circle.**

CLAIRAUT EQUATION. A first-order differential equation

$$y = xp + f(p)$$

where $p = dy/dx$. Its general solution is $y = cx + f(c)$. It also has a (singular) solution obtained by elimination of p from the equations

$$y = px + F(p); \quad x + F'(p) = 0.$$

CLAPEYRON EQUATION. See **Clausius-Clapeyron equation.**

CLAPEYRON THEOREM. The equation of three moments was given by Clapeyron and Bertot:

$$M_{n-1} \frac{l_n}{E_n I_n} + 2M_n \left[\frac{l_n}{E_n I_n} + \frac{l_{n+1}}{E_{n+1} I_{n+1}} \right] + M_{n+1} \frac{l_{n+1}}{E_{n+1} I_{n+1}} = - \frac{6A_n a_n}{E_n I_n l_n} - \frac{6A_{n+1} b_{n+1}}{E_{n+1} I_{n+1} l_{n+1}}$$

where $n - 1, n, n + 1$ are three adjacent supports of a continuous beam of constant flexural rigidity EI span by span. $A_n a_n$ is the moment of the lateral load moment diagram between $n - 1$ and n about $n - 1$ and $A_{n+1} b_{n+1}$ of the lateral load moment diagram between n and $n + 1$ about $n + 1$.

CLASS. A complete set of mutually conjugate elements of a group.

CLASSICAL. The adjective "classical" is in general applied to any physical theory or treatment that is based on the assumption of Newtonian mechanics. Such treatments include all electrical and magnetic discussions based on the **Coulomb law**, the **Ampere law**, and the **Maxwell equations**. Classical theory is usually to be distinguished from **relativity theory** and **quantum theory**, although relativistic treatments not involving the quantum hypothesis are occasionally referred to as classical, as are treatments involving quantum theory but not **quantum mechanics**.

CLASSICAL APPROXIMATION. See **Wentzel-Kramer-Brillouin approximation.**

CLASSICAL ELASTICITY THEORY. The theory of the relation between the forces and deformation in bodies of elastic or perfectly plastic material, in which it is assumed that the

displacement gradients are infinitesimally small. The strain-energy function is then a quadratic function of the displacement gradients, the stress components are linear functions of the displacement gradients and, throughout the theory, terms of the second and higher degrees in the displacement gradients are neglected in comparison with those of the first degree. Also called *linear elasticity theory*.

CLASSICAL ELECTRON ENERGY. See **electron energy (classical)**.

CLASSICAL ELECTRON ORBIT. See **electron orbit (classical)**.

CLASSICAL ELECTRON RADIUS. See **electron radius (classical)**.

CLASSICAL ELECTRON THEORY. The theory, primarily due to H. A. Lorentz (1906), to account for the varied phenomena (e.g., optics, electricity, chemistry) involving electrons. The fundamental assumptions of the theory were the following: The electron is an elementary particle with a charge e and a mass m ; the motion of the electrons is determined by classical mechanics with the force acting on the electron given by the expression

$$\mathbf{F} = e\mathbf{E} + \frac{e}{c}\mathbf{v} \times \mathbf{H}$$

where e and \mathbf{v} are the charge and velocity of the electron and \mathbf{E} and \mathbf{H} the electric and magnetic field strength. The dynamics of the electromagnetic field in turn is governed by Maxwell's equations

$$\frac{1}{c} \frac{\partial \mathbf{E}}{\partial t} - \nabla \times \mathbf{H} = 4\pi \mathbf{j} \quad \nabla \cdot \mathbf{E} = 4\pi \rho$$

$$\frac{1}{c} \frac{\partial \mathbf{H}}{\partial t} + \nabla \times \mathbf{E} = 0 \quad \nabla \cdot \mathbf{H} = 0.$$

The source of the field strengths are the charge density ρ and current density \mathbf{j} which are produced by the electrons.

To account for the constitution of matter Lorentz assumed that there are several electrons in each atom which are elastically bound to an equilibrium position and thus are able to perform harmonic vibrations with a given frequency. In electric conductors additional electrons were assumed to move freely about. With these assumptions Lorentz was able to

account qualitatively and often semi-quantitatively for such diverse effects as the absorption, scattering and refraction of light by matter, the Zeeman effect, the optical properties of metals and many more.

In the explanation of the aforementioned phenomena it is possible to consider the electron as a point particle. Lorentz investigated how far such a picture is tenable. If the electric and magnetic energy of the electron's own field is given by E_{em} , then from Einstein mass-energy relation, $E = mc^2$, this electromagnetic self-energy will contribute to the mass, m , of the electron an amount E_{em}/c^2 and one can write

$$m = m_o + E_{em}/c^2$$

where m_o is the "mechanical" mass of the electron, by which is meant all the contributions which are not of electromagnetic origin. For an electron of radius a the electrostatic self-energy is proportional to e^2/a , and thus in the limit as $a \rightarrow 0$ (point-electron) the self-energy is infinite. Within the framework of the Lorentz theory one is forced to abandon the motion of a point electron. In fact, no classical theory is able to account for or answers the questions concerned with the structure of the electron. Attempts at describing the electron as a charged sphere of radius $r_o = e^2/mc^2$, whose mass is entirely of electromagnetic origin runs into the difficulty that it cannot be stable (Earnshaw's theorem). Also this procedure does not allow a consistent explanation of the mass of a moving electron, since the electromagnetic field that the moving particle generates carries energy and momentum which are related to each other differently from the energy and momentum of a particle.

CLASSICAL LIMIT. See **principle of correspondence**.

CLASSICAL STATISTICS. See **Boltzmann statistics**.

CLAUDE REFRIGERATOR. See **reversed Rankine cycle**.

CLAUSIUS. The unit of **entropy** in calculations in which heat is measured in calories and temperature is measured on the Kelvin thermodynamic temperature scale. Hence 1 clausius = 1 cal/°K.

CLAUSIUS-CLAPEYRON EQUATION. An equation relating the latent heat l to the dis-

continuous change in volume accompanying a phase change and to the slope dp/dT of the pressure-temperature relation for the respective phase equilibrium:

$$l = (v'' - v')T \frac{dp}{dT}.$$

Here v'' is the specific volume of one phase, v' is the specific volume of the other phase, and l is reckoned algebraically. For example, for evaporation $l > 0$; $v'' > v'$.

When one phase (say v'') is a vapor, the equation can be used to calculate the vapor pressure curve approximately. For evaporation or sublimation $v'' \gg v'$, and the equation becomes

$$\frac{dp}{p} = \frac{l}{R} \frac{dT}{T^2}$$

where R is the gas constant for the vapor phase assumed to obey the perfect gas law $PV = RT$. This can be integrated with a suitable assumption concerning l . For $l = \text{const.}$, we have

$$\log_e p = -\frac{l}{RT} + \text{const.}, \quad (\text{a})$$

and for $l = a - bT$, we have

$$\log_e p = -\frac{a}{RT} - \frac{b}{R} \log_e T + \text{const.} \quad (\text{b})$$

Equation (a) shows that a plot of a sublimation or a vapor pressure curve in the coordinates $\log_e p$, T^{-1} will yield approximately a straight line whose slope is proportional to the latent heat. Equations (a) or (b) can be used for the interpolation of experimental results in ranges sufficiently far removed from the critical point where the assumptions break down.

A similar relation is valid for chemical reactions in the gaseous phase.

CLAUSIUS CONDITION. If $\Delta\sigma$ is a line element inclined at an angle ϕ to the normal plane of the principal ray of a pencil of angular half-aperture θ in object space and if n , n' are the indices in object, image space, respectively, then in order that the image of $\Delta\sigma$ be a line element in image space $\Delta\sigma'$ with corresponding angles ϕ' , θ' it is sufficient that

$$(n \cos \phi \sin \theta) \Delta\sigma = (n' \cos \phi' \sin \theta') \Delta\sigma'.$$

This is Clausius' condition for the sharp imagery of curves by an axially symmetrical optical system.

CLAUSIUS EQUATION OF STATE. A form of the equation of state, relating the pressure, volume, and temperature of a gas, and the gas constant. The Clausius equation applies a correction to the van der Waals equation to correct the pressure-correction term a for its variation with temperature. The Clausius equation takes the form

$$\left[p + \frac{a}{T(V+c)^2} \right] (V-b) = RT$$

in which p is the pressure of the gas, T is the absolute temperature, V is the volume, R is the gas constant, b is a constant, a is a temperature-dependent constant, and c is a function of a and b .

CLAUSIUS EQUATION OF STATE FOR STEAM. As applied to steam, the Clausius equation of state takes the form

$$\left[p + \frac{\phi(T)}{(V+c)^2} \right] (V-b) = RT'$$

or

$$p(V-b) = RT - \phi(T) \frac{V-b}{(V+c)^2}.$$

In the lower ranges of pressures and temperatures this can be simplified to

$$V-b = \frac{RT}{p} - \psi(T).$$

(See also Berthelot equation.)

CLAUSIUS EQUATIONS. The Clausius equations give the general relations which exist between the thermal coefficients. For the variables T , p , and ξ (extent of reaction) they are

$$\left(\frac{\partial C_{p,\xi}}{\partial p} \right)_{T,\xi} = \left[\frac{\partial(h_{T,\xi} + V)}{\partial T} \right]_{p,\xi} \quad (1)$$

$$\left[\frac{\partial h_{T,p}}{\partial T} \right]_{p,\xi} = \left(\frac{\partial C_{p,\xi}}{\partial \xi} \right)_{T,p} \quad (2)$$

$$\left(\frac{\partial h_{T,p}}{\partial p} \right)_{T,\xi} = \left[\frac{\partial(h_{T,\xi} + V)}{\partial \xi} \right]_{T,p}. \quad (3)$$

The second equation is especially important; it relates the temperature coefficient of the

heat of reaction to the heat capacities of the components which take part in the reaction. It may also be written

$$\frac{\partial}{\partial T} h_{T,p} = \sum_i \nu_i c_{p,i} \quad (4)$$

where $c_{p,i}$ is the partial molar specific heat at constant pressure of component i (see **partial molar quantities**) and ν_i the **stoichiometric coefficient** of i in the reaction.

Equations (2) and (4) are also called the *Kirchhoff equations*.

Similar equations exist for the thermal coefficients in variables V , T , ξ .

For non-reactive systems consisting of pure substances, equation (1) above gives

$$\left(\frac{\partial C_p}{\partial p}\right)_T = -T \left(\frac{\partial^2 V}{\partial T^2}\right)_p.$$

CLAUSIUS FORMULATION OF THE SECOND LAW OF THERMODYNAMICS.

Clausius derived the full contents of the second law of thermodynamics from the following statement of experimental fact: Heat cannot pass spontaneously from a body of lower temperature to a body of higher temperature. For a comparison with other statements, see second law of **thermodynamics**.

CLAUSIUS INEQUALITY. The statement that the **Clausius integral** taken around any cycle is negative, or

$$\oint \frac{dQ}{T} \leq 0$$

where the sign of equality refers to *reversible* cycles only. It is a consequence of the second law of **thermodynamics**. Alternatively, depending on the sequence in the exposition of the second law, it plays an important part in the argument. (See **thermodynamics, second law of**.)

CLAUSIUS INTEGRAL. The expression

$$\int_1^2 \frac{dQ}{T}$$

Along any *reversible* path, the Clausius integral is independent of the path, and hence

$$\oint \frac{dQ}{T} = 0,$$

or

$$dS = \frac{dQ}{T},$$

which can be used as a definition of entropy. (See **Clausius inequality; thermodynamics, second law of**.)

CLAUSIUS-MOSSOTTI EQUATION. The **polarizability** α of simple *non-polar* molecules and atoms can be calculated from the density N_o , in particles per unit volume, and from the static dielectric constant ϵ_s by the Clausius-Mossotti equation

$$\frac{\epsilon_s - 1}{\epsilon_s + 2} = -\frac{4\pi}{3} N_o \alpha. \quad (1)$$

For a constant density, the dielectric constant is, according to (1), practically independent of temperature, and, at constant temperature, the dielectric constant of a gas depends strongly on the pressure. This formula is valid as long as the short range intermolecular forces can be neglected (see **internal fields in dielectrics**).

An alternate form for (1) is:

$$\frac{\epsilon_s - 1}{\epsilon_s + 2} \frac{M}{\rho} = [P] \quad (2)$$

where M is the molecular mass, ρ the density, and $[P] = \frac{4\pi}{3} N\alpha$ is the *molar polarization* (N is Avogadro's constant).

In this form, the Clausius-Mossotti equation is practically identical with the *Lorentz-Lorenz relation*:

$$\frac{n^2 - 1}{n^2 + 2} \frac{M}{\rho} = [R]$$

where n is the index of refraction, $[R] = \frac{4\pi}{3} N\alpha(\omega)$, in the molar refraction, and $\alpha(\omega)$ is the polarizability for an electrical field of angular velocity ω . In fact, the Clausius-Mossotti equation is the limiting value of the Lorentz-Lorenz equation for non-polar substances and for $\omega \rightarrow 0$, since, according to Maxwell's law, the static dielectric constant can then be identified with the square of the index of refraction for an electromagnetic field of 0 frequency.

CLAUSIUS-RANKINE CYCLE. See **Rankine cycle**.

CLAUS STRUCTURE. See **benzene, structures of**.

CLEAR. To restore a storage or memory device in a digital computer to a prescribed state, usually that denoting zero. (See also **reset**.)

CLEARANCE RATIO. See **clearance volume**.

CLEARANCE VOLUME. The volume V_c contained between the piston and cylinder head of a reciprocating engine when the piston is at inner dead center position (maximum travel on inward stroke). The ratio of clearance volume V_c to swept volume V_s is known as the *clearance ratio*

$$\epsilon_o = V_c/V_s.$$

CLEBSCH-GORDAN COEFFICIENTS. Coefficients $C_{jj'}(JMmm')$ in

$$\mathcal{Y}_{J_{jj'}}^M = \sum_{m=-j}^j \sum_{m'=-j'}^{j'} C_{jj'}(JMmm') \mathcal{Y}_{jm}(1) \mathcal{Y}_{j'm'}(2)$$

where

$$\begin{aligned} J_z^{(1)} \mathcal{Y}_{jm}(1) &= m \mathcal{Y}_{jm}(1), \\ J_z^{(2)} \mathcal{Y}_{j'm'}(2) &= m' \mathcal{Y}_{j'm'}(2), \\ \{J^{(1)}\}^2 \mathcal{Y}_{jm}(1) &= j(j+1) \mathcal{Y}_{jm}(1), \\ \{J^{(2)}\}^2 \mathcal{Y}_{j'm'}(2) &= j'(j'+1) \mathcal{Y}_{j'm'}(2) \end{aligned}$$

and

$$\begin{aligned} \{J_z^{(1)} + J_z^{(2)}\} \mathcal{Y}_{J_{jj'}}^M &= M \mathcal{Y}_{J_{jj'}}^M, (M = m + m') \\ \{J^{(1)} + J^{(2)}\}^2 \mathcal{Y}_{J_{jj'}}^M &= J(J+1) \mathcal{Y}_{J_{jj'}}^M, \end{aligned}$$

the operators $J^{(1)}$, $J^{(2)}$ being vector **angular momentum operators**.

CLERK-MAXWELL RELATION. See **Maxwell relation**.

CLOCK PARADOX. If two identical clocks A , B are synchronized and A is accelerated arbitrarily and then brought back to compare with B , which has not been accelerated, then A will record a shorter time interval than B . This conclusion is a consequence of, and is understandable in terms of, relativity theory:

$$t_B = t_A \left(1 + \frac{v^2}{2c^2} \right).$$

t_A is the time interval as it appears to A and t_B is the time interval as it appears to B . v is the relative velocity of A with respect to B during its unaccelerated motion. (See also **relativity, general**.)

CLOSED. A set of points in a **topological space** is closed if it contains all its limit points.

A set of functions $f_1, f_2, \dots, f_n, \dots$ in **Hilbert space** is closed if every function g in the space can be approximated in the form

$$g = a_1 f_1 + a_2 f_2 + \dots + a_n f_n + \dots,$$

with suitable constants a_i .

CLOSED CURVE. See **curve**.

CLOSED EDGE TRAIN. See **edge train, closed**.

CLOSED LOOP. (1) Portion of a **Feynman diagram** describing the virtual creation of a number of electron-positron pairs together with the annihilation of all of them, as for example in the scattering of light by light. (2) See **contour; Ampere law**.

CLOSED QUADRATURE FORMULA. A quadrature formula which explicitly includes the values of the ordinates at the end points, to be contrasted with an **open quadrature formula** in which the ordinate of at least one end point does not appear. Closed formulas are used as **correctors**, open formulas as **predictors**, in the numerical solution of **ordinary differential equations**.

CLOSED SHELLS. If particles obeying **Fermi-Dirac statistics** (i.e., electrons or nucleons) move to a first approximation independently of each other in orbits about a common central field of force, each particle will possess certain discrete energy levels characterized by definite values of the angular momentum l . The **Pauli principle** restricts the number of identical particles having a given energy and the angular momentum to a maximum of $2(2l + 1)$. Such a collection of $2(2l + 1)$ identical particles is called a closed shell, since no further particles having the same energy and angular momentum can be added to it. Owing to the similarity of the radial wave functions of the particles in a closed shell, the structure acquires a special stability. The term is usually used in a slightly enlarged sense, to take account of all the particles allowed by the Pauli principle to occupy a group of levels lying close together in energy. Thus, for example, in a hydrogenic potential ($V = e^2/r$) the $2s$ and $2p$ levels are degenerate. The corresponding closed shell would be considered to be made up of all the particles, 8 in this case, which can simultaneously be put into these two levels. In the

case of light atoms whose potentials do not differ too much from the hydrogenic potential, one obtains closed shells of electrons corresponding to the filling of the 1s level (atomic number $Z = 2$, i.e., He), then the 2s and 2p levels are filled at $Z = 10$ ($= 2 + 8$), i.e., at Ne. In this way one obtains the series of noble gases He, Ne, Ar, Kr, Xe, and Rn. In a similar manner, one obtains especially stable nuclei containing 2, 8, 20, 28, 50, 82, or 126 neutrons or protons. (See **magic numbers**.)

CLOSED SYSTEMS. Thermodynamic systems which can exchange energy but not matter with the outside world. (See also **isolated systems**; **open systems**; **thermodynamic systems**.)

CLOSURE. The closure of a set of points is the set containing the given set and all its limit points. (See **topological space**.)

CLOTHOID. See **Cornu spiral**.

CLUSTER. (1) A group of atoms in a gas where each of the atoms in the group can be reached from any other one by traveling over a chain of atoms, of which any two consecutive atoms are lying within each other's sphere of action. (2) A small group of liquid molecules with much the same spatial arrangement as in a solid crystal. Clusters are found in liquids for temperatures not far removed from the melting point.

CLUSTERING PHENOMENA IN GASES. At any finite temperature, and especially near the condensation point, real gases contain clusters of atoms.

CLUSTER INTEGRALS. Integrals over clusters of atoms occurring in the Mayer theory of virial coefficients.

CLUSTERS, STAR. See **star clusters**.

CLUSTER THEORY OF VIRIAL COEFFICIENTS. In statistical mechanics the virial coefficients are evaluated by considering clusters of atoms.

c-NUMBER. Physical quantities correspond in quantum mechanics to linear operators which do not commute in general. Ordinary numbers which commute with all operators are called sometimes c-numbers to distinguish them from the operator quantities.

COANDA EFFECT. When a two-dimensional jet of fluid is discharged tangentially along a convex solid surface, the jet tends to follow the curve of the boundary. The jet may remain attached to the surface for a considerable distance and be deflected through a large angle. Deflections up to about 180° have been observed.

COCHRAN THEOREM. A theorem in statistics concerning the distribution of quadratic forms. If x_i ($i = 1, 2, \dots, n$) are independent standardized normal variates and q_j ($j = 1, 2, \dots, k$) are quadratic forms in the x 's with ranks n_j ($j = 1, 2, \dots, k$) and if

$$\sum_{j=1}^k q_j = \sum_{i=1}^n x_i^2,$$

then a necessary and sufficient condition for the q_j to be distributed as χ^2 (see **chi-square**) with n_j degrees of freedom respectively is that

$$\sum_{j=1}^k n_j = n.$$

CODAZZI EQUATIONS OF THE SURFACE. See **equations of Gauss and Codazzi**.

CODDINGTON SHAPE AND POSITION FACTORS. Coddington introduced dimensionless factors in third order optical theory that lead to expressions for aberrations in terms of homogeneous polynomials. The shape factor of a lens is

$$\sigma = \frac{r_2 + r_1}{r_2 - r_1}$$

where r_1 and r_2 are the radii of the first and second surface of the lens. The position factor of a lens is

$$\tau = \frac{q - v}{q + p}$$

where p and q are object and image distances.

CODE. For any given **stored-program computer**, each operation of its repertory is represented by a code symbol, which is a particular sequence of characters. Also each cell in the storage unit is designated by a code symbol, the **address** of the cell. An ordered sequence of symbols representing operations and operands (in the form of addresses) when represented in the storage unit, directs the computer to perform the operations upon the operands

in the specified sequence, and this ordered set of code symbols is a machine code, and it defines a **routine** (or **program**).

If more than one address is used, the code is called a *multiple-address code*. In a typical instruction of a four-address code the addresses specify the location of two operands, the destination of the result, and the location of the next instruction in the sequence. In a typical three-address code, the fourth address specifying the location of the next instruction is dispensed with and the instructions are taken from storage in a preassigned order.

In a typical one-address or single-address code, the address may specify either the location of an operand to be taken from storage, the destination of a previously prepared result, or the location of the next instruction. The arithmetic element usually contains at least two storage locations, one of which is an accumulator. For example, operations requiring two operands may obtain one operand from the main storage and the other from a storage location in the arithmetic element which is specified by the operation part.

CODE, ALPHANUMERIC. A binary coded decimal system in which the space combinations are employed to represent the alphabet, quotation marks, and other special symbol requirements.

CODE, BINARY. Any code employing two distinguishable types of **code elements**.

CODE CHARACTER. A particular arrangement of code elements used in a code, to represent a single value.

CODE ELEMENT. One of the discrete events in a code, such as the presence or absence of a pulse, or of a dot or a dash or space as used in a Morse code.

CODE, EXCESS-THREE. A number code in which the decimal digit n is represented by the four-bit binary equivalent of $n + 3$.

CODE, HOLLERITH. The IBM card code in which information is represented on a punched card by the position and number of punches.

CODE OPERATION. (1) The list of operation parts occurring in an instruction code, together with the names of the corresponding operations (e.g., "add," "unconditional trans-

fer," "add and clear," etc.). (2) Synonym for operation part of an instruction.

COEFFICIENT. (1) An algebraic factor. (2) A quantity or parameter characteristic of a substance or a system. With the exception of some entries immediately following, coefficients are listed in this book under the appropriate characteristics.

COEFFICIENT OF ASSOCIATION. See **association**.

COEFFICIENT OF COMPRESSIBILITY. See **compressibility**.

COEFFICIENT OF DETERMINATION. See **determination, coefficient of**.

COEFFICIENT OF HEAT TRANSFER. See **heat transfer**.

COEFFICIENT OF MUTUAL DIFFUSION. See **mutual diffusion, coefficient of**.

COEFFICIENT OF PERFORMANCE. See **refrigeration; Carnot cycle**.

COEFFICIENT OF PROBABILITY. Gibbs' name for the **ensemble density**.

COEFFICIENT OF TENSION. The relative change of pressure with temperature at constant volume of a pure substance, or the expression

$$\beta = \frac{1}{p} \left(\frac{\partial p}{\partial T} \right)_v$$

when p is given at an arbitrary reference state. For a **perfect gas** the coefficient of tension β is equal to the **coefficient of thermal expansion** α , and for both we have

$$\alpha = \beta = \frac{1}{T}$$

COEFFICIENT OF THERMAL CONDUCTIVITY. See **Fourier law**.

COEFFICIENT OF THERMAL EXPANSION. (Also called coefficient of expansion.) The expression

$$\alpha = \frac{1}{V} \left(\frac{\partial V}{\partial T} \right)_p$$

or the relative rate of change of volume with temperature at constant pressure.

For perfect gases

$$\alpha = \frac{1}{T}$$

In general there is no particular advantage in using the coefficient of expansion to describe the properties of gases in preference to the **equation of state**, but in the case of liquids or solids the coefficient of thermal expansion is independent of pressure (except for very high pressures) and nearly independent of temperature (over sufficiently wide temperature ranges). When this is the case, the use of the coefficient of thermal expansion offers some practical advantages.

COEFFICIENT OF VARIATION. The coefficient of variation of a distribution, V , is defined as the **standard deviation** divided by the **mean**,

$$V = \frac{\sigma}{m}$$

It is appropriate only where m is not close to zero. Some authors define it as

$$V = 100 \frac{\sigma}{m}$$

in order to avoid decimals.

COEFFICIENT OF VISCOSITY. See **viscosity**, **kinetic theory of**.

COERCIVE FORCE, H_c . The magnetizing force at which the magnetic flux density is zero when the material is in a symmetrical cyclically magnetized condition. Coercive force is not a unique property of a magnetic material, but depends upon the conditions of measurement.

COERCIVITY. The property of a magnetic material measured by the **coercive force** corresponding to the saturation induction for the material. This is a quasi-static property only.

COFACTOR. The cofactor of an element a_{ik} of a square **matrix** is the complementary minor of a_{ik} , namely the determinant of the matrix obtained by crossing out the i^{th} row and the k^{th} column, multiplied by $(-1)^{i+k}$.

COGRADIENT. A word used to describe the relationship of two tensorial quantities which have the same transformation properties. (See **tensor field**; **contragradient**.)

COHERENT RADIATION. In coherent radiation there is a definite statistical correlation between radiation at different positions in a cross section of the radiant energy beam (or beams), whereas in noncoherent radiation these relationships are random. For example, a slit is filled with approximately coherent radiation when it receives light from a small distant source. Interference bands are observed only between coherent beams. (See **partial coherence**.)

COHESION. Forces between the particles of any given mass by virtue of which it resists physical disintegration. The connotation of the term cohesion implies a difference from adhesion, in which the forces are operative chiefly in surfaces.

COHESION ENERGY. See **energy**, **cohesion**.

COHESION, FORCES OF. Attractive forces acting between molecules; these appear when the distance between two molecules is greater than a certain magnitude; below that magnitude the **intermolecular forces** are *repulsive*.

COHESION PRESSURE. The addition term a/V^2 used in the **van der Waals equation** to correct the pressure by adding the attractive force of the molecules. V is the volume of the gas, and a is approximately constant for a given gas.

COHESION, WORK OF. The work required to separate a column of liquid 1 cm^2 in cross section into two parts. It is given by

$$W_c = 2\gamma_L$$

γ_L is the **surface tension** between liquid and vapor in ergs per cm^2 .

COLLAPSE AND COLLAPSE LOAD. The term collapse is applied primarily to excessive deflection or actual collapse in the plastic range. Often perfect plasticity is assumed. (See **limit theorems**.)

COLLAPSE, INCREMENTAL. When live loads of sufficient intensity are applied repeatedly to a structure, it is possible that plastic deformation will continue to occur and that deflections will grow. If the deflections grow without limit the structure is said to suffer incremental collapse. (See **shakedown**.)

COLLECTIVE ELECTRON THEORY OF FERROMAGNETISM. The electrons re-

sponsible for ferromagnetism are supposed to be more or less free. Parallel alignment of their spins is favored by the **exchange interaction**. With the introduction of **Fermi-Dirac statistics**, it is possible to show that a transition from the ferromagnetic to the paramagnetic state occurs at a certain temperature, which is identified with the **Curie point**.

COLLINEATION EQUATIONS OF OPTICS. The mapping of object points into image points in **Gaussian optics** is a non-singular collineation, so the equations of this transformation in an appropriate coordinate system are the collineation equations of optics. One form of these equations is discussed under the **paraxial ray tracing equations**.

COLLISION. Any **interaction** between free particles, aggregates of particles, or rigid bodies in which they come near enough to exert a mutual influence, generally with exchange of energy. The term does not necessarily imply actual contact. The process is always subject to conservation of momentum, and in an elastic collision (see **collision, elastic** and **collision, inelastic**) also to conservation of energy. In the latter case, if the initial velocities are given, the velocities of the bodies after collision can be calculated by applying these two conservation principles. The subject is of special significance in atomic physics, where a collision is defined as a close approach of two or more photons, particles, atoms or nuclei during which an interchange occurs of charge, energy, momentum or other quantities.

COLLISIONAL TRANSFER. The momentum or energy transfer in a fluid can be resolved into two main contributions:

(1) Energy and momentum are carried through a surface element dS by those molecules whose trajectories cross this surface. This is the main mechanism of heat and momentum transfer in dilute gases, i.e., in the density domain for which the **Boltzmann equation** is valid.

(2) At higher densities, one must also consider the collisional transfer which becomes increasingly important: it is the instantaneous transfer of energy and momentum from the *center* of one molecule to the *center* of the other during the collision. If these centers occupy opposite sides of the surface element

dS during the collision, energy and momentum may be carried across dS even though neither molecule crosses the surface.

COLLISION DENSITY, NEUTRON. The number of collisions of neutrons with matter taking place in unit time in unit volume of material. Quantitatively, it is the product of total macroscopic cross section of the material, and the neutron flux.

COLLISION DIAMETER OF MOLECULES. The distance of closest approach between the centers of any two molecules in a collision.

COLLISION, DIRECT. See **direct and inverse collision**.

COLLISION, ELASTIC. A collision during which no change occurs in the internal energy of the participating systems; or in the sum of their kinetic energies of translation. The total mechanical energy is conserved, hence the **coefficient of restitution** is unity.

COLLISION FREQUENCY. The average number of collisions undergone by a particle per unit time. If v is the particle velocity and λ its **mean free path**, the collision frequency ν_c is given by the equation

$$\nu_c = v/\lambda.$$

COLLISION FREQUENCY BY MAXWELL'S EQUATION. See **Stosszahlansatz**.

COLLISION, INELASTIC. A collision during which changes occur both in the internal energy of one or more of the participating systems, and in the sums of their kinetic energies of translation before and after the collision.

COLLISION INTEGRAL. See **Boltzmann transport equation**.

COLLISION INTERVAL. The average period between two consecutive collisions. It is equal to the reciprocal of the **collision frequency**.

COLLISION, INVERSE. See **direct and inverse collision**.

COLLISION OF THE FIRST KIND. The collision of an accelerated particle (e.g., electron) with an atom resulting in a transfer of energy whereby the atom becomes excited and the electron is slowed.

COLLISION OF THE SECOND KIND.

The **collision** of an excited atom with a slow particle (e.g., electron) whereby the atom undergoes transition to a lower energy-state and the other particle is accelerated.

COLLISION PARAMETER. See **impact parameter**.

COLLISION PROBABILITY. (1) When a beam of particles is passing through matter, the probability that any single particle be removed from the beam in a distance dx is $k dx$, where k is in general the inverse of the **mean free path**. (2) The fraction of the particles removed from a collimated beam per centimeter path length and per millimeter of pressure at 0°C. (3) For incident electrons, the number of electrons removed per unit electron current sometimes replaces the fraction.

COLLISION PROBABILITY, FIRST FLIGHT. The probability that a neutron, originating with equal probability at any point in the interior of a body and having random direction of velocity, v , will escape from the body without undergoing a collision. It is denoted by the symbol P_0 .

COLLISION THEORY OF CHEMICAL KINETICS. Consider a chemical reaction involving only one step, of the form

A well studied example is

This is a second order reaction (see **order of a chemical reaction**). The elementary collision theory of chemical kinetics assumes that the probability of reaction in a collision depends only on the *translational degrees of freedom*. For example one may assume that this probability is equal to a constant α when the relative translational energy along the line of centers has a specified value greater than E^x and is otherwise zero.

One obtains then for the rate constant (see **order of a chemical reaction**)

$$k = \alpha^2 D^2 \left(\frac{2\pi kT}{\mu} \right)^{1/2} \cdot \exp \left(- \frac{E^x}{kT} \right) \quad (3)$$

where D is the collision diameter, and μ the reduced mass; E^x is called the *activation energy*, and k is **Boltzmann's constant**.

This expression gives often the correct order of magnitude for simple processes. One may write (3) in the more general form

$$k = \alpha \Gamma e^{-E^x/kT}. \quad (4)$$

$\alpha \Gamma$ is known as the *frequency factor*. In some cases one finds, however, values of α larger than 1 or abnormal temperature dependence. In such cases the simple collision theory cannot be applied. (See **absolute reaction rate theory**.)

COLOGARITHM. The **logarithm** of the reciprocal of a number. Sometimes used in logarithmic computation to avoid the use of negative **mantissas** or of subtraction of logarithms.

COLOR. Color is (1) that characteristic of visual sensation which enables the observer to distinguish differences in the quality of the sensation, of the kind which can be caused by differences in the spectral composition of the light; (2) that characteristic of the light stimulus (light source or object), which gives rise to the visual sensation in (1), e.g., a red light, a white light, a red face, etc.; (3) as defined in (1) and (2), but restricted to the appearance of redness, greenness, etc., as distinct from whiteness, grayness or blackness; i.e., chromatic color in contradistinction to achromatic color. (See **additive mixture of colors**; **additive complementary colors**.)

COLORED BODY. A body for which the **spectral transmission** or **reflection factor** varies with wavelength.

COLOR EQUATION. An algebraic representation of the match of two stimuli, one of which, for instance, can appear as the result of an additive mixture.

COLORIMETRIC PURITY. Colorimetric purity is calculated from the formula

$$p_c = p_e y_d / y$$

where the symbols have the same meanings as in the definition of **excitation purity**.

COLOR INDEX. See **stellar magnitudes** and **spectral classification of the stars**.

COLOR SOLID. That part of the **color space** which is occupied by **surface colors**.

COLOR SPACE. A manifold of three dimensions for the geometrical representation of colors.

COLOR STIMULUS FUNCTION. The relative **spectral distribution** of the radiation from a reflecting or transmitting body. If the light incident on the body has the radiation function S_λ then the color stimulus function of a reflecting body is given by $\phi_\lambda = S_\lambda \cdot \beta_\lambda$, where β_λ is the *spectral luminance factor*, and that of a transmitting body is $\phi_\lambda = S_\lambda \cdot \tau_\lambda$, where τ_λ is the *spectral transmission factor*.

COLOR STIMULUS SPECIFICATION. A set of **tristimulus values** of a light (monochromatic or otherwise).

COLOR TEMPERATURE. The absolute temperature of the full radiator for which the ordinates of the **spectral distribution** curve of emission are proportional (or approximately so), in the visible region, to those of the distribution curve of the radiation considered, so that both radiations have the same chromaticity. (In German: *Verteilungstemperatur*.) In certain countries, by extension, the term color temperature is used in the case of a selective radiator when, for the **colorimetric standard observer**, this radiator has the same color (or at least approximately the same color) as a full radiator at a certain temperature; this temperature is then called the color temperature of the selective radiator. (In German: *Farbtemperatur*.)

COLOR TRIANGLE. The color triangle (**chromaticity diagram**) is a plane diagram showing the results of mixing color stimuli, every color being represented unambiguously by a single point on the diagram.

COLUMN. A column is that part of a structure whose purpose is to transmit, through compression, the weight of the structure and the superimposed loads to the foundation. Other **compression members** are often termed columns because of the similar stress conditions. The ratio of the length of the column to the least **radius of gyration** of its cross section is called the *slenderness ratio*. This ratio affords a means of classifying columns. All the following are approximate values used for convenience. A short steel column is one whose slenderness ratio does not exceed 50; an intermediate length steel column has a slenderness ratio ranging from 50 to about

200, while a long steel column may be assumed as one having a slenderness ratio greater than 200. A short concrete column is one having a ratio of unsupported length to least dimension of the cross section not greater than 10. If the ratio is greater than 10 it is a long column.

If the load on a column is applied through the center of gravity of its cross section it is called an **axial load**. A load at any other point in the cross section is known as an **eccentric load**. A short column under the action of an axial load will fail by direct **compression** but a long column loaded in the same manner will fail by buckling (bending), the buckling effect being so large that the effect of the direct load may be neglected. The intermediate length column will fail by a combination of direct stress and bending.

Euler derived a formula which gives the maximum axial load that a long, slender ideal column can carry without buckling. An ideal column is one which is perfectly straight, homogeneous and free from initial stress. This maximum load, sometimes called the critical load, causes the column to be in a state of unstable equilibrium, that is, any increase in the loads or the introduction of the slightest lateral force will cause the column to fail by buckling. The Euler formula for columns is given below.

$$P = \frac{K\pi^2 EI}{l^2}$$

in which P is the maximum or critical load. E is the modulus of elasticity. I is the moment of inertia of cross-sectional area. l is the unsupported length of column. K is a constant whose value depends upon the conditions of end support of the column. For both ends free to turn $K = 1$; for both ends fixed, $K = 4$; for one end free to turn and the other end fixed $K = 2$ approximately, and for one end fixed and the other end free to move laterally $K = 1/4$.

Since the moment of inertia of a surface is its area multiplied by the square of a length called the **radius of gyration**, the above formula may be rearranged as follows. Using the **Euler** formula for hinged ends, and substituting Ar^2 for I the following formula results:

$$\frac{P}{A} = \frac{\pi^2 E}{\left(\frac{l}{r}\right)^2}$$

$\frac{P}{A}$ is the allowable unit stress of the column, and the quantity $\frac{l}{r}$ is the slenderness ratio.

Since the structural column is generally an intermediate length column and it is impossible to obtain an ideal column, the Euler formula has little practical value for ordinary design. Consequently, various empirical column formulae have been developed to agree with test data, all of which embody the slenderness ratio. For design, appropriate factors of safety are introduced into these formulae.

COLUMN ANALOGY. Hardy Cross gave the analogy between the bending moment in an arch or frame fixed at its ends and the total stress in an eccentrically-loaded stub column. The actual calculations are equivalent to the method of the **elastic center**, and in turn both can be arrived at simply through the general **theorem of virtual work**.

COLUMN-BEAM. See **beam-column**.

COLUMN BUCKLING. See **buckling, column**.

COLUMN, EFFECTIVE LENGTH OF. The Euler buckling load for elastic columns hinged top and bottom, $K = 1$, is arbitrarily chosen as the standard (see **columns**). The effective length of a column is the length of a hinged-ended elastic column of the same cross section which has the same buckling load. A cantilever column of length L has an effective length of $2L$; a fixed-ended column, an effective length of $L/2$.

COLUMN FORMULAS. See **column**.

COLUMN, PIN-ENDED. A pin-ended column or hinged-ended column is free to rotate, but not free to translate laterally at each end.

COMA. (1) Qualitatively, coma is the image error due to the variation of **magnification** in a pencil of rays outside the paraxial region. The image point of intersection of a ray with the focal plane will vary in its distance from the axis according to the ray. In third order optics a comatic pattern is formed by a bundle of rays in the form of **comatic circles** whose envelope is a pair of lines intersecting in an angle of $\pi/3$. (2) Quantitatively, the second of the five **Scidel aberrations** is the coma function of a system.

COMATIC CIRCLES. Rays from an off-axis point through any zone of a lens meet the focal plane in a comatic circle, the radius of which is proportional to the radius of the lens zone.

COMBINATION. An assignment of a group of objects into two or more mutually exclusive sets. The **binomial coefficient** $\binom{n}{k}$ is the number of **combinations** or ways of selecting k objects from a set of n objects. If the k objects are permuted among themselves, no new combinations are formed, but there are $k!$ new arrangements of each combination.

COMBINATION DIFFERENCES AND COMBINATION SUMS. In the analysis of molecular spectra, correctly chosen combinations of the wave numbers of different lines form the basis for the determination of the individual molecular constants and of the distances between different energy levels. For instance the combination differences

$$\begin{aligned} R(J-1) - P(J+1) &= F_v''(J+1) - F_v''(J-1) \\ &= \Delta_2 F''(J) \\ &= (4B_v'' - 6D_v'')(J + \frac{1}{2}) - 8D_v''(J + \frac{1}{2})^3 \\ R(J) - P(J) &= F_v'(J+1) - F_v'(J-1) \\ &= \Delta_2 F'(J) \\ &= (4B_v' - 6D_v')(J + \frac{1}{2}) - 8D_v'(J + \frac{1}{2})^3 \end{aligned}$$

are used to separate the rotational energy levels of the upper and lower vibrational states and to determine the rotational constants.

The combination sums

$$\begin{aligned} R(J-1) + P(J) &= 2\nu_0 + 2(B_v' - B_v'')J^2 \\ &\quad - 2(D_v' - D_v'')J^2(J^2 + 1) \end{aligned}$$

are used to determine the band origins (**zero lines**) and the differences $(B_v' - B_v'')$ and $(D_v' - D_v'')$ of the rotational constants.

Similar combination relations apply to the S and O branches observed in the **Raman effect**.

COMBINATION PRINCIPLE. The principle, first recognized empirically by Ritz, that the frequency of every spectral line can be represented as the difference (combination) of two "terms"

$$\nu = T_1 - T_2$$

selected from a comparatively small number of such terms which are characteristic for the atom in question.

In its modern form

$$\nu = \frac{\nu'}{c} = \frac{1}{\lambda} = \left[\frac{E_1}{hc} - \frac{E_2}{hc} \right] \text{cm}^{-1}$$

the combination principle expresses the fact that every spectral line corresponds to a transition in the atom (or molecule, etc.) between two energy levels and that the energy of the emitted or absorbed photon is equal to the difference in energy between the initial and final level. The quantities

$$\frac{E_1}{hc}; \frac{E_2}{hc}, \text{ etc.}$$

are the spectroscopic term values. ν , ν' , and λ stand, respectively, for wave number, frequency, and wavelength of the spectral line, E for the energy of the level, h for Planck's constant, and c for the velocity of light.

COMBINATION SUMS. See combination differences and combination sums.

COMBINATION VIBRATION. A vibration in a polyatomic molecule in which two or more normal vibrations are simultaneously excited.

COMBINED LOADING. Combinations of bending, torsion, axial load, interior or exterior pressure, etc.

COMBINED STRESS. See stress, combined.

COMBUSTION CALCULATIONS IN ENGINEERING. Combustion is the exothermic reaction between a fuel and oxygen carried out at elevated or high temperature in an industrial appliance, such as a furnace, burner, internal combustion engine, combustion chamber, etc. By far the greatest proportion of the heat utilized in industry is obtained from combustion. The required oxygen is supplied chiefly by feeding atmospheric air (for composition, see air, atmosphere). Sometimes oxygen is supplied directly or in the form of easily decomposed compounds (oxygenizers in rockets). The products of combustion are, as a rule, gaseous, and leave the device at a relatively high temperature.

The chief components of all industrial fuels are carbon, C, and hydrogen, H; small amounts

of sulfur, S, may also be present. Solid and liquid fuels may consist of a mixture of the above elements and their compounds. Liquid fuels are mostly mixtures of hydrocarbons. Gaseous fuels are mostly mixtures of gaseous combustible and inert compounds.

Most combustion processes can be reduced to the following basic chemical reactions:

- (a) $\text{C} + \text{O}_2 \rightarrow \text{CO}_2 + 174,960 \text{ BTU}$
(+97,200 kcal)
- (b) $\text{C} + \frac{1}{2} \text{O}_2 \rightarrow \text{CO} + 53,316 \text{ BTU}$
(+29,620 kcal)
- (c) $\text{CO} + \frac{1}{2} \text{O}_2 \rightarrow \text{CO}_2 + 121,644 \text{ BTU}$
(+67,580 kcal)
- (d) $\text{H}_2 + \frac{1}{2} \text{O}_2 \rightarrow (\text{H}_2\text{O})_{\text{liq}} + 123,300 \text{ BTU}$
(+68,500 kcal)
- (e) $\text{H}_2 + \frac{1}{2} \text{O}_2 \rightarrow (\text{H}_2\text{O})_{\text{vap}} + 103,950 \text{ BTU}$
(+57,750 kcal)
- (f) $\text{S} + \text{O}_2 \rightarrow \text{SO}_2 + 127,548 \text{ BTU}$
(+70,860 kcal)
- (g) $\text{CH}_4 + 2 \text{O}_2 \rightarrow \text{CO}_2 + 2 (\text{H}_2\text{O})_{\text{liq}}$
+ 382,320 BTU (+212,400 kcal)
- (h) $\text{C}_2\text{H}_4 + 3 \text{O}_2 \rightarrow 2 \text{CO}_2 + 2 (\text{H}_2\text{O})_{\text{liq}}$
+ 623,160 BTU (+346,200 kcal)
- (i) $\text{C}_2\text{H}_6 + 3.5 \text{O}_2 \rightarrow 2 \text{CO}_2 + 3 (\text{H}_2\text{O})_{\text{liq}}$
+ 671,220 BTU (+372,900 kcal)

The quantities of heat released are for the equations as written, i.e., per mole of fuel at 0°C (32°F). It may be noted that reactions (a) and (f) involve no change in volume, i.e., no positive or negative contraction (the volume of solid carbon or sulfur can be neglected) if the products of combustion are at the same temperature and pressure as the reactants. In the other cases the volume either increases or decreases on combustion. (In reaction (g), there is no actual change in volume because the H₂O is produced as vapor.)

The heat released by the combustion of a fuel and by cooling the products of combustion to the initial temperature is known as its **calorific value, H**. When the fuel is a mixture of simple components, its calorific value can be calculated by proportional parts. Otherwise it must be measured. (See also **VDI formula**.) The calorific value of a fuel depends on whether combustion is at constant volume (e.g., bomb calorimeter) or at constant pres-

sure (Boys calorimeter, Junkers calorimeter). Denoting reactants by subscript 1 and products by subscript 2, we have

$$H_v = U_1 - U_2 \quad (1)$$

$$H_p = H_1 - H_2 \quad (2)$$

and, since $H = U + PV$,

$$H_p - H_v = P(V_1 - V_2). \quad (3)$$

The difference $H_p - H_v$ depends on whether or not there is contraction.

The calorific value depends on the reference temperature, i.e., on the common temperature of the reactants and products at which it has been determined. (Normally these are listed for $t_0 = 0^\circ\text{C} = 32^\circ\text{F}$.) Given H_p at t_0 , we can calculate H_p at any temperature t from the law of conservation of energy. Assuming constant specific heats for products and reactants, we have:

$$H_p(t) - H_p(t_0) = (t - t_0) \left\{ \sum_{\text{react}} m_1 C_{p1} - \sum_{\text{prod}} m_2 C_{p2} \right\} \quad (4)$$

For H_v , C_p in (4) should be replaced by C_v . The calorific value in a **heat tone**, and Equation (4) applies to any heat tone at constant pressure. The rate of change of H_p or H_v with temperature, is not very large. As long as it is assumed that the air used in combustion as well as the products of combustion are perfect gases, the calorific value is independent of pressure.

All fuels which contain hydrogen or sulfur produce combustion gases with the easily condensable vapors, H_2O and SO_2 . Their calorific values are measured at temperatures at which H_2O or SO_2 appear as liquids and, therefore, include the latent heats of condensation, l . On the other hand, in practical appliances, the combustion gases are discharged at a higher temperature and the latent heats are not released. The temperature at which this condensation occurs is called the *dew point* of the combustion gas. Accordingly, it is necessary to distinguish between the *higher* or *gross calorific value* H_g which includes the latent heat, and the lower or net calorific H_n value which excludes it. If only steam is present, we have

$$\begin{aligned} H_{pg} - H_{pn} &= Ml = 19,381.6 \text{ Btu/lbmol} \\ &= 10,750 \text{ kcal/lbmol}, \end{aligned}$$

where M is the molar weight of steam ($M = 18.016 \text{ lbm/lbmol} = 18.016 \text{ kg/kmol}$; and

$l = 1075.8 \text{ Btu/lbm} = 592.1 \text{ kcal/kg}$ is the latent heat at $0^\circ\text{C} = 32^\circ\text{F}$). For pure hydrogen, H_n is approximately 19% lower than H_g . For pure carbon the two are equal. In practical calculations preference is given to the use of the lower calorific value.

Combustion is a highly complex, irreversible chemical process in which the dynamic conditions (motion of the gases), and the conditions for heat and mass transfer (diffusion) play important parts. The composition of the products of combustion and the actual amount of heat released depend on all those factors, and can seldom be predicted with certainty.

The highest possible amount of heat is released if all chemical elements in the fuel are oxidized to form the highest oxides. When this occurs, combustion is called *complete*. In the case of carbon, this implies that only CO_2 and no CO is present in the products. In the contrary case, combustion is called *incomplete*. In practice, hydrogen always oxidizes to H_2O .

Owing to the operation of the **law of mass action**, combustion can never be complete in practice, because at chemical equilibrium CO will always be present, even if only in minute amounts. On the other hand, owing to the highly irreversible nature of combustion, it must not be assumed that in a practical device the reactants and products are necessarily in chemical equilibrium. Moreover, owing to the inevitable motion of the gases, rapid compression or expansion may take place, leading to states of **frozen equilibrium**.

In practical devices an attempt is always made to approximate complete combustion as closely as possible. This could not be assumed if only enough air, X_{min} , were supplied to provide the exact, stoichiometric quantity of oxygen, O_{min} , necessary for combustion. Accordingly the actual amount of air supplied, X , exceeds X_{min} and their ratio

$$\lambda = X/X_{min} \quad (\lambda > 1)$$

is called the air ratio. Sometimes, the excess of air is described by the related quantity

$$\delta = 1 - \lambda,$$

called *excess air ratio*. An excess of air is required in order to provide the necessary concentration gradients within the combustion zone, and to secure an excess of oxygen in order to shift the chemical equilibrium in the

direction of more complete combustion in accordance with (Le) Chatelier's principle.

Since complete combustion constitutes a desirable, if unattainable, ideal, calculations relating to it are important in the design of combustion equipment. A complication arises in that it is customary to indicate the composition of solid and liquid fuels by specifying mass fractions (denoted c , h , o , etc., for the elements, and w for the moisture content); on the other hand, the composition of gaseous fuels as well as that of all products of combustion is customarily given in mole-fractions or parts by volume, denoted, e.g., $(\text{CH}_4)_f$ for the fuel gas and, e.g., $(\text{CO}_2)_p$ for the products of combustion. It is always assumed that all gases are perfect. Often, in addition, it is stipulated that their specific heats are constant.

The combustion gases are normally analyzed at a temperature below the dew point and, therefore, the analysis does not contain any indication about the H_2O and SO_2 content. The analysis is then said to refer to dry (combustion) gases. The gases actually leaving the combustion zone, being at a temperature above the dew point, are referred to as wet (combustion) gases.

The composition of a fuel can be conveniently characterized by two dimensionless quantities σ and ν . For solid or liquid fuels:

$$\sigma = 1 + \frac{3}{c} \left(h - \frac{o - s}{8} \right)$$

$$\nu = \frac{3n}{7c}$$

Very often ν is small and we may put $\nu \approx 0$. For a gaseous fuel of the following general composition:

$$(\text{CO})_f + (\text{H}_2)_f + (\text{CH}_4)_f + (\text{C}_2\text{H}_4)_f + (\text{O}_2)_f + (\text{N}_2)_f + (\text{CO}_2)_f = 1, \quad (4)$$

$$\sigma = \frac{\left\{ \begin{array}{l} o \cdot s [(\text{CO})_f + (\text{H}_2)_f] + 2(\text{CH}_4)_f \\ + 3(\text{C}_2\text{H}_4)_f - (\text{O}_2)_f \end{array} \right\}}{(\text{CO})_f + (\text{CH}_4)_f + 2(\text{C}_2\text{H}_4)_f + (\text{CO}_2)_f};$$

$$\nu = \frac{(\text{N}_2)_f}{(\text{CO})_f + (\text{CH}_4)_f + 2(\text{C}_2\text{H}_4)_f + (\text{CO}_2)_f}.$$

For solid and liquid fuels, we can write (all volumes refer to normal temperature and pressure):

theoretical (stoichiometric) oxygen:

$$O_{min} = 29.92c\sigma \text{ ft}^3/\text{lbm} = 1.566 \text{ m}^3/\text{kg}$$

theoretical air:

$$X_{min} = 142c\sigma \text{ ft}^3/\text{lbm} = 7.461 \text{ m}^3/\text{kg}$$

volume of combustion gases:

$$V_p = \lambda X_{min} + \frac{3.59}{12}(3h + \frac{3}{8}o + \frac{2}{3}w) \text{ ft}^3/\text{lbm}$$

$$= \lambda X_{min} + \frac{1.87}{120}(3h + \frac{3}{8}o + \frac{2}{3}w) \text{ m}^3/\text{kg}$$

$$\text{H}_2\text{O content: } \left(\frac{h}{2} + \frac{w}{18} \right) \text{ lbmol/lbm}$$

$$\text{SO}_2 \text{ content: } \frac{s}{32} \text{ lbmol/lbm.}$$

For gaseous fuels of the general composition (4) we have:

$$O_{min} = 0.5[(\text{CO})_f + (\text{H}_2)_f] + 2(\text{CH}_4)_f + 3(\text{C}_2\text{H}_4)_f - (\text{O}_2)_f \text{ ft}^3/\text{ft}^3 \text{ (m}^3/\text{m}^3)$$

$$X_{min} = \frac{1}{0.21} O_{min} \text{ ft}^3/\text{ft}^3 \text{ (m}^3/\text{m}^3)$$

$$V_p = 1 + \lambda X_{min} - 0.5[(\text{CO})_f + (\text{H}_2)_f]$$

$$\text{H}_2\text{O content: } (\text{H}_2)_f + 2(\text{CH}_4)_f + 2(\text{C}_2\text{H}_4)_f.$$

In all cases, the molar (volumetric) composition of the dry gases is given by the equations:

$$(\text{CO}_2)_p = 0.21/y$$

$$(\text{O}_2)_p = 0.21(\lambda - 1)\sigma/y$$

$$(\text{N}_2)_p = (0.79\lambda\sigma + 0.21\nu)/y$$

$$y = (\lambda - 0.21)\sigma + 0.21(\nu + 1)$$

$$(\text{CO}_2)_p + (\text{O}_2)_p + (\text{N}_2)_p = 1.$$

The excess air used can be calculated from the composition of the dry gases, with the aid of the formula:

$$\lambda = \frac{0.21}{\sigma} \left[\frac{1}{(\text{CO}_2)_p} + \sigma - 1 - \nu \right].$$

When combustion is incomplete, the above equations do not apply, but owing to the complexity of the process, no general rules for calculations can be indicated. Very often the assumption is made that the reactants and products in the combustion chamber are in chemical equilibrium, and calculations are made with the aid of the law of mass action. This leads to several equations with several

unknowns and to considerable computational difficulties. The temperature prevailing in the combustion chamber appears as an important, unknown parameter. Since it is usually high, **dissociation** must be allowed for.

The highest possible temperature of combustion is obtained when it is assumed that the process occurs in an adiabatic vessel, that combustion is complete, and that dissociation does not occur. The resulting (quite unrealistically high) temperature t is known as the *adiabatic flame temperature* or the theoretical temperature of combustion. With the usual assumptions, it can be determined from the following equations:

Solid or liquid fuels (H_n per unit mass)

$$H_n + [\bar{c}]_{t_r}^{t_f}(t_f - t_r) + \lambda X_{min}[\bar{C}_p]_{t_r}^{t_a}{}_{air}(t_a - t_r) \\ = \left\{ \frac{c}{12} [\bar{C}_p]_{t_r}^{t_f}{}_{CO_2} + \left(\frac{h}{2} + \frac{w}{18} \right) [\bar{C}_p]_{t_r}^{t_f}{}_{H_2O} \right. \\ \left. + 0.21(\lambda - 1)X_{min}[\bar{C}_p]_{t_r}^{t_f}{}_{O_2} \right. \\ \left. + 0.79\lambda X_{min}[\bar{C}_p]_{t_r}^{t_f}{}_{N_2} \right\} (t - t_r).$$

Gaseous fuels (H_n per mole)

$$H_n + (t_f - t_r) \sum_{fuel\ gas} x[\bar{C}_p]_{t_r}^{t_f} \\ + (t_a - t_r)\lambda X_{min}[\bar{C}_p]_{t_r}^{t_a} \\ = (t - t_r) \sum_{burnt\ gases} X[\bar{C}_p]_{t_r}^{t_f}.$$

Notation: t_r is an arbitrary reference temperature; H_n is assumed given at t_r ; t_a is the temperature of air supplied; t_f is the temperature of fuel supplied; X is the mole fraction; $[\bar{c}]_{t_r}^{t_f}$ is the mean specific heat per unit mass within temperature limits as indicated; $[\bar{C}_p]_{t_r}^{t_f}$ is the mean molar specific heat at constant pressure within temperature limits indicated; and t is the unknown adiabatic flame temperature.

Dissociation (important above 1500°C) and heat losses through radiation, convection and incomplete mixing cause the real flame temperature to be non-uniform throughout the combustion zone and always lower than the adiabatic flame temperature t above. The combustion temperature increases with H_n and t_f and t_a (pre-heating); it is higher with pure O_2 than with air, because no nitrogen need be heated. The highest combustion temperatures of about 3100°C (5600°F) are attained in

welding (oxy-acetylene) burners. Higher temperatures can be obtained in electric arcs. The flame temperature is reduced if λ is large, but as a rule there exists an optimum value for it. This, roughly, corresponds to the maximum excess of air which produces the best approximation to complete combustion. Chemical losses reflect on the calorific value and bear more heavily on the final result than do physical losses, consequently it is better to have too much air than too little.

The components of combustible mixtures can exist side by side indefinitely at normal temperatures. In order to start combustion the mixture must first be heated to a definite temperature, the *ignition temperature* (see **ignition limit**). The heat released on ignition must be sufficient for the combustion, initiated by ignition, to propagate itself through the combustible mixture. The velocity of propagation of the combustion zone relative to combustible mixture is called *flame* or *combustion velocity*; it depends on the physical and chemical properties of the mixture, and ranges from about 1 m/sec (3 ft/sec) for CO-air mixtures, to 30 m/sec (100 ft/sec) for H_2 - O_2 mixtures. The velocity of combustion can be reduced considerably, even to zero, by vigorous cooling (as in a Davy lamp); it is also strongly affected by the air-fuel ratio (see **ignition limit**), and can be appreciably increased by inducing turbulence in the combustible mixture (as in internal combustion engines). The slowly progressing mode of combustion, also known as *deflagation*, can be replaced by an extremely fast propagation, known as *detonation*, which is induced in a tube owing to the compressibility of the gases involved.

COMBUSTION VELOCITY. See **combustion calculations in engineering**.

COMMAND (COMPUTER). (1) One of a set of several signals (or groups of signals) which occurs as a result of an **instruction**; the commands initiate the individual steps which form the process of executing the instruction. (2) Synonym for instruction.

COMMENSURABLE. The term used to describe the relationship between several quantities, e.g., b_1 , b_2 , and b_3 , for which a number C , not necessarily an integer, can be found such that $b_1 = n_1C$, $b_2 = n_2C$, and $b_3 = n_3C$ where n_1 , n_2 , and n_3 are integers. If no such

number C exists, then b_1 , b_2 , and b_3 are said to be non-commensurable.

COMMUNAL ENTROPY. The contribution to the entropy of a system arising from the disorder when the molecules are sufficiently free to change positions frequently.

COMMUTATION RELATIONS. Physical quantities are represented in quantum mechanics by linear operators. Two linear operators A and B do not commute in general, $AB \neq BA$. The commutation relations give an expression for the commutator $AB - BA$. Canonically conjugate dynamical variables q , p satisfy the commutation relations $qp - pq = i\hbar$, where $\hbar = h/2\pi$ and h is Planck's constant. Components M_x , M_y , M_z of an angular momentum operator satisfy the commutation relations

$$M_x M_y - M_y M_x = i\hbar M_z,$$

$$M_y M_z - M_z M_y = i\hbar M_x,$$

$$M_z M_x - M_x M_z = i\hbar M_y.$$

(See Jordan-Wigner commutation rules.)

COMMUTATION RULES FOR BOSONS. The commutation rules satisfied by the creation and destruction operators for particles obeying Bose-Einstein statistics. If a_n and a_n^* are the destruction and creation operators for a Bose particle in the (one-particle) state characterized by the observable n , the Jordan-Klein commutation rules for them state that

$$[a_n, a_m] = [a_n^*, a_m^*] = 0 \quad (1)$$

$$[a_n, a_m^*] = \delta_{nm}.$$

Consider the case of neutral (uncharged) spin 0 particles of mass μ in greater detail. In a quantum field theoretic description, to a system of free spin 0 particles corresponds a Hermitian field operator $\phi(x) = \phi^*(x)$ satisfying the equation

$$(\square + \mu^2)\phi(x) = 0.$$

Let f_j be a set of positive energy solutions of the Klein-Gordon equation orthonormal in the scalar product

$$(f, g) = -i \int d\sigma^\mu(x) \left(\frac{\partial \bar{f}}{\partial x^\mu} g(x) - \bar{f} \frac{\partial g}{\partial x^\mu} \right) \quad (2)$$

then one defines the annihilation operator as

$$a_j = -i \int d\sigma^\mu \left[\frac{\partial \bar{f}_j}{\partial x^\mu} \phi(x) - \bar{f}_j(x) \frac{\partial \phi(x)}{\partial x^\mu} \right] \quad (3)$$

and the creation operator a_j^* as the adjoint of the above. The commutation rules of the a 's and a^* 's are given by (1). It can be demonstrated that the inequivalent discrete representations of the commutation rules (1) are \aleph_j in number. For just one of the irreducible representations does a no particle-particle state and an operator $N = \sum a_j^* a_j$ corresponding to the total number of particles, exist.

COMMUTATIVE LAW. An operator, denoted by the small centered circle \circ , obeys the commutative law if $a \circ b = b \circ a$ for all a , b in its domain. Thus, in elementary arithmetic $a + b = b + a$, and $ab = ba$.

COMMUTATOR. The commutator of two linear operators A and B is the expression $[A, B] = AB - BA$.

COMMUTING VARIABLES. In quantum mechanics those dynamical variables whose quantum mechanical operators commute. The set of variables whose operators commute with the Hamiltonian operator are constants of motion.

COMPACT. A subset S of a metric space is compact if every infinite sequence of elements in S contains a sub-sequence which is convergent to an element of S . Thus the unit-sphere in a Euclidean space is compact, while the unit-sphere (the set of all vectors of unit norm) in Hilbert space is not compact.

COMPARISON THEOREM (FOR CONVERGENCE). A series $a_1 + a_2 + \dots$ is absolutely convergent if $|a_i| < |b_i|$ for $i = 1, 2, 3, \dots$, where $b_1 + b_2 + \dots$ is an absolutely convergent series. Similarly $a_1 + a_2 + \dots$ is divergent if $|a_i| > |b_i|$ for some divergent series b_i .

COMPATIBLE DISPLACEMENTS. See displacements, compatible.

COMPENSATION THEOREM. If a network is modified by making a change, ΔZ , in the impedance of one of its branches, the current increment thereby produced at any point in the network is equal to the current that would be produced at that point by a compensating electromotive force acting in series with the modified branch, whose value is $-i\Delta Z$, where i is the original current which flowed in the modified branch.

COMPLEMENT. (1) In decimal representation, the complement of a number x is $10^{\nu} - x$, where ν is some fixed integer, positive, negative, or zero. In binary representation it is $2^{\mu} - x$, where μ is an integer. The subtraction of a number is thus essentially equivalent to the addition of its complement, and in computer construction it is generally easier to mechanize the formation of a complement than that of an arbitrary difference. In binary notation, the one's-complement of x is the number obtained when each digit x_i of x is replaced by $1 - x_i$. (2) The complement of a subset S of a set A is the set of all elements of A not included in S . (3) For the algebraic complement of a minor determinant, see "minor."

COMPLEMENTARITY. A concept introduced by Niels Bohr to express an essential feature of the quantum description of atomic phenomena. Though these phenomena transcend the scope of classical physical explanation, the account of all observations must be expressed in classical terms. Because of the impossibility of any sharp separation between the behavior of atomic objects and the interaction with the measuring instrument, evidence obtained under different experimental conditions cannot be comprehended within a single picture. Different conditions lead to the observation of complementary aspects of the phenomenon, complementary in the sense that only the totality of mutually exclusive observations exhausts the possible information about the atomic object. Wave and particle aspects are complementary aspects in the description of light or elementary particles. The description of a particle motion in terms of position coordinates is complementary to that in terms of momentum components.

COMPLEMENTARY ACCELERATION. Another name for **Coriolis acceleration**.

COMPLEMENTARY COLORS. See **additive complementary colors**.

COMPLEMENTARY DIFFRACTION SCREENS. See **Babinet principle**.

COMPLEMENTARY ENERGY. Consider a body of elastic material, to which classical elasticity theory is applicable, to be in equilibrium under the action of specified body

forces and specified surface tractions applied over part Σ_T of the surface Σ , while displacements are specified over the remainder Σ_u . If the components of the corresponding displacements, in a rectangular Cartesian coordinate system, are u_i ($i = 1, 2, 3$) and the components of the surface tractions acting on the portion Σ_u of the surface are T_i , then the complementary energy is defined by

$$U = \int_{\Sigma_u} T_i u_i d\Sigma,$$

where U is the strain-energy associated with an arbitrary stress field and the **summation convention** is used. The *theorem of minimum complementary energy* states that the complementary energy is an absolute minimum for all variations of the stress field which leave the equations of equilibrium throughout the body and the boundary conditions on Σ_T satisfied. Also called *principle of complementary energy*. In the particular case when surface tractions are specified over the whole surface, the theorem is called the *theorem of minimum strain energy*, or *theorem of least work*, or *Castigliano second theorem*.

COMPLEMENTARY FUNCTION (OF A LINEAR DIFFERENTIAL EQUATION). A solution of the corresponding homogeneous equation. (See **linear**.)

COMPLEMENTARY WAVELENGTH. The complementary wavelength (of a light) is the wavelength of a spectrum light that, when combined in suitable proportions with the light considered, yields a match with the specified **achromatic light**.

COMPLEMENT OF A SUBGRAPH. See **subgraph complement**.

COMPLETE COMBUSTION. See **combustion**.

COMPLETE RADIATOR. A temperature radiator of uniform temperature whose **radiant flux** in all parts of the spectrum is the maximum obtainable from any temperature radiator at the same temperature. Such a radiator is called a **black body** because it will absorb all the radiant energy that falls upon it. No known surface is truly black at all wavelengths.

COMPLETE SET OF ORTHOGONAL FUNCTIONS, EXPANSION IN. (1) Consider the complete set of functions $S_n(x)$ that are orthogonal over an interval L , i.e.,

$$\int_0^L S_n(x)S_m^*(x)dx = 0$$

where $S_m^*(x)$ is the complex conjugate of $S_m(x)$ and that are normalized to unity, i.e.,

$$\int_0^L S_n(x)S_n^*dx = 1.$$

Then in the expansion

$$F(x) = \sum_n a_n S_n(x)$$

of an arbitrary function $F(x)$, satisfying the same boundary conditions as S_n , the coefficients are given by

$$a_n a_n^* = |a_n|^2 = \int_0^L F(x)S_n^*(x)dx.$$

Examples of complete orthogonal sets are the $\sin nx$ and $\cos nx$ functions of the **Fourier series** over the interval 0 to π ; the complex exponential functions e^{inx} , $n = \dots -2, -1, 0, +1, +2 \dots$, over the interval 0 to π ; the Legendre polynomials $P_n(x)$ over the interval 0 to 1; the functions $\sqrt{x} J_p(r_n x)$ over the interval 0 to 1, where J_p is the p^{th} order **Bessel function** of first kind and r_n is its n^{th} root; etc.

(2) The idea of expansion in a complete orthogonal set can be extended to the case where the expansion functions form a continuous, rather than a discrete, orthogonal set. Again the orthogonality of the functions allows the determination of the expansion coefficients which are now continuous functions rather than discrete constants. An example of such an expansion is the **Fourier transform**.

(3) In many problems of quantum mechanics, the quantum mechanical operators have both discrete and continuous **eigenvalues**. The complete set of **eigenfunctions** then includes both those belonging to the discrete spectrum and those belonging to the continuous spectrum of the eigenvalues. The expansion of an arbitrary state function is then a sum over the discrete eigenfunctions plus an integral over the continuous eigenfunctions.

COMPLETE SPACE. A metric space in which every **Cauchy sequence** is convergent to an element in that space.

COMPLEX COMPLIANCE. See **compliance, complex**.

COMPLEX INTEGRATION. See **contour integration**.

COMPLEXION. A microstate of a system.

COMPLEX MODULUS. See **modulus, complex**.

COMPLEX NUMBER. A complex number, usually written $a + bi$ (see below), is a pair of real numbers (a,b) with addition and multiplication defined as follows: $(a,b) + (c,d) = (a + c, b + d)$ and $(a,b) \times (c,d) = (ac - bd, ad + bc)$. The real number a is the *real part*, and the real number b is the *imaginary part*, of the complex number (a,b) . The names “real” and “imaginary” are historical accidents; since a complex number is a pair of real numbers, it is exactly as “real” as they are and, in fact, complex numbers are often useful for the representation of phenomena in the “real” world. A complex number $(a,0)$ with zero imaginary part may be identified with the corresponding real number a . A complex number $(0,b)$ with zero real part is called a pure imaginary. The pure imaginary $(0,1)$ is usually denoted by the symbol i ; since $(0,1) \times (0,1) = (-1,0)$, the number i is a square root of -1 . Since $(a,b) = (a,0) + (b,0)(0,1) = a + bi$, every complex number may be written, as indicated above, in the form $a + bi$. In books on electricity, the letter i is usually replaced by j . Choosing r and θ so that $a = r \cos \theta$ and $b = r \sin \theta$ leads to the polar or trigonometric form of a complex number $z = r(\cos \theta + i \sin \theta)$, and defining $e^{i\theta}$ by the series $e^{i\theta} = 1 + (i\theta) + (i\theta)^2/2! + \dots + (i\theta)^n/n! + \dots$, gives the exponential form $z = re^{i\theta}$, from which all the usual properties of complex numbers may be quickly derived. E.g., the **De Moivre identity** $(re^{i\theta})^n = r^n e^{in\theta}$.

COMPLEX OF A GROUP. Any set of elements of a **group**.

COMPLEX POTENTIAL (IN HYDRODYNAMIC FLOW IN TWO DIMENSIONS). If the motion of an incompressible fluid is plane, two-dimensional, and irrotational there exist a velocity potential ϕ and a stream function ψ such that the velocity is given by

$$u = \frac{\partial \phi}{\partial x} = \frac{\partial \psi}{\partial y}$$

$$v = \frac{\partial \phi}{\partial y} = -\frac{\partial \psi}{\partial x}.$$

These are the **Cauchy-Riemann equations**.

The complex potential then is $w = \phi + i\psi$. Also $\text{div } \mathbf{v} = \nabla^2\phi$ and $\text{curl } \mathbf{v} = \nabla^2\psi$, where $\mathbf{v} = (u, v)$. ϕ only exists in irrotational motion ($\text{curl } \mathbf{v} = 0$); ψ exists even if $\text{curl } \mathbf{v} \neq 0$, provided $\text{div } \mathbf{v} = 0$.

The velocity is given by

$$u - iv = \frac{dw}{dz}$$

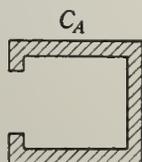

when $z = x + iy$.

Some authors place a minus sign in front of ϕ and ψ as given here.

COMPLEX RADIATION. Radiation composed of several monochromatic radiations.

COMPLEX TRUSS. See **truss, complex**.

COMPLIANCE, ACOUSTIC. The acoustic compliance of an enclosed volume of gas is equal to the magnitude of the ratio of the

Graphical representation of the element, acoustical compliance, C_A .

volume displacement of a piston forming one side of the volume to the pressure causing the displacement. It is measured in cm^5/dyne . It is also called the *acoustic capacitance*.

COMPLIANCE, BULK. Compliance based on **hydrostatic stress** and **dilatational strain**.

COMPLIANCE, COMPLEX. The reciprocal of the *complex modulus*, that is, the ratio of strain to stress in a steady-state oscillatory test, with oscillatory variables expressed in complex notation:

$$k^*(\omega) = k_1(\omega) - ik_2(\omega).$$

COMPLIANCE, CREEP. Subjection of a specimen to a **step function** of stress is known as a creep test. The resulting ratio of strain to stress, $k(t)$, is called the creep compliance, and is a non-decreasing function of the time. The superposition principle enables the strain response, $\epsilon(t)$, to a general stress history $\sigma(\tau)$ to be expressed in terms of $k(t)$:

$$\epsilon(t) = \int_{-\infty}^t k(t - \tau) \frac{\partial \sigma(\tau)}{\partial \tau} d\tau.$$

This represents the constitutive equation of linear viscoelasticity in an integral form.

COMPLIANCE, EQUILIBRIUM. The limiting value of the **compliance** of a viscoelastic material for slow loading or zero frequency.

COMPLIANCE, GLASS. The limiting value of the **compliance** of a viscoelastic material for instantaneous loading or infinite frequency.

COMPLIANCE, LOSS. The imaginary part of the complex compliance $k_2(\omega)$.

COMPLIANCE, MECHANICAL. Compliance in a mechanical vibrating system is that coefficient which, when multiplied by 2π times the frequency, is the reciprocal of the negative imaginary part of the **mechanical impedance**. The unit is the centimeter per dyne.

COMPLIANCE, RECTILINEAL. See **rectilinear compliance**.

COMPLIANCE, ROTATIONAL. See **rotational compliance**.

COMPLIANCE, SHEAR. Compliance based on **shear stress** and **strain** components.

COMPLIANCE, STORAGE. The real part of the complex compliance, $k_1(\omega)$.

COMPONENT. (1) In its general usage, one of the ingredients of a mixture, or one of the distinct molecular or atomic species composing a mixture. In physical chemistry, one among the smallest number of chemical substances which need to be specified in order to reproduce a given chemical system. (2) The projection of a **vector** on a particular coordinate **axis** or along some specified direction. (3) For component of a tensor, see **tensor (tensor field)**.

COMPONENT ANALYSIS. In statistics, a branch of multivariate analysis which seeks to exhibit a multivariate complex as dependent on a number of independent components, each component being a linear function of the original variables. If the components are chosen so that the first accounts for as much of the variation as possible, the second as much of the variation which remains, and so on, they are known as *principal components*.

COMPONENT OF A SCALAR. See **scalar**.

COMPONENT OF A VECTOR. In many problems it is useful to replace a vector, such as a force, by two or more vectors equivalent to it. The two or more vectors are called

components of the original vector. The process of finding the components is called the *resolution of the vector into components*.

COMPONENTS, INDEPENDENT. See independent components.

COMPONENTS OF SYSTEM. See indicial notation.

COMPONENTS OF TENSOR (TENSOR FIELD). See tensor (tensor field).

COMPOSITE BEAM. See beam, composite.

COMPOSITION OF FORCES. See forces, composition of.

COMPOSITION OF TWO TENSORS (TENSOR FIELDS). The operation of forming an inner product of two tensors (tensor fields). Also called *inner multiplication*. The inner product is said to be *compounded* of the two tensors from which it is formed.

COMPOSITION OF VECTORS. See vector addition.

COMPOSITION SERIES (OF A GROUP).

Let G_1 be a normal subgroup of a finite group G which is maximal, that is, such that the only normal subgroup of G which includes G_1 is G itself; similarly, let G_2 be a maximal normal subgroup of G_1 and so on until in n steps we reach $G_n = E$, the group consisting of the identity element alone. Then the sequence of groups so obtained

$$G, G_1, G_2, \dots, G_{n-1}, E$$

is called a composition series for G .

"COMPOUND" DISTRIBUTION. See convolution.

COMPOUND MULTIPLET. See multiplet.

COMPOUND NUCLEUS. The intermediate state produced in a nuclear reaction between capture of the bombarding particle and emission of the reaction product. For example, in the reaction $N^{14} + n \rightarrow O^{14} + p$ the compound nucleus is N^{15} . The appearance of sharp resonances in the cross section (i.e., reaction probability) as a function of energy of the bombarding particle can be interpreted only as the formation of an intermediate state long-lived relative to the time it takes a particle to traverse the nucleus, the mean life being $\tau = \hbar/\Gamma$, where $2\pi\hbar$ is Planck's constant and

Γ the width of the resonance. For example, level widths of about 0.1 eV are frequently observed in the interaction of slow neutrons, of energy about 1 eV, with heavy nuclei. The time required for a 1 eV neutron to cross a distance of about 10^{-12} cm is about 10^{-18} sec, whereas the mean life of the state τ is about 7×10^{-15} sec, which is much longer. During this relatively long time the compound state "forgets" its mode of formation, and can be expected to break up in a manner independent of how it was formed. Thus, the properties of the compound nucleus dominate the behavior of nuclear reactions in the neighborhood of resonances of the cross section (i.e., at low energies). At higher energies, when the de Broglie wavelength of the bombarding particle becomes comparable with the average spacing of particles in the nucleus, only a small portion of the target nucleus interacts with the bombarding particle, so that a compound nucleus is no longer formed. The concept of the compound nucleus was introduced in 1936 by N. Bohr, since when it has had much success in the understanding of nuclear reactions.

COMPOUND TRUSS. See truss, compound.

COMPRESSIBILITY. The coefficient of (isothermal) compressibility is defined by

$$\kappa \text{ (or } \kappa_T) = -\frac{1}{V} \left(\frac{\partial V}{\partial p} \right)_T. \quad (1)$$

The adiabatic (**isentropic**) compressibility coefficient κ_S is similarly defined by

$$\kappa_S = -\frac{1}{V} \left(\frac{\partial V}{\partial p} \right)_S. \quad (2)$$

One has

$$\frac{\kappa_S}{\kappa} = \frac{C_v}{C_p} \quad (3)$$

where C_v/C_p is the ratio of the heat capacities at constant volume and at constant pressure.

COMPRESSIBILITY FACTOR. (1) The semi-theoretical factor Y in the standard-nozzle discharge formula which takes into account the compressibility of the fluid being metered:

$$\dot{m} = \frac{CY}{\sqrt{1 - m^2}} A_o \sqrt{2\rho(p_1 - p_2)}.$$

(See **standard nozzle**.) (2) Value of the ratio

$$z = \frac{pV}{RT}$$

for a **real gas**. Since for a **perfect gas** $z = 1$, the compressibility factor can serve as a measure of the deviation of the properties of a real gas from perfect-gas behavior.

COMPRESSION. (1) In general usage, compression is descriptive of the decrease of volume of a compressible substance (solid, liquid or gaseous) due to the application of pressure. The common example of compression is found in cylinders filled with gas being compressed by the motion of a piston moving in the cylinder. The pressure increase required for any given reduction of volume of a gas depends upon the particular condition surrounding the act of compression; for example, if the cylinder is thoroughly insulated against heat transmission, the compression will be of a type known as **isentropic**, and the temperature of the gas will rise during compression because the mechanical work expended on the piston in obtaining the compression is converted into internal energy in the gas. On the other hand, if the cylinder is a good conductor of heat, and passes heat to the atmosphere as rapidly as it is received by the gas, the temperature at the end of compression may be the same as that at the beginning. In this isothermal compression the pressure at the end of compression is less than that of an equivalent isentropic compression. In general, actual compressions are neither strictly isentropic nor isothermal. (2) In structural engineering compression is used to denote the type of stress which causes the fibers of a member to shorten. (3) In electronics, the ratio of the small-signal power gain g_0 of a device to the power gain g_1 at some higher power level. Expressed in decibels:

$$\text{Compression} = 10 \log_{10} \frac{g_0}{g_1}$$

(See **compressor**.) (4) In television, the reduction in **gain** at one level of a picture signal with respect to the gain at another level of the same signal. (See also **black compression** and **white compression**.) The gain referred to in the definition is for a signal amplitude small in comparison with the total peak-to-peak, **picture signal** involved. A quantitative

evaluation of this effect can be obtained by a measurement of **differential gain**.

COMPRESSION EFFICIENCY. See **enthalpy drop**.

COMPRESSION-IGNITION ENGINE. See **diesel engine**.

COMPRESSION MODULUS. The ratio between the applied hydrostatic pressure and the decrease in volume per unit volume of an isotropic elastic material. Often denoted k and, when the **generalized Hooke's law** is applicable to the material, given in terms of the Lamé constants by

$$k = \frac{1}{3}(3\lambda + 2\mu).$$

Also called *bulk modulus*, or *modulus of compression*.

COMPRESSION RATIO. In an internal combustion engine (gasoline, diesel), the ratio of the volume of the compression chamber (total of the swept volume, V_s , and the volume at end of compression, V_c) to the volume at end of compression

$$r = \frac{V_s + V_c}{V_c}$$

The designation is somewhat illogical, but its use is universal.

COMPRESSION WAVE. A **simple wave** or progressive disturbance in the one-dimensional **isentropic** flow of a compressible fluid, such that the pressure and density of a fluid particle increase on crossing the wave in the direction of its motion.

COMPRESSOR. A machine whose function it is to provide a supply of gas at a pressure higher than that available. Compressors can operate on the static principle, as when compression is effected in a cylinder with the aid of a reciprocating piston driven from a crankshaft, the gas being suitably led into and out of the cylinder by automatic (spring-loaded) or governed valves. Such machines are called reciprocating compressors or simply compressors. Compression can also be achieved by the dynamic principle, as when the gas is first accelerated with the aid of blades on a rotor and then decelerated in a suitably-shaped passage so that its pressure becomes (approximately) equal to the dynamic pressure of the stream. Such machines are called rotary compressors or turbo-compressors.

The thermodynamic process of compression is, in principle, independent of the details of the compressor, except that compression in a rotary compressor is more nearly **isentropic** than in a reciprocating compressor.

The work of compression w per unit mass of gas, assuming the process to be reversible, depends strongly on the type of process undergone by the gas, being highest for isentropic compression, lowest for isothermal compression, and intermediate for polytropic compression. In the case of perfect gases, we have: Ideal work of polytropic compression

$$w = \frac{n}{n-1} p_1 V_1 \left[\left(\frac{p_2}{p_1} \right)^{\frac{n-1}{n}} - 1 \right]$$

(for isentropic compression substitute $n = \gamma$).

Ideal work of isothermal compression

$$w = p_1 V_1 \ln \left(\frac{p_2}{p_1} \right)$$

where 1 is the state at inlet; $p_1 V_1 = mRT_1$; p_2 is the pressure at exit.

Reciprocating compressors necessarily possess a **clearance volume**. The ideal diagram of operation for such a compressor with clearance volume $\epsilon_o V_s$ (ϵ_o being the clearance ratio)

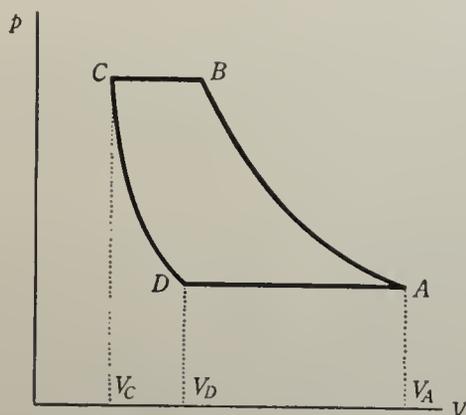

Fig. 1. Ideal p, V diagram of reciprocating compressor. In this diagram, the clearance volume is V_C , the swept volume V_s is equal to $V_A - V_C$, the clearance ratio ϵ_o is V_C/V_s , and the effective swept volume is $V_A - V_D$.

is shown in Figure 1. The work of compression is here

$$w = \frac{n}{n-1} p_A (V_A - V_D) \left[\left(\frac{p_B}{p_A} \right)^{\frac{n-1}{n}} - 1 \right]$$

for polytropic compression. The work of compression per unit mass is the same as without

a clearance volume, but the compressor behaves as if its swept volume had been reduced to $(V_A - V_D) = \mu V_s$ where μ is the **apparent volumetric efficiency**. Thus a larger compressor must be used and the actual work required increases because the losses are higher.

Owing to the existence of a clearance volume, the highest exit pressure attainable becomes

$$p'_B = p_A \left(\frac{1}{\epsilon_o} + 1 \right)^n$$

when the air filling volume $V_s(1 + \epsilon_o)$ attains pressure p'_B on reducing the volume to $\epsilon_o V_s$ so that none is left for delivery.

In order to achieve high exit pressures it is necessary to build multi-stage compressors by joining several of them (two, three, at most, four in practice) in series. When this is done, the gas can be cooled between the stages. In this manner the overall process of compression more nearly approaches an isothermal one, and the required work is reduced. The maximum saving is achieved when the work per unit mass in each stage is the same, which implies equal pressure ratios in each stage. In a two-stage compressor, the intermediate pressure

$$p_x = \sqrt{p_1 p_2}$$

where the gas is compressed to p_1 in the first stage, and to p_2 in the second. Dividing into stages also reduces thermal stresses.

The output of the compressor is judged by its **volumetric efficiency**

$$\lambda = \frac{\text{mass of gas delivered}}{\text{mass filling swept volume}}$$

The volumetric efficiency λ differs from the apparent volumetric efficiency μ because at the end of the inlet stroke (point A in Figure 1) the temperature of the gas T_A is higher than that at inlet T_o . Approximately

$$\frac{\lambda}{\mu} = \frac{T_o}{T_A}$$

The volumetric efficiency λ of a compressor can be improved and even made to exceed unity if a suitable long pipe is placed in front of its inlet. The periodic excitation from the piston causes high-amplitude pressure waves to travel through the inlet pipe. By proper steering it is possible to make the inlet pres-

sure higher than that outside. This process is sometimes called dynamic changing, Figure 2.

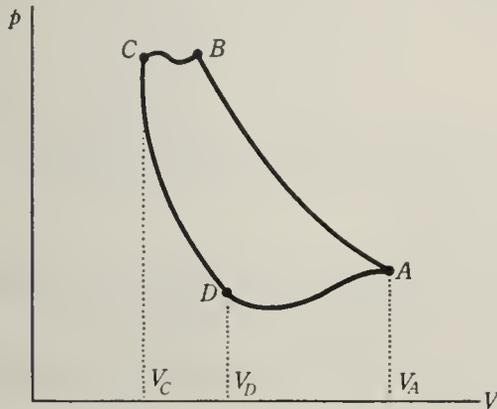

Fig. 2. p, V diagram of reciprocating compressor with dynamic changing.

A **vacuum pump** actually operates on the same principle as a compressor. The chamber to be evacuated is connected to the compressor inlet. The compressor draws gas at a decreasing pressure p_1 , compresses it to the constant atmospheric pressure p_2 and ejects it.

COMPTON EFFECT. Essentially, the scattering of a photon (quantum of electromagnetic radiation) by a free electron in which, owing to the conservation of energy and momentum, the scattered radiation suffers a wavelength change, increasing by

$$\Delta\lambda = \lambda_0(1 - \cos \theta),$$

where θ is the angle through which the beam is scattered and λ_0 , the Compton wavelength of the electron, is given by $\lambda_0 = h/mc$, where h is Planck's constant, m the rest mass of the electron, and c the velocity of light. At the same time, the electron recoils. Thus, the fractional change of wavelength $\Delta\lambda/\lambda$ increases with decreasing wavelength, i.e., with increasing photon energy. The effect was discovered in 1923 by Compton who observed the change of wavelength of a beam of X-rays scattered by carbon. Although electrons are normally bound, at energies $h\nu \gg \epsilon$, the binding energy, they can be considered as essentially free. The Compton effect is one of the famous effects which first demonstrated the corpuscular behavior of light. At long wavelengths, the Compton scattering becomes simply the classical, or Thomson, scattering. Compton scattering is peaked at forward angles compared with Thomson scattering. (See **scattering**.)

COMPUTATIONAL INSTABILITY. An instability in a finite difference equation which does not exist in the differential equation approximated thereby.

COMPUTER. Any physical device used as an aid in computing. It is customary to distinguish two general classes, **analog computers** and **digital computers**. (Also see **calculator**.)

COMPUTER, ANALOG. See **analog computer**.

COMPUTER, DIGITAL. See **digital computer**.

COMPUTER FLOW DIAGRAM. A graphical representation of a **program** or a **routine**.

CONCENTRATED FORCE. See **force, concentrated**.

CONCENTRATION. (1) The process of increasing the quantity of a substance or form of energy or other entity that exists in a volume of space, as in increasing by evaporation the amount of solute contained in unit volume in a solution, or as in gathering heat, light, electricity, or other energy or form of energy. (2) The quantity itself of matter or other entity that exists in a unit volume, as the strength of a solution in mass of solute per unit mass of solution, or in the number of moles, hydrogen ions, etc., contained per unit volume or per unit mass. (3) In statistics, the measure of **dispersion** known as the coefficient of concentration is defined as G where

$$G = \frac{\Delta_1}{2\mu_1}$$

Δ_1 being Gini's mean difference and μ_1 being the mean of the **distribution**.

CONCRETE, REINFORCED. Plain concrete will carry relatively heavy compressive stresses, but any attempt to impose tensile stresses of appreciable magnitude will result in rupture and consequent failure. For this reason plain concrete cannot be used for structural members subjected to a bending action or to a direct tensile action. However, if steel bars are incorporated in such a manner as to carry such tensile action as may develop in the member, then a safe and satisfactory "reinforced concrete" member may be used where otherwise a plain concrete member of the same

size, or even larger size, would be wholly inadequate and unsafe.

There are two physical phenomena which are primarily responsible for the successful use of steel and concrete jointly to form structural units or members: (1) The **coefficients of expansion** and contraction for concrete and steel are very nearly the same, thus preventing undesirable, or even disastrous, internal stresses due to differential expansion or contraction. (2) When the concrete hardens it grips the steel bars very tightly and securely and thus permits stress action between the two materials, the result of this joint action being exhibited as the strength of the structural member to resist the imposed load. Usually the steel bars are roughened to give the so-called "corrugated bar" which further assists in strengthening the adhesion between the concrete and steel by affording a sort of mechanical or interlocking bond.

CONDENSATE. The liquefied working fluid in a steam power installation.

CONDENSATION. (1) Change from gaseous (or vapor) state to liquid state. (See **change of state**.) (2) In general, increase in density. (3) The local increase in density in a sound wave, as contrasted with **rarefaction**: quantitatively,

$$s = \frac{\rho - \rho_0}{\rho_0},$$

where s is the condensation, ρ the local instantaneous density, ρ_0 the constant mean density at a point. (4) Accumulation of electric charge, as of electrons in a **capacitor**. (5) Convergence of light, or formation of a beam of parallel light rays. (6) In chemistry, various combination reactions of molecules to form larger molecules.

CONDENSATION, COEFFICIENT OF. It can be shown from kinetic theory that for a solid or liquid in equilibrium with its vapor at pressure p and temperature T , the mass of vapor molecules striking (and therefore also leaving) unit area per second is

$$\mu = p \sqrt{M/2\pi RT}$$

where M is the molecular weight of the vapor, and R the gas constant. If it can be assumed that every molecule striking the surface is condensed, this expression will also give the rate

of loss of weight of the solid or liquid at temperature T in a vacuum. If the assumption is not justified, the rate of loss of weight can be written

$$\mu = \alpha p \sqrt{M/2\pi RT}$$

the constant α being known as the coefficient of condensation. Experiments appear to show that this may be considerably less than unity in some cases.

CONDENSATION CURVE. See **boiling curve and condensation curve**.

CONDENSATION, EINSTEIN. See **Einstein condensation**.

CONDENSED SYSTEM. A substance or mixture of substances in the liquid or solid state. The term has also been applied to the condensation into a state of zero momentum of the particles in an ideal gas obeying **Bose-Einstein statistics**. (See **Einstein condensation**.)

CONDENSER. (1) For the electric condenser, see **capacitor**. (2) A device for liquefying gases or vapors. In power plant practice, in particular, a device for liquefying steam, especially the steam leaving a steam engine or steam turbine. In this manner the exit pressure is kept low, being roughly equal to the **saturation pressure** of steam which corresponds to the temperature of the available cooling water. This increases the efficiency of the power plant by a considerable amount.

CONDITIONAL CONVERGENCE. A series which is convergent but is not absolutely convergent is said to be conditionally convergent. (See **convergence**.)

CONDITION NUMBER. An indicator of **numerical stability**. In particular, the condition number of a matrix is usually taken to be a number that is equal to unity for a scalar matrix, and that is large when the matrix is in some sense nearly singular. Hence if the problem is to solve the linear system

$$\mathbf{Ax} = h,$$

the problem is unstable in case the condition number of \mathbf{A} is large. Among the several functions of the matrix that have been proposed, the most suitable seems to be

$$\gamma(\mathbf{A}) = \|\mathbf{A}\| \|\mathbf{A}^{-1}\|$$

for some appropriately chosen **norm**. The reason for this is that for small changes in \mathbf{A} , the ratio of the relative change in the solution to the relative change in \mathbf{A} can be shown not to exceed $\gamma(\mathbf{A})$. This is to say that if $\delta\mathbf{A}$ represents a small change in \mathbf{A} , and $\delta\mathbf{x}$ the induced change in \mathbf{x} , then

$$\begin{aligned} (\|\delta\mathbf{x}\|/\|\mathbf{x}\|)/(\|\delta\mathbf{A}\|/\|\mathbf{A}\|) &\leq \|\mathbf{A}\| \|\mathbf{A}^{-1}\| \\ &= \gamma(\mathbf{A}), \end{aligned}$$

provided second-order effects are neglected. More exactly, if $\mathbf{E} = \mathbf{A}^{-1}\delta\mathbf{A}$ and $\|\mathbf{E}\| < 1$, then

$$\begin{aligned} (\|\delta\mathbf{x}\|/\|\mathbf{x}\|)/(\|\delta\mathbf{A}\|/\|\mathbf{A}\|) \\ \leq \gamma(\mathbf{A})/(1 - \|\mathbf{E}\|). \end{aligned}$$

It should be observed that this condition number relates only to the invertibility of a matrix, and has no relation to the finding of its **eigenvalues and eigenvectors**. If \mathbf{A} is diagonalizable,

$$\mathbf{A} = \mathbf{P}\mathbf{\Lambda}\mathbf{P}^{-1}$$

where $\mathbf{\Lambda}$ is diagonal, then $\|\mathbf{P}\| \|\mathbf{P}^{-1}\|$ seems to be the appropriate condition number for this problem.

CONDON PARABOLA. In the Deslandres table of the **band system** of a diatomic molecule, the most intense bands are found to lie roughly on a parabola, the so-called Condon parabola. This effect finds a natural explanation in the **Franck-Condon principle**.

CONDUCTANCE. A term used in electrical circuits and by analogy in acoustical or mechanical systems to denote the real part of admittance. If the circuit or system has no **reactance**, its impedance consisting only of resistance, then its conductance is the reciprocal of its **resistance**.

CONDUCTION. The transmission of energy (heat, sound, electricity) by means of a medium without movement of the medium itself, as distinguished from convection, in which such movement occurs, or from radiation in which the energy quanta pass through the medium and so the transmission does not occur by means of the medium. (See **conduction, electric; thermal conduction**.)

CONDUCTION BAND. In the **band theory of solids**, materials are assumed to have a band of energy levels where electrons can move

freely and carry current. In semiconductors and insulators, this band, known as the conduction band, is normally empty, and is separated from the filled bands below it by an energy gap.

CONDUCTION BAND, DEGENERATE. See **degenerate conduction band**.

CONDUCTION BAND, DENSITY OF QUANTUM STATES IN. See **density of quantum states in conduction band**.

CONDUCTION, ELECTRIC. The transfer of electricity is accomplished by the motion of electric charge. In most metals, the moving charges are electrons; in semiconductors, both electrons and holes are important; in ionic crystals and electrolytes, positive and negative ions are the carriers; in gas discharges both ions and electrons play their parts.

CONDUCTION ELECTRONS, ORBITAL DIAMAGNETISM OF. See **orbital diamagnetism of conduction electrons**.

CONDUCTION ELECTRONS, SPIN PARAMAGNETISM OF. See **spin paramagnetism of conduction electrons**.

CONDUCTION, EXCESS. In a semiconductor, conduction by excess electrons, for example, by electrons introduced by donor impurities and promoted to the conduction band.

CONDUCTION, IONIC, IN SOLIDS. Since the ions of an ionic crystal may diffuse through the lattice, a small electrical conductivity is possible even though the material should otherwise be insulating. The process is very sensitive to temperature, and at low temperatures is also strongly dependent on the structure and purity of the material.

CONDUCTION, METALLIC. The conduction of electricity through solids wholly (or almost so) by the migration of electrons.

CONDUCTION OF HEAT. See **heat transfer; Fourier law**.

CONDUCTION, THERMAL. See **heat transfer; Fourier law**.

CONDUCTIVITY, ACOUSTIC. The ratio of the volume current through an orifice to the difference in **velocity potential** between the two sides of the orifice.

CONDUCTIVITY, ELECTRICAL. Strictly defined only for a material which obeys the Ohm law and equal to the ratio:

$$\sigma = J/E,$$

where **J** is the **current density** and **E** the **electrical field vector**. In any system of units, except the Gaussian, the conductivity is numerically equal to the inverse of the resistance of a cubical block of material having a current flow perpendicular to one pair of faces. The most commonly used unit is the mho per centimeter. In anisotropic materials the conductivity is a **tensor**, instead of a scalar.

CONDUCTIVITY OF HEAT AND ELECTRICITY, STATISTICAL TREATMENT. See **electron theory of metals**.

CONE IN SUPERSONIC FLOW. For a cone at zero incidence in a supersonic stream, provided the open angle is not too large, a conical shock wave is formed with axis and apex coinciding with those of the cone. There is then no characteristic length in the problem, and conditions are constant over any conical surface whose axis and apex coincide with those of the cone. Numerical solutions for a wide range of cone angles and Mach numbers have been tabulated.

This type of flow cannot occur if the cone angle is so large that the equations cannot be satisfied with an *attached* shock wave. The shock wave then becomes *detached* from the apex of the cone and is no longer conical. (See Z. Kopal, *Tables of Supersonic Flow about Cones*, M.I.T. Center of Analysis, Technical Report No. 1, 1947.)

CONFIDENCE LIMITS. Suppose that we are given a series of samples from a population whose distribution contains a parameter θ , and that we can find a rule of procedure which enables us to derive from each sample an assertion of the form $t_1 \leq \theta \leq t_2$. If the rule is such that this assertion has a probability of being correct of $\alpha\%$, then t_1, t_2 are called $\alpha\%$ confidence limits for θ .

CONFIGURATIONAL COMPRESSIBILITY. See **configurational heat capacity**.

CONFIGURATIONAL ELASTICITY OF A LIQUID. The compressibility of a liquid depends in part on resistance to compression

owing to the thermal agitation of the molecules and in part on disturbance of the **short range order**. The contribution from the latter is the configurational elasticity.

CONFIGURATIONAL EXPANSION. See **configurational heat capacity**.

CONFIGURATIONAL HEAT CAPACITY. Consider the heat capacity at constant pressure of a system in which a transformation defined by a parameter ξ may occur: we have (see **thermal coefficients**)

$$C_p = \left(\frac{dQ}{dT} \right)_p = C_{p,\xi} + h_{T,p} \left(\frac{d\xi}{dT} \right)_p. \quad (1)$$

The second term on the right-hand side refers to the effect of the temperature on the **reaction coordinate** ξ . This second term may be called the configurational heat capacity, C_p^{conf} , because in many cases ξ refers to the internal configuration of the system.

Similar definitions may be given for the *configurational compressibility* κ^{conf} and the *configurational thermal expansion* α^{conf} . If there exists a single parameter ξ then one has

$$C_p^{conf} = VT \frac{(\alpha^{conf})^2}{\kappa^{conf}}. \quad (2)$$

CONFIGURATION, ATOMIC. The arrangement in space of the atoms of a molecule.

CONFIGURATION, ELECTRON. See **electron configuration**.

CONFIGURATION FACTOR. See **shape factor**.

CONFIGURATION, INTERACTION. Calculations of bond energy of molecules depend on assuming that the electrons are to be found in certain **orbitals**, for which approximate forms must be assumed. To improve the calculation it is necessary to consider the admixture into the wave function of functions corresponding to other electronic configurations, supposed to represent excited states of the molecule.

CONFIGURATION SPACE. The space of the coordinates of a system of particles. In the configuration space method in quantum mechanics, the state of a system is described by a **wave function** which is a function of a

point in configuration space, that is, a function of all the coordinates of the particles.

CONFLUENCE. (1) If a_1, a_2 are distinct singular points (see **regular singularity**) of a differential equation, another differential equation may frequently be obtained as a limiting form when a_2 approaches a_1 . The second equation is then said to result from the first by confluence. The importance of this procedure arise chiefly from the fact that many of the linear equations of mathematical physics can be obtained by confluence from the generalized **Lamé equation**. (2) In fluid flow, a confluence is a region in which the spacing between streamlines decreases in the direction of flow.

CONFLUENT HYPERGEOMETRIC FUNCTIONS. There are four functions known as confluent hypergeometric functions: Kummer's function, ${}_2F_1[a; b; x]$, its associated solution $U(a; b; x)$ and the two Whittaker functions $M_{k,m}(x)$ and $W_{k,m}(x)$.

Most of the commonly used functions of mathematical physics, such as the **Weber functions** and **Bessel functions**, are special cases of confluent hypergeometric functions.

They can be derived from the *generalized hypergeometric function*

$${}_A F_B [a_1, a_2, \dots, a_A; b_1, b_2, \dots, b_B; x] = \sum_{n=0}^{\infty} \frac{(a_1)_n (a_2)_n \dots (a_A)_n x^n}{(b_1)_n (b_2)_n \dots (b_B)_n n!} \quad (1)$$

where $(a)_n \equiv a(a+1)(a+2)\dots(a+n-1)$ and $(a)_0 \equiv 1$, for all a_r, b_r and x , real or complex, provided that no b is a negative integer; it is the solution of the *generalized hypergeometric differential equation*

$$\left\{ x \frac{d}{dx} \left(x \frac{d}{dx} + b_1 - 1 \right) \left(x \frac{d}{dx} + b_2 - 1 \right) \dots \left(x \frac{d}{dx} + b_B - 1 \right) - x \left(x \frac{d}{dx} + a_1 \right) \left(x \frac{d}{dx} + a_2 \right) \dots \left(x \frac{d}{dx} + a_A \right) \right\} y = 0. \quad (2)$$

If $A = B = 1$, Kummer's equation results:

$$x \frac{d^2 y}{dx^2} + (b-x) \frac{dy}{dx} - ay = 0. \quad (3)$$

Its simplest solution is *Kummer's function*

$${}_1F_1(a; b; x) \equiv 1 + \frac{a}{b} x + \frac{a(a+1)x^2}{b(b+1)2!} + \frac{a(a+1)(a+2)x^3}{b(b+1)(b+2)3!} + \dots \quad (4)$$

If $A = B + 1$ in Equation (2), the equation becomes a *Fuchsian equation* of the general type

$$x^B(1-x) \frac{d^{B+1} y}{dx^{B+1}} + \sum_{n=1}^B x^{n-1} (a_n x - b_n) \frac{d^n y}{dx^n} + a_0 y = 0. \quad (5)$$

If $B = 1$, this equation becomes

$$x(1-x) \frac{d^2 y}{dx^2} + \{c - (1+a+b)x\} \frac{dy}{dx} - aby = 0, \quad (6)$$

the **Gauss hypergeometric equation** and one of its solutions is the **Gauss hypergeometric function**

$${}_2F_1[a; b; c; x]. \quad (7)$$

If we replace x by x/b and let $b \rightarrow \infty$ in (6) and (7), then $(b)_n x^n / b^n \rightarrow x^n$ and (6) reduces to Kummer's equation (3), (7) to Kummer's function (4).

An alternative form of solution of Kummer's equation is

$$y = U(a; b; x) = \frac{\Gamma(1-b)}{\Gamma(1+a-b)} {}_1F_1[a; b; x] + \frac{\Gamma(b-1)}{\Gamma(a)} x^{1-b} {}_1F_1[1+a-b; 2-b; x] \quad (8)$$

Putting

$$y = \exp \left\{ \frac{1}{2} \int \left(1 - \frac{b}{x} \right) dx \right\} z = x^{-1/2 b} e^{1/2 x} z \quad (9)$$

in Kummer's equation, so that the coefficient of $\frac{dy}{dx}$ becomes zero, the equation assumes the form of *Whittaker's normalized equation*

$$\frac{d^2 z}{dx^2} + \left(-\frac{1}{4} + \frac{k}{x} + \frac{\frac{1}{4} - m^2}{x^2} \right) z = 0 \quad (10)$$

where $m = 1/2 b - 1/2$ and $k = 1/2 b - a$. The inverse transform from Whittaker's equation to

Kummer's equation is $z = x^{1/2} b e^{-1/2 x} y$ where $a = 1/2 + m - k$ and $b = 1 + 2m$.

One of the solutions of Equation (10) is *Whittaker's function*

$$z = M_{k,m}(x) \\ = x^{1/2+m} e^{-1/2 x} {}_1F_1\left[\frac{1}{2} + m - k; 1 + 2m; x\right].$$

Any general solution of Whittaker's equation is called a Whittaker function.

An alternative solution for Whittaker's equation is the second Whittaker function

$$W_{k,m}(x) = \frac{\pi}{\sin 2m\pi} \\ \left\{ \frac{-M_{k,m}(x)}{\Gamma(\frac{1}{2} - m - k)\Gamma(1 + 2m)} \right. \\ \left. + \frac{M_{k,-m}(x)}{\Gamma(\frac{1}{2} + m - k)\Gamma(1 - 2m)} \right\}$$

for all values real or complex of k , m and x .

Using the standard notation for **Bessel functions**, they can be expressed in terms of confluent hypergeometric functions, in particular Whittaker functions, as follows:

$$M_{o,m}(2x) = \Gamma(1 + m) 2^{2m+1/2} x^{1/2} I_m(x)$$

$$W_{o,m}(x) = \sqrt{\frac{x}{\pi}} K_m\left(\frac{1}{2}x\right)$$

$$M_{o,m}(\pm 2ix)$$

$$= \Gamma(1 + m) \exp\left\{\pm \frac{1}{2}\pi i\left(\frac{1}{2} + m\right)\right\} 2^{2m+1/2} x^{1/2} J_m(x)$$

$$W_{o,m}(2ix)$$

$$= \sqrt{\frac{1}{2}\pi x} \exp\left\{-\frac{1}{4}i\pi(2m + 1)\right\} H_m^{(2)}(x)$$

$$W_{o,m}(-2ix)$$

$$= \sqrt{\frac{1}{2}\pi x} \exp\left\{\frac{1}{4}i\pi(2m + 1)\right\} H_m^{(1)}(x).$$

(For a discussion of all main properties of confluent hypergeometric functions, and tables of ${}_1F_1[a;b;x]$, see *Confluent Hypergeometric Functions* by L. J. Slater, Cambridge University Press, 1960.)

CONFORMAL MAPPING. A mapping of one region upon another that is one-to-one and continuous, and such that angles are preserved. Thus let arcs C_1 and C_2 in one region intersect in a point P ; and let these be mapped into arcs C'_1 and C'_2 intersecting in P' . Let P_1 be any point on C_1 , mapped into P'_1 on C'_1 . Let ϕ be the angle between tangents to C_1 and

C_2 at P , ϕ' that between tangents to C'_1 and C'_2 at P' . Preservation of angles means that $\phi' = \phi$. In case the regions are two-dimensional and simply connected, they can be regarded as regions of two complex planes, and the mapping is then defined by $z' = f(z)$, where $f(z)$ is analytic in z throughout the region.

CONFORMAL REPRESENTATION. See **representation**.

CONFORMAL SOLUTIONS. Suppose that one may describe the interaction between one molecule of species r and one molecule of species s by the expression

$$\epsilon_{rs}(r) = f_{rs}\epsilon(g_{rs}r) \quad (1)$$

where f_{rs} and g_{rs} are constants depending only on the chemical nature of r and s , and where $\epsilon(r)$ is some simple two parameter law of interaction (see **intermolecular forces**). If all constants f_{rs} , g_{rs} are of the same order we may consider a "first order" treatment in which differences $\left(\frac{f_{rs} - f_{r's'}}{f_{rs}}\right)^n$ are neglected for $n > 1$.

In this case it is possible to develop a simple perturbational treatment (Longuet-Higgins) without any supplementary assumptions. The final **excess functions** are expressed in terms of the thermodynamic properties of one component (called the reference component) and in terms of the differences in the f and the g 's. Solutions which satisfy the conditions which we have stated above are called conformal solutions.

CONFOUNDING. In the **design of experiments**, a method which reduces the size of a factorial experiment by sacrificing some of the comparisons which could be made with the full factorial layout. The comparisons usually relate to higher order interactions and are said to be confounded.

CONGRUENCE. See **rectilinear congruence; congruent**.

CONGRUENCE, NORMAL. See **rectilinear congruence**.

CONGRUENCE OF CURVES. A family of curves whose equations involve two independent parameters. Also called *curvilinear congruence*, or *congruence*.

CONGRUENCE OF STRAIGHT LINES. See **rectilinear congruence**.

CONGRUENT. (1) Two geometric figures are congruent if they differ only in their position in space; that is, they are congruent with respect to a given geometry if they can be transformed into each other by transformations belonging to the group of the geometry; e.g., in Euclidean geometry by translations, rotations and reflections. (2) Two elements a, b of a ring are congruent modulo m , written $a \equiv b \pmod{m}$, if there exist elements p, q, r in the ring such that $a = mp + r$, $b = mq + r$; roughly speaking, if they leave the same remainder when divided by m . Thus $3 \equiv 2 \pmod{5}$. (3) Two square matrices A, B are congruent if A can be transformed into B by a congruent transformation; that is, if there exists a non-singular matrix C such that $B = \hat{C}AC$, where \hat{C} is the transpose of C .

CONIC. The locus of a point in the plane such that the ratio of its distance from a fixed point, called the focus, to a fixed line, called the directrix, is a constant. The general equation of the second degree represents a conic. (See **ellipse**, **hyperbola**, **parabola**.)

CONICAL COORDINATES. A degenerate system of **curvilinear coordinates** obtained from an ellipsoidal system. The coordinate surfaces are: spheres with center at the origin of a rectangular system and radii u ($u = \text{const.}$); two sets of **cones** with apexes at the origin, one along the Z -axis and the other along the X -axis ($v, w = \text{const.}$). Conical coordinates are related to rectangular coordinates by the equations

$$x^2 = \frac{u^2 v^2 w^2}{b^2 c^2}$$

$$y^2 = \frac{u^2 (v^2 - b^2) (w^2 - b^2)}{b^2 (b^2 - c^2)}$$

$$z^2 = \frac{u^2 (v^2 - c^2) (w^2 - c^2)}{c^2 (c^2 - b^2)}$$

where $c^2 > v^2 > b^2 > u^2$.

CONICAL REFRACTION. A singular refraction where a single ray of light is refracted into the set of generators of a cone (see **cone**, **visual**). This can occur, for example, in a **biaxial crystal** for a suitable angle of incidence.

CONJUGATE. (1) See **complex number**. (2) See **transform**; **matrix**.

CONJUGATE BEAM. See **beam**, **conjugate**.

CONJUGATE BERTRAND CURVES. See **Bertrand curves**.

CONJUGATE DIRECTIONS (AT A POINT P ON A SURFACE). The directions of the straight line joining P to a neighboring point Q on the surface and the line of intersection of the tangent planes at P and Q , in the limiting case as Q tends to coincidence with P . If these two directions are the same, the direction is said to be a *self-conjugate direction*, or *asymptotic direction*. There are two real asymptotic directions at each point of a surface for which the two principal curvatures are of opposite signs. If the two principal curvatures have the same sign then the two asymptotic directions are imaginary. If one of the principal curvatures is zero, the two asymptotic directions at the point coincide.

CONJUGATE ELEMENTS OF A GROUP.

In a group G an element a is said to be conjugate to an element b if there exists an element p in G such that $b = pap^{-1}$. The relation of conjugacy is easily proved to be an equivalence, so that the whole group G is thereby divided into conjugate classes. A subgroup N is called a self-conjugate, or normal, subgroup if all the conjugates of every element of n (that is, all elements of the form pap^{-1} with a in N and p in G) are included in N .

CONJUGATE FOCI. The interdependent distances between object and lens and lens and image are known as the conjugate distances. As the distance from the object to the lens increases, that from the lens to the image decreases and vice versa. The formula expressing the geometrical relation between these distances is:

$$1/f = 1/v + 1/u$$

where f is the **focal length** of the lens, v , the lens-to-image distance, and u , the object-to-lens distance. The ratio of the conjugate distances determines the size of the image. Thus:

$$R = v/u$$

where R is the relative size of the image to the object. If $u = v$, $1/f = 2/u$ and $u = 2f$. Then the total $u + v = 4f$, which is the minimum

possible distance between real image and real object for a lens with positive focal length.

The definitions of v and u given here are applicable only to a thin lens. The equations apply to any lens system, however, if v and u are measured respectively from and to the appropriate **principal planes** of the lens or the lens system.

CONJUGATE GRADIENTS, METHOD OF.

A method of successive approximations for solving a system of linear equations which is exact after, at most, n steps. The successive approximations are so chosen that each residual is orthogonal to all preceding ones.

CONJUGATE IMPEDANCES. See **impedances, conjugate**.

CONJUGATE NUCLEI. A pair of nuclei of the same mass number for which the numbers of neutrons and protons are interchanged. Thus Be^7 , containing 4 protons and 3 neutrons is the conjugate of Li^7 containing 3 protons and 4 neutrons. Owing to the neutron excess of heavy nuclei, only light nuclei can be conjugate. Also known as *mirror nuclei*. A *self-conjugate nucleus* is one containing equal numbers of neutrons and protons, e.g., B^{10} .

CONJUGATE NUMBERS. Two algebraic numbers are conjugate over a given field if they are roots of the same irreducible equation with coefficients in the field. Thus the complex numbers $a + bi$, $a - bi$ are conjugate over the real field, since they are roots of the equation $x^2 - 2ax + (a^2 + b^2) = 0$.

CONJUGATE POINT. (1) A **singular point** on a curve which is the real intersection of imaginary **branches** of the curve. The condition which must be met is

$$\left(\frac{\partial^2 f}{\partial x \partial y}\right)^2 - \frac{\partial^2 f}{\partial x^2} \frac{\partial^2 f}{\partial y^2} < 0.$$

Also called an isolated point.

(2) The conjugate points of a compound pendulum are two support points on a line through the center of gravity for which the period of oscillation is the same.

(3) The correspondence of object points and image points in **Gaussian optics** is one-to-one, and a pair of corresponding points are called conjugate points. The correspondence is linear so we also have the notions of *conjugate lines* and *conjugate planes*.

CONJUGATE SUBGROUP. See **group**.

CONJUGATE SYSTEM OF CURVES ON A SURFACE. Two one-parameter families of curves on a surface such that at a point of intersection of two curves, one from each family, the directions of the two curves are **conjugate directions**.

CONJUGATE VARIABLES. See **canonically conjugate variables**.

CONJUGATION OF DOUBLE BONDS.

Two double bonds are said to be conjugated when they are separated by one single bond. Butadiene, hexatriene, benzene are typical examples of molecules with two or three conjugated double bonds. They are characterized by a high electron mobility, and a lowering of the heat of hydrogenation, i.e., an increased stability. (See **delocalization energy**.)

CONNECTED. A set of W of points in a **topological space** is said to be connected if it is not the union of two disjoint closed sets.

CONNECTED GRAPH. See **graph, connected**.

CONSECUTIVE MEAN. (Also called moving average, overlapping mean, running mean.) A smoothed representation of a **time series** derived by replacing each observed value with a mean value computed over a selected interval. For example, if the observations are of daily maximum temperature and the selected interval is five days, then the value assigned to February 5th is the mean of the daily maxima from February 3rd through 7th, etc.

Consecutive means are used in **smoothing** to eliminate unwanted periodicities or minimize irregular variations.

CONSERVATION LAWS. A conservation law is a statement that some physical quantity remains constant during processes or interactions occurring within an isolated (closed) system. Among the major conservation laws of science are those of energy (including rest mass energy), momentum, and angular momentum. (See following entries.) Some conservation laws such as **conservation of mass** in the non-relativistic limit and the conservation of parity in strong interactions, are of limited applicability. Other conservation

laws are discussed in the entries for the particular conserved quantities.

There is a close relationship between many of the conservation laws and the symmetry properties of nature, a given conserved quantity remaining invariant (conserved) under a given symmetry transformation. Thus the energy of a system remains constant under time inversion (replacing t by $-t$); the momentum of a system is invariant under a linear transformation of the space coordinates; angular momentum is invariant under a rotational transformation. In situations where parity is conserved, it remains invariant under an inversion of the space coordinates. (See also **Lagrangian formalism**.)

CONSERVATION OF ANGULAR MOMENTUM. If the total external **torque** or moment on a rigid body or a system of particles about a point vanishes, the total **angular momentum** of the system about this point is a constant. (See also **moment of momentum**.)

CONSERVATION OF ENERGY. In a closed system the form and availability of energy may change, but the total energy is constant. Conservation of energy in an isolated mechanical system is an idealization. Friction and other dissipative forces and actions are supposed negligible so that the sum of the **potential energy** and the **kinetic energy** is constant. For a mechanical system, which is non-dissipative, work done on the system = increase in mechanical energy of the system. (See **energy conservation in closed systems**; **energy conservation in continuous systems**; **energy conservation in thermodynamics**.)

CONSERVATION OF MASS IN CLOSED SYSTEMS. Consider an homogeneous closed system containing c components ($\gamma = 1 \cdots c$) among which a single chemical reaction is possible. In such a system any variation in the masses will result only from the chemical reaction. Thus the change of the masses m_γ of component γ during the time interval dt can be written as

$$dm_\gamma = \nu_\gamma M_\gamma d\xi \quad (1)$$

where M_γ is the molar mass of component γ and ν_γ its stoichiometric coefficient in the chemical reactions (see **stoichiometric coefficients**). This coefficient is generally counted positive when γ appears in the right hand member of

the reaction equation, negative when it appears in the left hand member; ξ is the degree of advancement or **extent of reaction**.

The total mass of the system is given by $m = \sum_\gamma m_\gamma$. Summing (1) over γ , the conservation of mass for a closed system is expressed by

$$dm = \left(\sum_\gamma \nu_\gamma M_\gamma \right) d\xi = 0. \quad (2)$$

The equation

$$\sum_\gamma \nu_\gamma M_\gamma = 0 \quad (3)$$

is called the equation of the chemical reaction or, more briefly, the stoichiometric equation.

Instead of the mass of the components it is often useful to consider the mole numbers $n_1 \cdots n_c$. We then have, instead of (1)

$$dn_\gamma = \nu_\gamma d\xi. \quad (4)$$

Equations (1) and (4) are extended easily to r simultaneous reactions. We shall always designate the different reactions by indices ($\rho = 1 \cdots r$). We then have instead of (1) and (4)

$$dm_\gamma = M_\gamma \sum_{\rho=1}^r \nu_{\gamma\rho} d\xi_\rho \quad (5)$$

$$dn_\gamma = \sum_{\rho=1}^r \nu_{\gamma\rho} d\xi_\rho \quad (6)$$

where $\nu_{\gamma\rho}$ denotes the stoichiometric coefficient of γ in the reaction ρ .

CONSERVATION OF MASS IN CONTINUOUS SYSTEMS. The conservation of mass in a **continuous system** is expressed by the equation of continuity for the density

$$\frac{\partial \rho}{\partial t} = - \operatorname{div} \rho \omega \quad (1)$$

where ω is the macroscopic velocity. This equation expresses the fact that the local change of the density is equal to the negative divergence of the flow of matter.

Equation (1) holds also for a mixture; ω is then related to the macroscopic velocities of the different components by

$$\omega = \left(\sum_\gamma \rho_\gamma \omega_\gamma \right) / \rho. \quad (2)$$

Thus ω is simply the velocity of the center of gravity in an element of volume.

In general, the local change of a physical quantity is due not only to the divergence of the current which is associated with it, but a "source" term has also to be taken into account. For instance, the equation of continuity for the density ρ_γ of a component γ participating in a chemical reaction is

$$\frac{\partial \rho_\gamma}{\partial t} = -\operatorname{div} \rho_\gamma \omega_\gamma + \nu_\gamma M_\gamma V_v \quad (3)$$

where V_v is the rate of the chemical reaction per unit volume.

CONSERVATION OF MASS IN OPEN SYSTEMS. In an open system we may split the change of mass of component γ into an external part $d_e m_\gamma$ supplied from the exterior and an internal part $d_i m_\gamma$ due to changes inside the system

$$dm_\gamma = d_e m_\gamma + d_i m_\gamma. \quad (1)$$

Taking into account the Equations (5) and (6) introduced in the article on **conservation of mass in closed systems** we have

$$dm_\gamma = d_e m_\gamma + M_\gamma \sum_{\rho=1}^r \nu_{\gamma\rho} d\xi_\rho \quad (2)$$

or

$$dn_\gamma = d_e n_\gamma + \sum_{\rho=1}^r \nu_{\gamma\rho} d\xi_\rho. \quad (3)$$

Summing (2) over γ and taking into account the stoichiometric equations $\sum_\gamma \nu_{\gamma\rho} M_\gamma = 0$, we obtain for the total change of mass

$$dm = d_e m. \quad (4)$$

This relation expresses the conservation of mass in open systems and indicates that the change of the total mass is equal to the mass exchanged with the outside world.

The process of splitting the total change of mass of a component into an external part and an internal part may be used on arbitrary extensive property. (See **energy conservation in thermodynamics; thermodynamics, second law of.**)

CONSERVATION OF MASS, LAW OF. This law has been put in the form that matter can neither be created nor destroyed. More accurately, the total mass of any system remains constant under all transformations. (For the interpretation of this law in the light of relativity theory, see **mass-energy relation.**)

CONSERVATION OF MOMENTUM. For a dynamical system consisting of n material particles of masses $m_1, m_2 \cdots m_n$ respectively and position vectors $\mathbf{r}_1, \mathbf{r}_2 \cdots \mathbf{r}_n$ respectively, if the only forces acting are the mutual interaction forces of the particles the total momentum of the system remains constant; for example,

$$\sum m_i \frac{d\mathbf{r}_i}{dt} = \text{constant.}$$

The law of conservation of momentum is as fundamental to science as the law of **conservation of mass** or the law of **conservation of energy**. Like these laws, it holds in **quantum theory** and **relativity theory** as well as in more classical theories.

CONSERVATION OF VORTICITY. (1) The statement that in the horizontal flow of an inviscid autobarotropic fluid, the vertical component of **absolute vorticity** of each individual fluid particle remains constant. The principle was first applied to the atmosphere by Rossby and is the dynamical principle underlying the **equivalent-barotropic model** of the atmosphere. (2) The hypothesis that the **vorticity** of individual **eddies** is conserved during the turbulent mixing of a fluid. (See **vorticity transport hypothesis.**)

CONSERVATIVE FORCE (FIELD). If the work integral $\int_A^B \mathbf{F} \cdot d\mathbf{r}$ is independent of the path, the force \mathbf{F} is said to be conservative. \mathbf{F} is a function of position \mathbf{r} only and a potential energy V must exist, $\mathbf{F} = -\nabla V$.

CONSERVATIVE SYSTEM. A closed system in which mechanical energy is constant is called a conservative system, as is an **open system** in which all external work is available as potential and kinetic energy of the system.

CONSERVED QUANTITIES. Those quantities which obey conservation laws, e.g., **mass-energy**, **momentum**.

CONSISTENT DEFORMATION, PRINCIPLE OF. See **compatibility**.

CONSISTENT ESTIMATOR. In statistics, an estimator which converges in probability, as the sample size increases, to the parameter which it estimates.

sumer's risk arises from the error of accepting lots which should be rejected.

CONTACT ANGLE. The angle formed by a liquid on the surface of a solid at the gas-solid-liquid interface, measured as the dihedral angle in the liquid. Its value depends on the relative surface energies of the three interfaces, vapor-solid, vapor-liquid and solid-liquid.

CONTACT POTENTIAL. The potential difference observed between the surfaces of two metals in contact. It is due to the differences in **work function**; the electrons in each metal tend to reach the same **Fermi level**, and potential builds up until this is established. A distinction must be made between the contact potentials in air and the so-called "intrinsic" contact potentials in a vacuum with all adsorbed gases removed. According to Millikan, the intrinsic potential difference between two metals A and B is expressed by $V_{AB} = h(\nu_A - \nu_B)/e$, in which h is the **Planck constant**, ν_A and ν_B are the critical frequencies of photoelectric emission for the two metals, and e is the electronic charge. In any case, if the electronic work functions of the metals are p_A and p_B , the contact potential difference is $V_{AB} = (p_A - p_B)/e$. The work functions, and hence V_{AB} , are in general dependent upon the medium surrounding the metals. Accurate measurements of these potentials are, unfortunately, very difficult.

CONTACT RECTIFICATION CURRENT. For a metal-semiconductor contact, the relation between the current density, j , and the voltage, V , applied across the contact, is of the form

$$j = j_o(E)[\exp(eV/kT) - 1]$$

where e is the electronic charge, k is Boltzmann's constant, and T is the absolute temperature. E is the electric field strength at the contact due to surface charge, and $j_o(E)$ is given by the approximate expression

$$j_o(E) \sim \sigma_o |E| \exp\left(\frac{-e|V_b|}{kT}\right)$$

where σ_o is the conductivity of the semiconductor in its deep interior, and V_b is the difference in electric potential between the inner boundary of the space-charge region and the peak of the space-charge barrier.

CONTACT TRANSFORMATION. Let $(q_1, q_2, \dots, q_n, p_1, p_2, \dots, p_n)$ be a set of $2n$ variables

and let $(Q_1, Q_2, \dots, Q_n, P_1, P_2, \dots, P_n)$ be $2n$ other variables which are defined in terms of them by $2n$ equations. If the equations connecting the 2 sets of variables are such that the differential form $P_1dQ_1 + P_2dQ_2 + \dots + P_ndQ_n - p_1dq_1 - p_2dq_2 - \dots - p_ndq_n$ is, when expressed in terms of $(q_1, q_2, \dots, q_n, p_1, p_2, \dots, p_n)$ and their differentials, the perfect differential of a function of $(q_1, q_2, \dots, q_n, p_1, p_2, \dots, p_n)$ then the change from the set of the variables $(q_1, q_2, \dots, q_n, p_1, p_2, \dots, p_n)$ to the other set $(Q_1, Q_2, \dots, Q_n, P_1, P_2, \dots, P_n)$ is called a contact transformation. The name derives from its property in 3-dimensional space: If two surfaces σ and σ' touch at a point, and if Σ and Σ' are the new surfaces resulting from them under a contact transformation, then Σ and Σ' touch again at the image point of the original point. The **canonical transformation** is a special case of a contact transformation. The **canonical equations of motion** preserve their form under such a transformation.

CONTINGENCY. If the members of an aggregate can bear the qualities A_1, A_2, \dots, A_p of one characteristic and B_1, B_2, \dots, B_q of a second, they can be arranged in a $p \times q$ table, the number in the j^{th} row and k^{th} column, say f_{jk} , being the frequency of individuals bearing A_j and B_k . This is called a *contingency table*. If the frequency in the marginal total of the i^{th} row is f_i and that in the k^{th} column is f_j ; the *square contingency* is defined as

$$\phi^2 = \sum_{i,j} \frac{(f_{ij} - f_i \cdot f_j / n)^2}{f_i \cdot f_j / n}$$

The mean-square contingency, ϕ^2/n is equal to χ^2 (**chi-square**) for the table and is used as a test of independence of A and B .

Pearson's coefficient of contingency is defined as

$$C = \left(\frac{\phi^2}{1 + \phi^2}\right)^{1/2}$$

CONTINGENCY TABLE. See **contingency**.

CONTINUANT. A determinant of the form

$$K \begin{pmatrix} a_1 & \dots & a_n \\ b_0 b_1 & \dots & b_n \end{pmatrix} = \begin{vmatrix} b_0 & a_1 & 0 & \dots & 0 \\ -1 & b_1 & a_2 & \dots & 0 \\ 0 & -1 & b_2 & \dots & 0 \\ \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & 0 & \dots & b_n \end{vmatrix},$$

so called because the n th numerator and n th denominator of the **continued fraction**

$$F = b_0 + a_1/\sqrt{b_1} + \dots$$

are

$$A_n = K \begin{pmatrix} a_0 & \dots & a_n \\ b_0 b_1 & \dots & b_n \end{pmatrix}$$

$$B_n = K \begin{pmatrix} a_1 & \dots & a_n \\ b_1 b_2 & \dots & b_n \end{pmatrix}.$$

CONTINUATION. See **analytic continuation**.

CONTINUED FRACTION. See **fraction, continued**.

CONTINUITY EQUATION. A continuity equation can be applied to the flow of any conserved, indestructible quantity. The continuity equation may be written in general form as

$$\nabla \cdot (\rho \mathbf{v}) = -\dot{\rho} \quad \text{or} \quad \nabla \cdot \mathbf{J} = -\dot{\rho},$$

where \mathbf{v} is a flow velocity, ρ is a density, and $\mathbf{J} = \rho \mathbf{v}$ is a current density.

The continuity equation may be alternatively written in integral form as

$$\int \mathbf{J} \cdot d\mathbf{a} = -\frac{d}{dt} \int \rho dV$$

which may be interpreted as the statement that the net outward current of a quantity from a closed surface is equal to the rate of decrease of that quantity in the volume enclosed by the surface.

(1) In fluid flow, mass is conserved and the equation of continuity holds, where ρ is mass per unit volume and \mathbf{v} is the velocity of mass flow. In the case of an incompressible fluid, ρ is constant and the continuity equation becomes $\nabla \cdot \mathbf{v} = 0$.

(2) In electric currents, charge is conserved and the equation of continuity holds, where ρ is the charge per unit volume, \mathbf{v} is the velocity of charge flow, and $\mathbf{J} = \rho \mathbf{v}$ is the electric current density. If the current is in a steady state, $\nabla \cdot \mathbf{J} = 0$.

(3) In the flow of electromagnetic energy in charge-free space, this energy is conserved and the equation of continuity becomes:

$$\nabla \cdot \mathbf{P} = -\frac{\partial}{\partial t} \left(\frac{\mathbf{E} \cdot \mathbf{D}}{2} + \frac{\mathbf{B} \cdot \mathbf{H}}{2} \right).$$

Here $\mathbf{P} = \mathbf{E} \times \mathbf{H}$ is **Poynting's vector**, the intensity of the radiation or power flow per unit

area, and $\frac{1}{2}(\mathbf{E} \cdot \mathbf{D} + \mathbf{B} \cdot \mathbf{H})$ is the electromagnetic energy density.

If the space is not charge free, energy can be transferred to the charges and be lost from the field. In this case a term $\mathbf{E} \cdot \mathbf{J}$ must be added to the left hand side of the equation, representing the rate of dissipation of energy per unit volume.

(4) In quantum mechanics, probability is conserved, and the continuity equation can be written: $\nabla \cdot \mathbf{S} = -\dot{P}$, where P is the probability density, $\psi\psi^*$, and \mathbf{S} is the probability density current given by $\mathbf{S} = (\hbar/2mi)(\psi^*\nabla\psi - \psi\nabla\psi^*)$.

CONTINUITY OF A BEAM. When applied to a beam, the term continuity means continuity of slope and deflection at junction and support points. Transmission of moment is implied as well.

CONTINUITY OF PATH, PRINCIPLE OF. See **ergodic theorem**.

CONTINUITY OF STATE. Transition between two states, as between the gaseous and liquid states, in either direction, without discontinuity, or abrupt change in physical properties. The existence of a **critical point** makes it possible to pass from the liquid state to the vapor or vice versa, without at any stage observing the appearance of a new phase. This is the principle of the continuity of state first pointed out by James Thomson.

CONTINUOUS BEAM. See **beam, continuous**.

CONTINUOUS CREATION HYPOTHESIS. Hypothesis that the universe is being created continuously by the formation, without apparent mechanism, of one nucleon per 10^9 year-liter, a rate too small to be directly detected, but sufficient to keep the average density constant despite the expansion of the universe. Galaxies which have receded to a distance of more than 2×10^9 years are supposed to disappear from view, and the whole universe is in dynamic equilibrium, recently created matter forming into galaxies to replace those which are lost. Thus the universe is in a steady state, although the matter which composes it is being continually changed. This creation of matter throughout all space, without local energy conservation, is so great a mystery that the theory has not been generally accepted.

CONTINUOUS FUNCTION. The function $f(x)$ is continuous at the point p if, for every $\epsilon > 0$, there exists a δ such that if $|x - p| < \delta$, then $|f(x) - f(p)| < \epsilon$. (Compare **absolute continuity**.)

CONTINUOUS SPECTRUM. See **spectrum, continuous**.

CONTINUOUS SYSTEMS. Systems in which the intensive state variables are not only functions of time but also continuous functions of the space coordinates. A piece of metal heated at one end and cooled at the other is an example of a continuous system. (See also **discontinuous systems**.)

CONTINUOUS SYSTEMS, LAGRANGIAN AND HAMILTONIAN FORMALISM FOR.

In a continuous system one introduces a Lagrangian density $L = L(\psi, \text{grad } \psi, \frac{\partial \psi}{\partial t} \cdot t)$ where the ψ 's are the field variables, e.g., the **metric tensor** in general relativity or the **scalar and vector potentials** in electrodynamics. The corresponding **Lagrangian equations** (of the second type) are,

$$\frac{\partial L}{\partial \psi} - \sum_{xyz} \frac{\partial}{\partial x} \left[\frac{\partial L}{\partial \left(\frac{\partial \psi}{\partial x} \right)} \right] - \frac{\partial}{\partial t} \left[\frac{\partial L}{\partial \left(\frac{\partial \psi}{\partial t} \right)} \right] = 0.$$

The *Hamiltonian density* is defined as

$$H = \frac{\partial L}{\partial \left(\frac{\partial \psi}{\partial t} \right)} - L.$$

The quantities $\frac{\partial \psi}{\partial t}$ are the *generalized velocity-densities* and $\pi \equiv \frac{\partial L}{\partial \left(\frac{\partial \psi}{\partial t} \right)}$ are the *generalized*

momentum-densities. Thus one can also write

$$H = \pi \frac{\partial \psi}{\partial t} - L.$$

The **canonical equations of motion** are,

$$\frac{\partial H}{\partial \psi} - \sum_{xyz} \frac{\partial}{\partial x} \frac{\partial H}{\partial \left(\frac{\partial \psi}{\partial x} \right)} = - \frac{\partial \pi}{\partial t}$$

and

$$\frac{\partial H}{\partial \pi} - \sum_{xyz} \frac{\partial}{\partial x} \frac{\partial H}{\partial \left(\frac{\partial \pi}{\partial x} \right)} = + \frac{\partial \psi}{\partial t}.$$

CONTINUUM. A **compact connected** set containing at least two points.

CONTOUR INTEGRATION. This term usually refers to **integration** over a (closed) simple rectifiable curve in the complex plane. An integral $\int_C f(z) dz$ of a continuous function $f(z)$ around such a curve C is most easily defined in case C is given in parametric form $z = z(t)$ with real t , $a \leq t \leq b$, when $\int_C f(z) dz$ is defined by

$$\int_C f(z) dz = \lim_{n \rightarrow \infty} \sum_{i=1}^n f(\eta_j) \left[z(t_i) - z(t_{i-1}) \right]$$

where the maximum length of the subintervals $(t_i - t_{i-1})$, with $t_0 = a$ and $t_n = b$, tends to zero.

CONTRACTED RIEMANN-CHRISTOFFEL TENSOR. The tensor $G_{\mu\nu} = B_{\mu\nu\epsilon}{}^\epsilon$ where $B_{\mu\nu\sigma}{}^\epsilon$ is the **Riemann-Christoffel tensor**. Summation on the repeated index ϵ is implied.

CONTRACTION (AS A RESULT OF COMBUSTION). See **combustion**.

CONTRACTION (WHEN INDICIAL NOTATION IS USED). The operation of setting two indices on a symbol or product of symbols equal to each other and summing over the values which may be taken by the indices. In tensor analysis one of the symbols must be a superscript and the other a subscript. In Cartesian tensor analysis they may both be subscripts.

CONTRACTION, COEFFICIENT OF. The ratio of the sectional area of the parallel jet of liquid issuing from an orifice to the area of the orifice. Its value depends on the nature of the orifice and varies between 0.5 and 1.

CONTRAFLOW. See **heat exchanger**.

CONTRAGRADIANT. A word used to describe the relationship of two tensors which have different transformation properties. (See **tensor field**.)

CONTRAST. This term is used in physical science and statistics with at least four meanings. (1) In photography, the slope of the curve plotted between **density** and the log of **exposure** (see **H and D curve**). (2) In television, the ratio between the maximum and minimum brightness values in a picture. (3) In psychophysics, the change in the response to a stimulus as a result of the proximity in space or time of other stimuli. In general, the response to a stimulus of given physical intensity is reduced if neighboring stimuli have greater intensities, and vice versa. A measure of contrast is the contrast sensitivity which may be expressed, for example, for brightness by the expression $\Delta B/B$, where B is the brightness of a background, and ΔB is the difference in brightness of a small spot that is just discernible against that background. (4) In statistics, a contrast between a set of independent observations x_i of equal accuracy is a linear function $\Lambda = \sum \lambda_i x_i$ in which the sum of the coefficients $\sum \lambda_i = 0$. If σ^2 is the **variance** of a single observation and Λ, Λ' are two contrasts with coefficients λ_i, λ'_i , then the variance of Λ is $\sum \lambda_i^2 \sigma^2$ and the **covariance** of Λ and Λ' is $\sum \lambda_i \lambda'_i \sigma^2$. If $\sum \lambda_i \lambda'_i = 0$, the contrasts are said to be **orthogonal**.

CONTRAVARIANCE, ORDER OF. See **tensor field**.

CONTRAVARIANT METRIC TENSOR. See **metric tensor**.

CONTRAVARIANT STRESS TENSOR. See **stress tensor**.

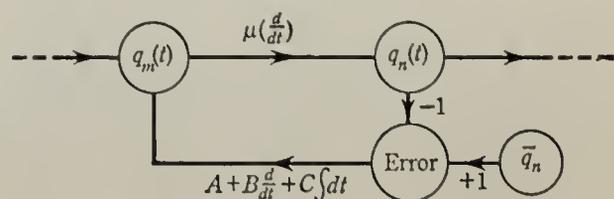

CONTRAVARIANT TENSOR (TENSOR FIELD). See **tensor field**.

CONTRAVARIANT VECTOR (VECTOR FIELD). Contravariant tensor (tensor field) of order one. (See **tensor field**.)

CONTROL. (1) A system or device which exerts a restraining, governing or direction influence. (2) An experiment or test done to confirm or to rule out error in experimental observations. (3) Usually, those parts of a digital computer which effect the carrying out of instructions in proper sequence, the interpretation of each instruction, and the application of the proper signals to the arithmetic unit and other parts in accordance with this interpretation. (4) Frequently, one or more of the components in any mechanism respon-

sible for interpreting and carrying out manually-initiated directions. Sometimes called **manual control**.

CONTROL, PROPORTIONAL, DERIVATIVE AND INTEGRAL. Terms used mainly in connection with process control engineering. Most process control systems are regulating systems, that is, their aim is to keep the controlled quantity constant in the face of internal or external disturbances. In such systems the "input" is therefore constant and corresponds to some pre-set value of the output or controlled quantity; deviation of the output from this set point constitutes the **error**, which must be measured and some function of which must be fed back to a suitable quantity occurring earlier in the process which thus modifies the output in such a way as to reduce the error. The function of error fed back normally consists of not more than three terms, the first (which must be present), being proportional to the error, the second proportional to its time derivative, the third proportional to its time integral. A proportional control system has only the first term present, a proportional plus derivative control system has only the first two terms present and so on.

From a signal flow diagram point of view, such systems may be typified by the general diagram shown, in which the through line of dependence represents the process, $q_n(t)$ is the controlled quantity, \bar{q}_n its constant desired value, $q_m(t)$ is the quantity receiving the feedback from error and A, B, C , determine the magnitudes of the proportional, derivative and integral feed-back terms respectively.

In **Laplace transform** notation the output is therefore contributed to by the error via the relation

\mathcal{L} contribution to output

$$\mathcal{L} \text{ error} = \mu(s)(A + Bs + C/s).$$

The disturbance, which brings the control into operation by setting up an error, may occur prior to q_m or between q_m and q_n .

CONTROL ROD, EFFECTIVE RADIUS OF. See radius, effective, of control rod.

CONTROL SYSTEM EQUATIONS. See system equations.

CONTROL SYSTEM SIGNAL FLOW DIAGRAMS. See signal flow diagrams.

CONTROL SYSTEM, STABILITY OF. See stability (of system).

CONTROL SYSTEM, TYPE NUMBER. The number of integrations contained in the relation connecting output to error, i.e., the (non-negative) power of $\frac{1}{s}$ contained in the output to error transfer function. Also called by some authors the "order" of the system.

The type number is related to the ultimate error (as $t \rightarrow \infty$) of the system when the input has the form of an impulse function or any of its integrals, as follows:

Let the output to error transfer function be $G(s)$ and let this transfer function be expressed in the form

$$G(s) = \frac{KG_o(s)}{s^n}$$

where n is the type number of the system and the gain factor K has such a value that $G_o(0) = 1$. Then, denoting error and input by $\theta_e(t)$, $\theta_i(t)$ respectively

$$\frac{\Theta_e(s)}{\Theta_i(s)} = \frac{1}{1 + G(s)} = \frac{s^n}{s^n + KG_o(s)}$$

If, further, $\Theta_i(s) = \frac{1}{s^m}$ ($m \leq 0$), so that $\theta_i(t)$ is the m th integral of unit impulse function at $t = 0$,

$$\Theta_e(s) = \frac{s^{n-m}}{s^n + KG_o(s)}$$

Hence by the Laplace transform limit theorem, assuming the system is stable,

$$\lim_{t \rightarrow \infty} \theta_e(t) = \lim_{s \rightarrow 0} s\Theta_e(s) = \lim_{s \rightarrow 0} \frac{s^{n-m+1}}{s^n + KG_o(s)} = \left. \begin{aligned} &= \lim_{s \rightarrow 0} \frac{s^{1-m}}{1 + K} \text{ if } n = 0 \\ &= \lim_{s \rightarrow 0} \frac{s^{n+1-m}}{K} \text{ if } n > 0 \end{aligned} \right\}.$$

These results are best stated in the form of a table of the ultimate error:

Input		$n=0$	$n=1$	$n=2$	$n=3$
$m=0$	$\theta_i(t) = \delta(t)$	0	0	0	0
$m=1$	$\theta_i(t) = u(t)$	$\frac{1}{1+K}$	0	0	0
$m=2$	$\theta_i(t) = tu(t)$	∞	$\frac{1}{K}$	0	0
$m=3$	$\theta_i(t) = \frac{t^2}{2} u(t)$	∞	∞	$\frac{1}{K}$	0

In practical systems the number of integrations is never greater than 2.

CONTROL VOLUME. See open system.

CONVECTED COORDINATE SYSTEM. A coordinate system embedded in a body undergoing deformation, so that as the body deforms the coordinates of a particle in the coordinate system remain unchanged.

CONVECTION. Transfer by the motion of a fluid, but often restricted to mean transfer by eddy motions only; sometimes used to refer to the eddy motion itself. Thermal, buoyant, or free convection refers to the transfer of heat (or buoyancy) by the motions which buoyancy forces produce. Forced convection is eddying motion produced mechanically as in a turbulent boundary layer or in a wind over a rough surface. (See also heat transfer.)

CONVECTION CELLS. See Bénard cells.

CONVECTION CURRENT, ELECTRIC. See discussion under current, electric.

CONVECTION, FORCED. See heat transfer.

CONVECTION, NATURAL. See heat transfer.

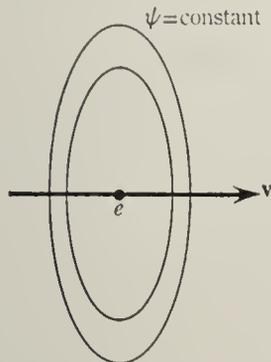

CONVECTIVE POTENTIAL. The convective potential, first introduced by Oliver Heaviside, is the scalar potential rigidly moving with an electric charge of uniform velocity v . For a point-charge e this potential is

$$\psi = \frac{e(1 - \beta^2)}{\sqrt{x^2 + (1 - \beta^2)(y^2 + z^2)}}$$

where

$$\beta = \frac{v}{c}$$

and the center of the coordinate system is at the location of the point charge. The surfaces of constant potential are ellipsoids of revolu-

tion (see figure). The axis of revolution coincides with the direction of the velocity v . (See also **field of moving charge in space**.)

CONVECTIVE (OR ADVECTIVE) RATE OF CHANGE. The rate of change produced by motion in a non-uniform field; equal to

$$\begin{aligned} \mathbf{v} \cdot \text{grad} &= u_i \frac{\partial}{\partial x_i} \\ &= u \frac{\partial}{\partial x} + v \frac{\partial}{\partial y} + w \frac{\partial}{\partial z} \end{aligned}$$

according to the notation used.

CONVENTIONAL YIELD LIMIT. See **limit, yield**.

CONVERGENCE. A sequence of real or complex numbers $a_1, a_2, \dots, a_n, \dots$ is convergent, or converges, to a number l , called the **limit** of the sequence, if, corresponding to each number ϵ , there exists an integer N , such that $|l - a_n| < \epsilon$ for all $n > N$, the vertical strokes denoting **absolute value**.

A **series** $a_1 + a_2 + \dots + a_n + \dots$ is convergent if the sequence of its partial sums s_1, s_2, \dots, s_n converges where $s_n = a_1 + a_2 + \dots + a_n$. A sequence or series which is not convergent is called *divergent*.

A series is *absolutely convergent* if the series of corresponding absolute values $|a_1| + |a_2| + \dots + |a_n| + \dots$ is convergent. A series such as $1 - \frac{1}{2} + \frac{1}{3} - \frac{1}{4} + \dots$, which is convergent but not absolutely convergent, is said to be *conditionally convergent*. Of the many tests for convergence of a series the following

are most often used: **comparison test**, **ratio test** (D'Alembert's), **Cauchy integral test**. Absolutely convergent series are important because they can be rearranged, multiplied together, and so forth, in very much the same way as finite sums. For every power series $a_0 + a_1z + a_2z^2 + \dots$ in a complex variable z , there exists a non-negative real number ρ (which may be zero or infinity) such that for $|z| < \rho$ the series converges absolutely and for $|z| > \rho$ the series diverges. The circle with center at the origin and radius equal to ρ is called the *circle of convergence* of the series.

An improper integral of the form $\int_c^\infty f(x)dx$, with $f(x)$ continuous for $x \geq c$, is convergent if, for every sequence $c < d_1 < d_2 < \dots$ of real numbers which is not bounded, the sequence $\int_c^{d_n} f(x)dx$ is convergent. Similarly, $\int_c^\infty f(x)dx$ is absolutely convergent if $\int_0^\infty |f(x)|dx$ is convergent, with corresponding definitions for improper integrals of other forms.

A sequence of functions $u_1(x), u_2(x), \dots$ defined over an interval $a \leq x \leq b$ is convergent over the interval if, for every p with $a \leq p \leq b$ the sequence of numbers $u_1(p), u_2(p), \dots$ is convergent. The sequence of functions is *uniformly convergent* to a function $f(x)$ if corresponding to each positive ϵ , there exists an integer N , depending on ϵ but not on x , such that

$$|l(x) - f_n(x)| < \epsilon \quad \text{for all } x,$$

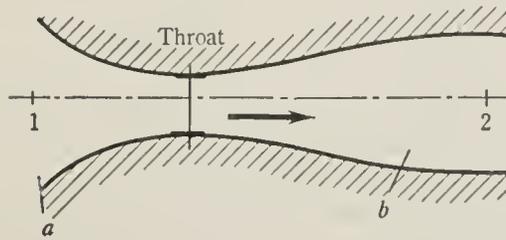

provided only that $n > N$. Uniformly convergent series are important because they allow **termwise integration**, a property which is particularly valuable in the applications of **Fourier series**. The most important test for uniform convergence is the **Weierstrass M-test**.

CONVERGENCE, ANGLE OF. See **angle of convergence**.

CONVERGENCE, CONDITIONAL. See **conditional convergence**.

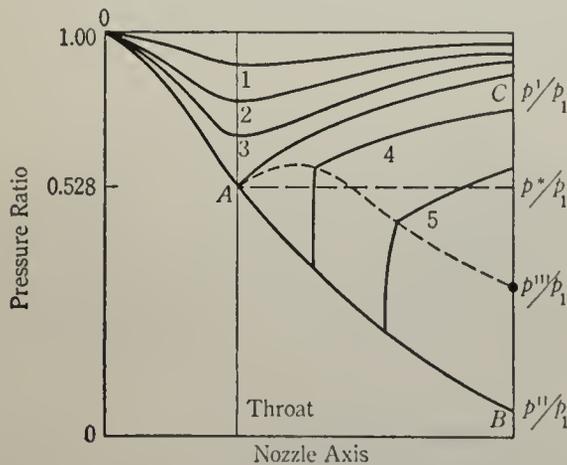

CONVERGENT-DIVERGENT NOZZLE. A channel shaped so that a convergent portion a is followed by a divergent portion b , Figure 1. The narrowest part of the convergent-divergent nozzle is called a *throat*. Convergent-divergent nozzles are used in turbines to accelerate the working fluid (steam or gas) to

high velocities. They are also used in wind tunnels to produce a parallel stream of air at very high velocities.

Convergent-divergent nozzle.

In view of these applications it is important to understand the behavior of a compressible fluid as it flows through a convergent-divergent nozzle. Assuming ideal flow (isentropic process of expansion), it is found that essentially two regimes of flow are possible. (1) Flow when the velocity at the throat is subsonic (throat Mach number < 1). The flow through the entire nozzle is subsonic, and the mass flow depends on the pressure ratio p_2/p_1 , where p_1 is the stagnation pressure in section 1, and p_2 is then the static pressure at 2. Hence, by measuring this pressure ratio one can determine the mean flow. Actually, the pressure at the throat is then measured (by Venturi meter). The variation of pressure along the nozzle axis for different back-pressure ratios p_2/p_1 , is shown in Figure 2. As

the back pressure decreases from unity to p'/p_1 the preceding flow regime prevails, curves 1, 2, 3.

When the back-pressure is reduced to p' , the velocity in the throat becomes sonic (throat Mach number = 1) and the nozzle becomes choked. Any further reduction in back-pressure has no effect on the pressure (or velocity or temperature) distribution in the convergent part of the nozzle. The pressure at the throat

then becomes equal to the so-called critical pressure.

$$p^* = \left(\frac{2}{\gamma + 1} \right)^{\frac{\gamma}{\gamma - 1}} \times p_1$$

$$(\text{= } 0.528p_1 \text{ for } \gamma = 1.4, \text{ i.e., for air})$$

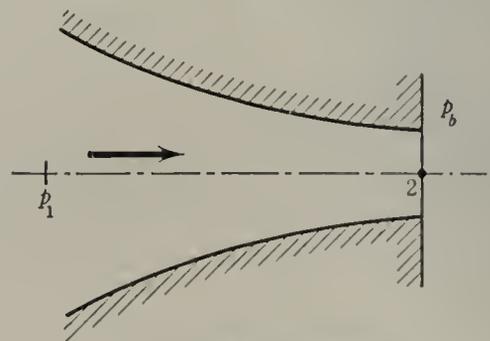

Isentropic flow all along the nozzle is then only possible for two back-pressures, p' and p'' whose values depend on the area ratio A_2/A_t (curves OAC and OAB). For p' the flow at exit is subsonic, for p'' it is supersonic, the Mach number depending also on the area ratio A_2/A_t . Any reduction of back-pressure below p'' has no effect on the flow in the nozzle at all.

The flow patterns for back-pressures between p' and p'' are complex. In a range p' to p''' (where p''' also depends on the area ratio A_2/A_t for a given gas) a normal shock appears in the divergent portion (curves 4,5) moving from the throat towards the exit and gathering strength as p_2 varies from p' down to p''' . For back-pressures between p''' and p'' , ideally, the flow pattern is the same as for $p_2 = p''$, but boundary layer effects and the possibility of separation complicate the process and give rise to more complex patterns.

Supersonic flow in a compressible fluid can be achieved in a steady-state only if a convergent-divergent nozzle is used for the purpose. If the nozzle is rigid (fixed-geometry nozzle) only one particular supersonic Mach number can be reached at exit. In order to regulate the exit Mach number it is possible to use a flexible nozzle, which varies A_t , and so varies the area ratio A_2/A_t for a given A_2 .

A convergent-divergent nozzle used to produce a supersonic stream is also called a deLaval nozzle.

CONVERGENT NOZZLE. A channel in which the cross-sectional area decreases along the flow axis. Convergent nozzles are used in

Convergent nozzle.

turbines to produce high-velocity streams of steam or gases. They are also used in many other engineering devices.

When a compressible fluid flows through a convergent nozzle, the behavior of the nozzle depends essentially on the ratio of back-pressure p_b to the upstream stagnation pressure p_1 . The (static) pressure in the exit section p_2 need not be equal to the back-pressure p_b . There are two distinct regimes of flow: (1) When the exit velocity is subsonic ($M_2 < 1$), we have $p_b = p_2$ and $p_2 > p^*$, where p^* is the so-called *critical pressure*.

$$p^* = \left(\frac{2}{\gamma + 1} \right)^{\frac{\gamma}{\gamma - 1}} \times p_1$$

(= 0.528 p_1 for $\gamma = 1.4$, i.e., for air)

(2) When the back-pressure p_b becomes equal to or smaller than the critical pressure p^* the nozzle becomes choked, and $p_b \neq p_2$. The exit velocity is then sonic ($M_2 = 1$). In fact, the exit pressure $p_2 = p^*$ and changes in the back-pressure (provided only that $p_b < p^*$) have no effect on the operation of the nozzle.

Thus in the range $p^* \leq p_b < p_1$ the mass flow varies, increasing from 0 to a maximum \dot{m}^* at $p_b = p^*$, increasing with decreasing p_b . In the range $p_b < p^*$ the mass flow remains constant at \dot{m}^* and unaffected by p_b .

In a convergent nozzle it is not possible to accelerate the stream to a supersonic velocity ($M > 1$).

CONVERSION. In general, a change, often with the force of a directed or induced change. One specific use is a change in numerical value of a quantity resulting from the use of a different unit in the same or a different system of measurement.

CONVERSION FRACTION. The ratio of the number of internal conversion electrons to the number of quanta emitted plus the number of conversion electrons emitted in a given mode of de-excitation of a nucleus. Partial conversion fractions refer to conversion fractions for various electron shells, e.g., *K*-conversion fractions, *L*-conversion fractions, etc. Sometimes called *conversion coefficient*.

CONVERSION GAIN. In nuclear reactor theory, synonymous with **breeding gain**, but often used when the fissionable nucleus produced is different from the nucleus consumed.

CONVERSION RATIO. (1) The ratio of the number of internal conversion electrons to the number of gamma quanta emitted in the de-excitation of a nucleus of an atom. (See **conversion fraction**; **internal conversion coefficient**.) (2) In nuclear reactor theory, synonymous with **breeding ratio**, but often used when the fissionable nucleus produced is different from the nucleus consumed.

CONVOLUTION. Given two functions $f(t)$, $g(t)$ of some independent variable t , the convolution integral of $f(t)$ and $g(t)$ is (provided the integral exists)

$$f(t) * g(t) = \int_{-\infty}^{\infty} f(\tau)g(t - \tau)d\tau$$

or, changing the variable of integration from τ to $(t - \tau)$

$$f(t) * g(t) = \int_{-\infty}^{\infty} f(t - \tau)g(\tau)d\tau.$$

The convolution integral is therefore a function of t and is symmetrical with respect to the functions $f(t)$ and $g(t)$.

The range of integration is sometimes restricted by limitations on $f(t)$ and $g(t)$. For instance if $f(t)$, $g(t) = 0$ when $t < 0$, then clearly the only valid range of integration is $\tau = 0$ to $\tau = t$.

Convolutions are of particular importance in the theory of the Laplace transform, since the transform of the convolution of two functions is given by the product of their transforms.

In probability theory, a term denoting the "sum" of a number of random variables. If ξ_1 and ξ_2 are two independent random variables with distribution functions $F_1(x_1)$ and $F_2(x_2)$, their convolution is the random variable ζ with distribution function $F(z)$ where

$$F(z) = \iint_{x_1 + x_2 < z} dF_1(x_1)dF_2(x_2).$$

The definition is easily extended to n variables which may be dependent.

The expression "compound" distribution in the sense of convolution is to be avoided. It has been used in two senses: (1) where a statistical distribution is mixed in the sense that its members emanate from two or more different populations: (2) when a random variable ξ has a distribution depending on a parameter α , cases arise where α itself may be regarded as having a probability distribution: the distribu-

tion of ξ obtained by integrating over the course of α may then be described as compound.

CONVOLUTION INTEGRAL. See first paragraph under convolution.

CONVOLUTION THEOREM. See Laplace transform theorems.

CONWELL-WEISSKOPF FORMULA. The mobility μ of electrons in a semiconductor in the presence of donor or acceptor impurities is given by

$$\mu = [2^{7/2} \epsilon^2 (kT)^{3/2} \log(1 + x^2)] / N e^{\pi^2/4} m^{3/2}$$

where

$$x = 6\epsilon dkT/c^2$$

and ϵ is the dielectric constant of the medium, N is the concentration of ionized donors (or acceptors), $2d$ is the average distance between ionized donors, e and m the electronic charge and mass, etc.

COOLANT. The fluid used to carry heat away from a system or device, such as an internal combustion engine, etc.

COOLING. The process of reducing the temperature of a body or of extracting heat by circulating a fluid (coolant).

COOLING BY ADIABATIC DEMAGNETIZATION. See adiabatic demagnetization.

COOPERATIVE PHENOMENA. Such processes as order-disorder transformations in binary alloys, ferromagnetism, and melting, where certain subsystems will combine to form units which hold together in spite of the disrupting influence of thermal agitation.

It is to a large extent possible to treat all these phenomena at the same time. The simplest model for such systems, and the one most investigated, is the **Ising model**.

If one considers a simple cubic **AB substitutional alloy**, depending on whether the energy of an **AB** pair is less or larger than the average of an **AA** and a **BB** pair, there will be a tendency for order, that is, for the formation of a superstructure of two sublattices, one a pure **A** and one a pure **B** lattice, where each **A** atom is surrounded by **B** atoms and vice versa, or a tendency for phase separation. At the absolute zero the order will be complete, but when the temperature is increased, there will

be a chance that an **A** atom will move to the place of a **B** atom (β -site) and thus be replaced by a **B** atom on an α -site. The presence of an **A** atom on a β -site will induce a tendency for the neighboring α -sites to be occupied by **B** atoms, and a disordering tendency will set in which will lead to an avalanche effect, and at and above the **Curie temperature** there will no longer be a tendency of **A** atoms to be on α -sites, or **B** atoms to be on β -sites, but there will still be a tendency for **A** atoms to be surrounded by **B** atoms and vice versa. The short range order parameter measures this latter tendency while the long range order parameter measures the tendency of **A** atoms to be on α -sites.

In any statistical treatment of cooperative phenomena one derives an (approximate) expression of the free energy in terms of the two order parameters, and by evaluating its extremum, the equilibrium values of the order parameters are found. The statistical approximations which are used most are the Bragg-Williams, and the **quasi-chemical approximation**.

COORDINATE. One of a set of numbers which determine the position in space of a geometric entity, usually a point but sometimes a line, surface, etc., in such a way that a continuous change in the coordinates corresponds to a continuous change of position, and conversely. The commonest system of coordinates is the Cartesian (or rectangular Cartesian) system in the plane or in 3-dimensional space. In a plane, the homogeneous coordinates of a point, whose Cartesian coordinates are x and y , are any three (not all zero) numbers (x_1, x_2, x_3) for which $x_1/x_3 = x$ and $x_2/x_3 = y$. The points for which $x_3 = 0$ form the **line at infinity**. Homogeneous coordinates are defined analogously for spaces of 3 or more dimensions. If $u = u(x, y)$ and $v = v(x, y)$, then p, q are the **curvilinear coordinates** (the u, v coordinates) of a point P if P is the intersection of the curve $u(x, y) = p$ with the curve $v(x, y) = q$. Commonly used coordinates of this sort are **polar, cylindrical, spherical, elliptic and parabolic coordinates**.

COORDINATE BOND. Some molecules, such as H_2O , NH_3 , HF , $\text{HCl} \cdots$ have in their outer shell one or more free electron doublets which they can eventually share with an atom

or molecule which has an incomplete outer shell. The resulting bond, where the doublet is shared between the two particles, is called a coordinate bond. Its properties are quite similar to those of covalent bonds: such bonds have directed valencies, and limited coordination numbers. The reactions $\text{NH}_3 + \text{H}^+ \rightarrow \text{NH}_4^+$ and $\text{HCl} + \text{O} \rightarrow \text{HClO}$ are typical of the formation of such bonds. Coordinate links are also important in the formation of many ion-solvent complexes in aqueous and ammoniacal solutions. (See **directed valency; bond types.**)

COORDINATE LINES ON A SURFACE. See **surface.**

COORDINATES AND MOMENTA, GENERALIZED. Generalized coordinates are coordinates chosen to describe the motion of a mechanical system, without having their exact nature immediately specified. The generalized coordinates associated with a system having n degrees of freedom are denoted by q_1, q_2, \dots, q_n .

The generalized momenta p_1, p_2, \dots, p_n are defined by the equation:

$$p_i = \frac{\partial L}{\partial \dot{q}_i}$$

where L is the **Lagrangian function** for the system. The generalized momentum p_i is said to be conjugate to the generalized coordinate q_i . The **Lagrange equations** and the **Hamilton canonical equations** are expressible in terms of generalized coordinates and momenta.

COORDINATES IN POLYATOMIC MOLECULES, NORMAL. See **normal vibrations** and **normal coordinates in polyatomic molecules.**

COORDINATES, NORMAL. See **normal modes.**

COORDINATE SYSTEM, ROTATING. See **rotating coordinate system.**

COORDINATION NUMBER. (1) For an atom or group of atoms, the maximum number of coordinate bonds which the atom, or group of atoms can form. (See **coordinate bond.**) (2) For a covalent crystal, the coordination number is the same as (1), but for an ionic crystal, it is the number of atoms at

closest distance (nearest neighbors) of the given atom.

COORDINATIVE VALENCY OF AN ION. See **principal valency of an ion.**

CORE. See also **kern.**

CORIOLIS EFFECTS. The Coriolis force, which is alternatively called the **geostrophic force**, or the deviating force, is the apparent force on particles moving relative to the earth when observed from the earth. For unit mass it is equal to $2\mathbf{v} \times \boldsymbol{\Omega}$ where \mathbf{v} is the velocity relative to the earth and $\boldsymbol{\Omega}$ is the earth's rotation vector. The vertical component is negligible compared with gravity and the horizontal component is equal to $\mathbf{v} \times \mathbf{f}$ where \mathbf{f} is twice the vertical component of the earth's rotation.

A generalized discussion of Coriolis effects, not limited to the earth as a frame of reference, is given in polar coordinates as follows: A particle which is subject to no forces in a polar coordinate system r, θ experiences a radial acceleration $r(d\theta/dt)^2$ and a tangential acceleration $-2(dr/dt)(d\theta/dt)$. These accelerations result from the fact that every point fixed in a coordinate system rotating with an angular velocity $d\theta/dt$ (with the exception of the origin) is accelerated with respect to an inertial frame. The radial acceleration is known as the **centrifugal acceleration**; the tangential acceleration is called the **Coriolis acceleration**. If Newton's second law of motion is applied to the particle without correction for the motion of the coordinate system, a **centrifugal force** $mr(d\theta/dt)^2$ and a **Coriolis force** $-2m(dr/dt)(d\theta/dt)$, where m is the mass of the particle, must be postulated to account for the behavior of the particle.

CORIOLIS PARAMETER. Twice the vertical component of the earth's angular velocity about the local vertical Ω ; usually denoted by

$$f = 2\Omega \sin \phi$$

where ϕ is the latitude.

CORNU SPIRAL. James Bernoulli introduced the plane curve, defined intrinsically by the curvature being proportional to the arc length, and known as the Cornu spiral or *clothoid*. The Cornu spiral is represented parametrically by $x = C(v)$, $y = S(v)$ in terms of the **Fresnel integrals**.

$$C(v) = (2\pi)^{-1/2} \int_0^v t^{-1/2} \cos t dt$$

$$= \int_0^v \cos \frac{\pi}{2} u^2 du,$$

$$S(v) = (2\pi)^{-1/2} \int_0^v t^{-1/2} \sin t dt$$

$$= \int_0^v \sin \frac{\pi}{2} u^2 du.$$

Böhmer has considered the generalization

$$C(v, \alpha) = \int_v^\infty t^{\alpha-1} \cos t dt,$$

$$S(v, \alpha) = \int_v^\infty t^{\alpha-1} \sin t dt.$$

The curve $x = C(v, \alpha)$, $y = S(v, \alpha)$ for fixed α , $0 < \alpha < 1$ is a spiral and becomes the Cornu spiral when $\alpha = 1/2$. The intrinsic equation is

$$\rho = (\alpha s)^{1-1/2}$$

where ρ is the radius of curvature and s is the arc length.

Distances on the Cornu spiral are used in computing intensities in the diffraction pattern resulting from **Fresnel diffraction**. Here the parameter v is **wave velocity** and

$$v = l \sqrt{\frac{2B}{D\lambda(B + D)}}$$

where l is the distance along the diffracting screen, B the distance from the source to the screen, D the distance from the screen to the point of observation, and λ is the wavelength.

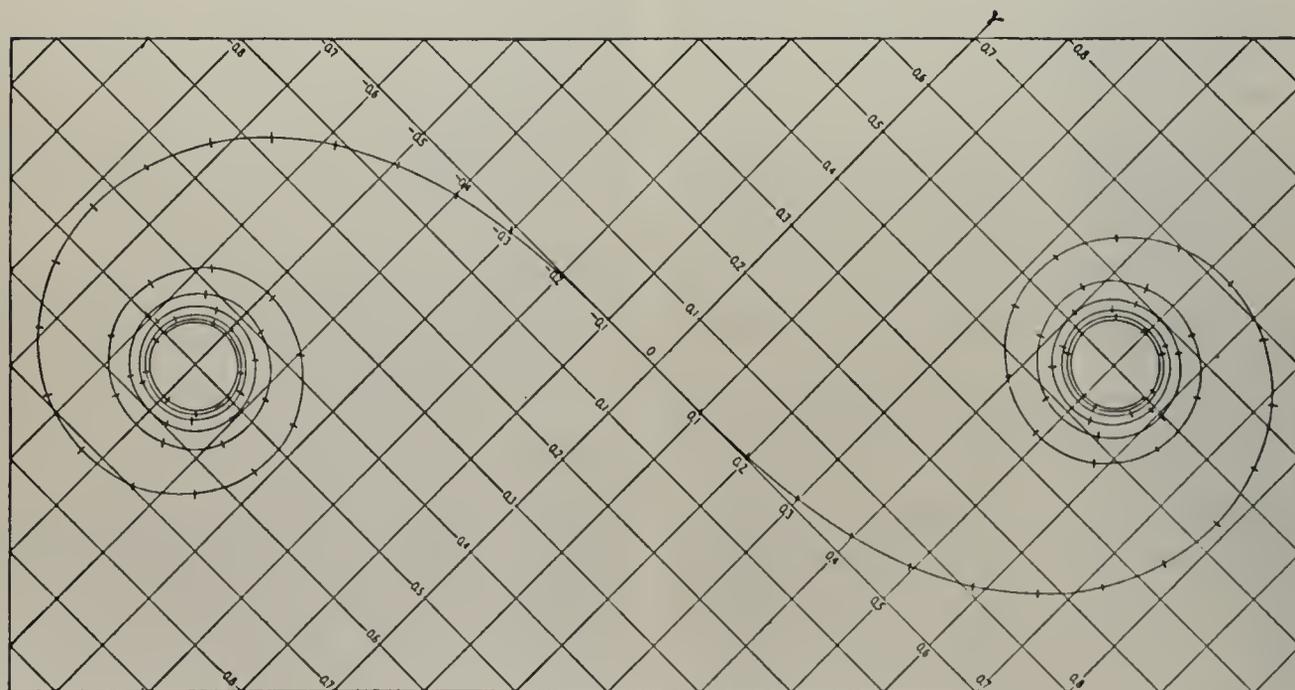

CORONA DISCHARGE. Leakage of charge brought about by the ionization of a gas surrounding a charged conductor. This occurs when the potential gradient exceeds a certain value, but is not sufficient to cause sparking.

CORPUSCULAR THEORY OF LIGHT. See dynamical equations of light rays.

CORRECTION. A quantity added to a previously obtained approximation to yield a better approximation. Sometimes the term is applied to $x - x^*$, where x is the true value and x^* the approximation, and is contrasted with the difference $x^* - x$ which is then designated the **error**. This sense is not the one adopted in this book.

CORRECTION TO VACUUM. The correction of wavelengths, or of the speed of light, as measured in air to the appropriate values *in vacuo*. The index of refraction of air is 1.00029 at 0° Centigrade, 1 atmosphere pressure, and at the wavelength of the mean of two yellow sodium lines, D (5892.9 Å).

CORRECTOR. In solving initial value problems in **ordinary differential equations**, a quadrature formula to be used for improving a given approximate value of the dependent

Cornu spiral.

variable at an advance point, and contrasted with a predictor used to obtain a first approximation. A predictor formula uses an **open quadrature formula**, a corrector formula a **closed quadrature formula**.

CORRELATION. In a general sense in statistics this expression denotes the co-relationship of two variables. A correlation coefficient attempts to measure the interdependence of the variables.

More specifically the correlation or product-moment correlation of two variates x and y is defined as

$$\rho = \frac{\text{cov}(x,y)}{\sqrt{(\text{var } x)(\text{var } y)}}$$

or, for a finite series of values $(x_1, y_1), \dots, (x_n, y_n)$ as

$$r = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\left\{ \sum_{i=1}^n (x_i - \bar{x})^2 \sum_{i=1}^n (y_i - \bar{y})^2 \right\}^{1/2}}$$

where \bar{x} and \bar{y} are the respective means.

Other definitions are possible. When the observations are ranked but not measured, coefficients of *rank correlation* of an analogous kind can be defined. For qualitative variables joint relationship is usually described in terms of *association* or *contingency*.

For variables which are distributed in the bivariate normal (Gaussian) form, the correlation defined above has a clear interpretation, ρ being the parameter or (in the case of a sample) an estimate of the parameter, in the equation of the frequency function,

$$f(x,y) = k \exp \left\{ -\frac{1}{2(1-\rho^2)} \left(\frac{x^2}{\sigma_1^2} - \frac{2\rho xy}{\sigma_1\sigma_2} + \frac{y^2}{\sigma_2^2} \right) \right\}.$$

In a multivariate complex, say for simplicity the three-variate case involving x_1, x_2, x_3 , each pair of variables has a correlation coefficient. It is also possible to consider the correlation of x_1 and x_2 for fixed x_3 . This is known as a *partial correlation*. If the correlation between x_j and x_k is ρ_{jk} , the partial correlation for fixed x_l , ρ_{jkl} is given by

$$\rho_{jkl} = \frac{\rho_{jk} - \rho_{jl}\rho_{kl}}{\left\{ (1 - \rho_{jl}^2)(1 - \rho_{kl}^2) \right\}^{1/2}}$$

In regression analysis, if a variable y is expressed as a linear regression on ρ variables x_1, x_2, \dots, x_ρ , say $\beta_1 x_1 + \beta_2 x_2 + \dots + \beta_\rho x_\rho$, the correlation between y and the regression $\sum \beta_i x_i$ is called a *multiple correlation*. It measures the closeness with which y is "predicted" by the regression equation. The multiple correlation is expressible in terms of the correlations between y and the individual x 's and of the x 's among themselves.

CORRELATION, BISERIAL. See **biserial correlation**.

CORRELATION, CANONICAL. See **canonical correlation**.

CORRELATION COEFFICIENT. (As used in the statistical theory of **turbulence**.) A measure of the **correlation** between two fluctuating quantities in the turbulent motion of a fluid. If u_P and $v_{P'}$ are the values of two fluctuating quantities u and v at points P and P' their correlation coefficient is defined as

$$\overline{u_P v_{P'}} / (\overline{u_P^2} \overline{v_{P'}^2})^{1/2}.$$

When $u = v$ this becomes the **autocorrelation coefficient**. The coefficient may also be defined to include a time interval which elapses between the measurement of u at P and of v at P' . For the turbulence to be represented by statistics such as correlation coefficients the mean values must be properly definable (see **autocorrelation coefficient**).

If u and v are the fluctuations of two components of velocity in isotropic turbulence $\overline{u_P^2} = \overline{v_{P'}^2}$, and if the turbulence is homogeneous $\overline{u_P^2} = \overline{v_{P'}^2}$, so that for homogeneous isotropic turbulence the correlation coefficient becomes

$$\overline{u_P v_{P'}} / \overline{u_P^2}.$$

The coefficient is used to measure transport by turbulence. Thus \overline{uv} is a measure of the transport of x -momentum in the y -direction (see **Reynolds stress**).

The transport of heat in the direction of the axis of a **buoyant jet** is not given simply by the integral

$$\int_{\text{area of jet section}} \bar{w} \bar{T} \rho c dS$$

where w , T , ρ , and c are the velocity, temperature, density, and specific heat of the fluid and

dS the element of area of the section; but there may also be an appreciable contribution from

$$\int \overline{w'T'} \rho dS$$

where w' and T' are the fluctuations of velocity and temperature, because the upward velocity fluctuations are probably correlated with the buoyancy which produces them. (Here the secondary effect of the simultaneous fluctuations of ρ are neglected.)

Likewise in a **turbulent jet** in which there are no buoyancy forces, in the transport of effluent along the direction of the axis, namely

$$\int \{\bar{w}\bar{\sigma} + \overline{w'\sigma'}\} dS$$

where $\sigma (= \bar{\sigma} + \sigma')$ is the concentration of effluent, there may be an appreciable contribution from the second term because the elements of greater concentration will tend to be those of greater velocity, so that w' and σ' will be correlated.

The transport of momentum along a turbulent jet of uniform density is

$$\int \{\bar{w}^2 + \overline{w'^2}\} \rho dS$$

and the second term may often be appreciable.

Correlation coefficients are usually only properly definable when the mean flow is approximately steady because only then can a satisfactory time mean value of a fluctuating quantity (denoted by a bar) be defined.

CORRELATION DIAGRAM. In molecular physics, a diagram showing the correlation between the electronic orbitals in the united atom and in the separated atoms, respectively (see also **building-up principle**). Such diagrams show the (approximate) energetic order of the different orbitals also for internuclear distances r intermediate between the limiting cases of $r = 0$ and $r = \infty$. (For more detail, see G. Herzberg, *Molecular Spectra and Molecular Structure, I. Spectra of Diatomic Molecules*, 2d ed., D. Van Nostrand Co., Inc., Princeton, 1945, p. 326 ff.)

CORRELATION ENERGY. The energy associated with the correlation effect in a metal, i.e., the tendency for electrons to keep apart, and hence for the positions of any two not to be entirely independent. It represents a cor-

rection to a naive calculation of **Coulomb energy**.

CORRELATION RATIO. In a one-way classification of observations y with classes defined by a quantitative variable x , the correlation ratio of y on x , η_{yx} , is defined by

$$\eta_{yx}^2 = \frac{\text{Sum of squares between classes}}{\text{Total sum of squares}},$$

the sum of squares being derived from an **analysis of variance**.

Problems for which the correlation ratio was formerly used can now be treated more simply by analysis of variance techniques.

CORRELATION, SERIAL. See **autocorrelation**.

CORRELOGRAM. The graph of the **autocorrelation coefficient** ρ_k as ordinate against k as abscissa. If the autocorrelations are estimated from a finite series as serial correlations r_k , the graph of r_k against k is also called a **correlogram**.

CORRESPONDENCE. See **mapping**.

CORRESPONDENCE PRINCIPLE. See **principle of correspondence**.

CORRESPONDING STATES, LAW OF. All gases whose constituent atoms interact according to a **Lennard-Jones potential** will have the same **equation of state** if this equation is expressed in terms of **reduced variables**, that is, in the form

$$\frac{p}{p_c} = \phi\left(\frac{T}{T_c}, \frac{V}{V_c}\right) \quad (1)$$

where p_c , T_c , V_c are the critical pressure, temperature and volume, and where ϕ is the same function for all substances of the group. The quantities p/p_c , T/T_c , V/V_c are also called the *reduced* pressure, temperature, and volume.

All equations of state containing two independent parameters like the **van der Waals equation** or the **Dieterici equation** (see **real gases**) may be put into the form (1) above, or using the van der Waals constants,

$$f(p, V, T, a, b) = 0. \quad (2)$$

The critical state (p_c , V_c , T_c) is given by the two conditions

$$\left(\frac{\partial p}{\partial V}\right)_T = 0 \quad (3)$$

$$\left(\frac{\partial^2 p}{\partial V^2}\right)_T = 0. \quad (4)$$

Thus, the two (and no more) parameters can be eliminated, and the **equation of state** can be written in terms of the reduced parameters

$$\pi = p/p_c$$

$$\phi = V/V_c$$

$$\theta = T/T_c$$

in the form

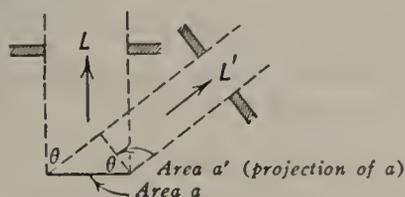

$$F(\pi, \phi, \theta) \quad (5)$$

which does not contain the parameters a and b . Thus Equation (5) does not contain any quantities which depend on the nature of the gas and should be a *universal* form of the equation of state. Such a universal equation of state written in terms of the reduced parameters or corresponding states (expressing the principle of corresponding states) is satisfied with a good degree of precision by simple gases like argon, krypton, xenon, carbon monoxide and xenon, while the corresponding equations of state when not expressed in terms of reduced variables show greater or less divergence.

If quantum effects become important, the law of corresponding states must be suitably altered.

COSET. If H is a subgroup of the group G , a set of elements of the form ah , where a is in G and h runs through H is called a (left) coset of H in G and a set of the form ha is a right coset. The number of such cosets is called the *index* of H in G .

COSINE EMISSION LAW. The energy emitted by a radiating surface in any direction is proportional to the cosine of the angle which that direction makes with the normal. Thus, let the radiating surface, of area a , be emitting a luminous flux L (lumens) in the

normal direction (see figure), and, in any other direction making an angle θ with the

normal, the smaller quantity L' . Then since the apparent brightness is unchanged, $L'/a' = L/a$. This gives $L'/L = a'/a$. But $a'/a = \cos \theta$, hence $L' = L \cos \theta$.

This law applies to thermal radiation as well as to light, and to diffusely reflected as well as directly emitted radiation. The law is true only for a perfectly diffusing surface, strictly, for a **black body**, but it is a good approximation to the behavior of many surfaces.

COSINE LAW. (1) See **cosine emission law**. (2) See **Knudsen cosine law**.

COSINE LAW, KNUDSEN. See **Knudsen cosine law**.

COTTON-MOUTON CONSTANT. See **Cotton-Mouton law**.

COTTON-MOUTON LAW. A dielectric placed in a magnetic field may become double-refracting with retardation δ of the ordinary ray over the extraordinary ray given by

$$\frac{\delta}{\lambda} = \frac{l(n_e - n_o)}{\lambda} = C_m l H^2$$

in which C_m is the Cotton-Mouton magnetic birefringence constant, l is the distance in the dielectric traversed by the light of wavelength λ , and H is the magnetic field strength. Further, n_e and n_o are the refractive indices of light polarized in planes parallel and perpendicular, respectively, to the direction of the magnetic field.

COUETTE FLOW. A two-dimensional steady flow without pressure gradient in the direction of flow and caused by the tangential movement of the bounding surfaces. The only practicable type is the flow between concentric rotating cylinders, although the flow between parallel planes with uniform relative velocity is used in the elementary discussion of **viscosity**.

COULOMB. A unit of electrical charge, abbreviation coul or Cb. (1) The absolute coulomb is defined as the amount of electrical charge which crosses a surface in one second if a steady current of one absolute ampere is flowing across the surface. The absolute coulomb has been the legal standard of quantity of electricity since 1950. (2) The International coulomb, the legal standard before 1950,

is the quantity of electricity which, when passed through a solution of silver nitrate in water, in accordance with certain definite specifications, deposits 0.00111800 gm of silver. 1 Int. coul = 0.999835 abs coul.

COULOMB BARRIER. A potential barrier produced by repulsive electrostatic forces, particularly just beyond the surface of an atomic nucleus.

COULOMB BOND ENERGY. See **Coulomb integral**.

COULOMB DEGENERACY. Identity of the energy levels of a charged particle bound in a Coulomb field for different values of the orbital angular momentum, provided that the principal quantum number and spin state is the same, e.g., the $2S_{\frac{1}{2}}$ and $2P_{\frac{1}{2}}$ states of the hydrogen atom. (See **Lamb shift**.)

COULOMB ENERGY. The contribution to the binding energy of a substance made by electrostatic interactions of ions and electrons. For a metal lattice, the Coulomb energy of a unit cell is approximately that due to a uniform distribution of electrons over an s -sphere of equal volume and is given by

$$U(r) = -\frac{3Ze}{2r_s} + \frac{Zer^2}{2r_s^3}$$

where Z is the number of conducting electrons, and r_s is the radius of the sphere.

COULOMB EXCITATION. If a high energy charged particle passes close to the nucleus of an atom, the time varying electric field felt by the nucleus can cause it to undergo a transition to an excited state. The necessary energy for the transition can be looked upon as having been radiated by the passing particle and absorbed by the nucleus. This excitation by the Coulomb field of the passing particle is called coulomb excitation.

COULOMB FIELD. The field of an electric charge which can be described by a **Coulomb potential**. The electrons of an atom move in the Coulomb field of the atomic nucleus.

COULOMB INTEGRAL. Consider a valence bond formed between two nuclei: A and B, carrying each a valence electron 1 or 2. If the bond energy is calculated by assuming that electron 1 is attached to atom A and electron

2 to atom B, one obtains for the potential interaction energy of the two atoms

$$H_{11} = \int \psi_A(1)\psi_B(2)W\psi_A(1)\psi_B(2)d\tau_1d\tau_2$$

where the ψ -terms represent the wave functions and where W is the perturbation potential. W is the sum of the repulsive Coulomb energy of the two electrons located in volume elements $d\tau_1$ and $d\tau_2$; of that of the two nuclei, and the attractive energy between electron 1 and nucleus B and electron 2 and nucleus A.

H_{11} expresses the electrostatic interactions of the system and is called the Coulomb integral. The corresponding energy is negligible for large internuclear distances; it becomes attractive for intermediate ranges, and leads to a strong repulsion at very small intermolecular distance.

The Coulomb energy behaves thus qualitatively just as one would expect a bond energy to do. However in absolute values, the bond energies calculated are usually much too small. The main contribution to the covalent bond energy results usually from the **exchange integral**. (See **exchange energy**.)

COULOMB LAW (ELECTROSTATICS). The force between two point charges in free space is a pure attraction or repulsion, and is given in rationalized MKSA units by

$$F = \frac{q_1q_2}{\epsilon_0r^2}$$

where q_1, q_2 are the magnitudes of the charges, r is their separation, and ϵ_0 is a constant of nature. The numerical value of ϵ_0 depends upon the system of units used (see **electric constant**). When the charges are immersed in a homogeneous medium, which extends to distances much greater than r in all directions

$$F = \frac{q_1q_2}{\epsilon r^2}$$

where ϵ is the **permittivity**, or absolute dielectric constant of the medium.

COULOMB LAW (MAGNETISM). See **magnetic pole strength**.

COULOMB POTENTIAL. The potential describing the field of an electrostatic charge. The potential energy acting between a charge e and a charge $-Ze$ is given by $V = -Ze^2/r$,

where r is the distance between the two charges.

COULOMB WAVE FUNCTION. The wave function of a charged particle moving in a **Coulomb field**. In non-relativistic quantum mechanics the radial part of a Coulomb wave function is related to **Laguerre polynomials**; in relativistic electron theory to **confluent hypergeometric functions**. (See **Gauss hypergeometric equation**.)

COUNTABLE. A set of objects is said to be countable if it can be put into one-to-one correspondence with the set of positive integers 1, 2, 3, \dots . Synonyms are enumerable, denumerable.

COUNTABLE SET. See **cardinal**.

COUNTER EFFICIENCY. Of a radiation counter tube, the probability that a tube count will take place with a specified particle or quantum incident in a specified manner.

COUNTER-FLOW. See **heat exchanger**.

COUPLE. A couple is a pair of equal and parallel but oppositely directed forces. The moment of a couple is a vector perpendicular to the plane of the two forces. Its magnitude is the same for all **center(s) of moment**.

COUPLED CHEMICAL REACTIONS. The **entropy** production due to two simultaneous chemical reactions is (see **thermodynamics**, **second principle of**)

$$T \frac{d_i S}{dt} = A_1 v_1 + A_2 v_2 \geq 0 \quad (1)$$

where A_1 , A_2 are the affinities of the two reactions (see **chemical affinity**) and v_1 , v_2 the reaction rates (see **chemical reaction rate**). Only the sum in (1) is positive (or zero at equilibrium). Thus it is possible to have

$$A_1 v_1 < 0 \quad A_2 v_2 > 0. \quad (2)$$

The first reaction is then called the coupled and the second the coupling reaction. Such reactions are of great biological interest.

COUPLE, THEOREMS ABOUT. (1) The moment of a couple has the same value when moments of each force are taken about any axis perpendicular to the plane of the couple. (2) A rigid body acted upon by a couple is

in translational equilibrium, but not rotational equilibrium. (3) A system of forces acting on a rigid body can be replaced by a single force acting at an arbitrary point of the body and a couple whose axis is parallel to the line of action of the force. The combination is called a *wrench*.

COUPLING. An interaction between systems, or between properties of a system. When there is little interaction, the coupling is sometimes said to be loose; with considerable interaction, it is called tight.

COUPLING CASES, HUND'S. See **Hund's coupling cases**.

COUPLING CONSTANT. A number, of the dimension of electric charge, measuring the strength of the interaction between interacting fields, defined in analogy with the electronic charge e which is the coupling constant between electrons and electromagnetic radiation. The interaction term between a Fermi field $\psi(x)$ and a boson field $\phi(x)$ is thus usually taken to be of the form $g\bar{\psi}(x)\Gamma\psi(x)\phi(x)$, where $\bar{\psi}$ is the Hermitian conjugate of ψ , Γ is some operator, and g is the coupling constant. In the case that g is small, transition probabilities are then proportional to the pure number $(g^2/\hbar c)$ in lowest order, where $2\pi\hbar$ is Planck's constant and c the velocity of light. In the case of electrodynamics, this quantity is the fine-structure constant $(e^2/\hbar c) \approx 1/137$.

COUPLING, IN ATOMIC AND MOLECULAR STRUCTURE. The energy of a stable state of an atom or molecule is affected by the strength of interaction or coupling of the spins and the orbital angular momenta of the individual electrons with each other, with the angular momentum of molecular rotation and with the electric field along the molecular axis ("coupling to the molecular axis"). In an actual case these interactions may present a very complicated picture. In general, however, a good approximation is obtained if it is assumed that certain interactions predominate. One can work therefore with simplified vector models of atoms or molecules in which the individual angular momentum vectors are added together (see **angular momentum vectors**, **quantum theoretical addition of**) in the order of their strength of coupling. (See **Russell-Saunders coupling**; **(j, j) coupling**; **Hund's coupling cases**.)

COUPLING, (j, j). See (j, j) coupling.

COUPLING, RUSSELL-SAUNDERS. See Russell-Saunders coupling.

COUPLING, SPIN-ORBIT. See Russell-Saunders coupling.

COUPLING, WEAK. Interaction between two particles by means of one or more fields which is such that the **interaction energy** may be expanded in powers of a dimensionless parameter which is small compared with unity, e.g., coupling of charged particles with each other through an electromagnetic field, where the dimensionless parameter is the **fine-structure constant**.

COURSE (NAVIGATION). The direction in which a ship is moving relative to the surface of the earth is known as the course of the ship. The term course is also applied to the direction (or directions) that a ship is supposed to follow from one place to another. During the long history of navigation the term "course" has become very loosely used. For example, we say that a ship is following a great circle course from point *A* to point *B* when, theoretically, its direction of motion relative to the surface of the earth is continually changing. In the discussion of modern navigation several different types of courses are recognized, e.g., Great Circle course, Mercator course, Rhumb Line course, Lambert line, etc. For each of these we have a compass (or gyro) course, a magnetic course, and a true course.

In a number of cases the terminology for courses is different for air- and sea-borne ships. Furthermore the different air services of the United States (Commercial, Army, Navy, or Air Force) use different terminology. For uniformity in this book, the terminology of the U.S. Navy surface navigation is used throughout.

COVALENT BOND. See **homopolar bond**; **atomic bond**; **bond types**.

COVARIANCE. (1) See entries under **covariant**. (2) In statistics, the covariance between two variates *x* and *y* is defined as $E(x - \xi)(y - \eta)$, where ξ , η are the means of *x*, *y* and *E* denotes the expected value. If the population is ρ and the standard deviations σ_x , σ_y , the covariance is equal to $\rho\sigma_x\sigma_y$. (See **analysis of covariance**.)

COVARIANCE MATRIX. See **dispersion**.

COVARIANCE, ORDER OF. See **tensor field**.

COVARIANT COMMUTATION RULES. There exist general methods for obtaining the commutation rules between functions *A*(*x*), *B*(*x*) of the field variables $\phi_s(x)$ due to Feynman, Peierls, Schrödinger and others. We outline here the method due to Peierls based on the **Lagrangian formalism**.

Consider the modified Lagrangian density

$$\mathcal{L}'(x) = \mathcal{L}(x) + \lambda A(x_1)\delta(x - x_1). \quad (1)$$

This Lagrangian \mathcal{L}' will yield modified field equations. The new solution for the field variable *B*(*x*) will be written in the form

$$B'(x) = B(x) + \lambda\delta_1 B(x) \quad (2)$$

where *B'* is completely defined by the equations of motion together with the boundary conditions $\delta_1 B \rightarrow 0$ as $t \rightarrow -\infty$. If *A* contains no time derivatives, the modified Hamiltonian will be

$$\begin{aligned} P'_0 &= H'(t) = H - \lambda A(x_1)\delta(t - t_1) \\ &= H - \delta H. \end{aligned} \quad (3)$$

It can be shown that *B'*(*x*) which is the solution of

$$i\hbar\partial_t B' = [H', B'] \quad (4)$$

and *B* which is a solution of

$$i\hbar\partial_t B = [H, B] \quad (5)$$

are related by the transformation

$$B'(x) = S(t)B(x)S(t)^{-1}, \quad x_0 = t \quad (6)$$

where *S*(*t*) satisfies the equation

$$i\hbar\frac{\partial S(t)}{\partial t} = \delta HS(t). \quad (7)$$

To first order in λ , the solution of (7) for *S* is

$$S(t) = 1 - \frac{i\lambda}{\hbar}\theta(t - t_1)A(x_1) \quad (8)$$

where $\theta(t) = 0$ for $t < 0$ and $\theta(t) = 1$ for $t > 0$. If we substitute this expression in Equation (6) and compare the result with (2) we find

$$i\hbar\delta_1 B(x_2) = [A(x_1), B(x_2)]\theta(t_2 - t_1) \quad (9)$$

and similarly

$$-i\hbar\delta_2 A(x_1) = [A(x_1), B(x_2)]\theta(t_1 - t_2) \quad (10)$$

combining these results in the symmetrical expression

$$[A(x_1), B(x_2)] = i\{\delta_1 B(x_2) - \delta_2 A(x_1)\}. \quad (11)$$

The above is as it stands applicable to boson fields. For example, consider the scalar meson field $\phi(x)$ [whose Lagrangian is $\mathcal{L} = -\frac{1}{2}(\mu^2\phi^2 - \partial_\mu\phi\partial^\mu\phi)$]. We wish to compute the commutator $[\phi(x_1), \phi(x_2)]$. Let us therefore construct the modified Lagrangian

$$\mathcal{L}' = \mathcal{L}(x) + \lambda\delta(x - x_1)\phi(x). \quad (12)$$

The equation determining $\delta_1\phi$ is then

$$(\square + \mu^2)\delta_1\phi(x) = \delta(x - x_1) \quad (13)$$

with $\delta_1\phi = 0$ for $t < t_1$. The solution of this equation is

$$\delta_1\phi(x) = \Delta_R(x - x_1) \quad (14)$$

where

$$\Delta_R(x) = -\frac{1}{(2\pi)^4} \int_{C_R} \frac{e^{-ik_\mu x^\mu}}{k^2 - \mu^2} d^4k \quad (15)$$

with C_R a contour in the complex k_o plane which goes from $-\infty$ to $+\infty$ above the singularities $k_o = \pm\sqrt{\mathbf{k}^2 + \mu^2}$. Similarly if

$$\Delta_A(x) = -\frac{1}{(2\pi)^4} \int_{C_A} \frac{e^{-ik_\mu x^\mu}}{k^2 - \mu^2} d^4k \quad (16)$$

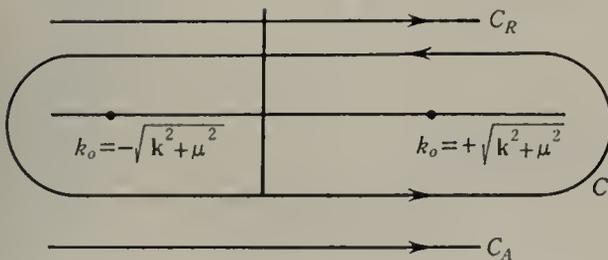

where C_A is a contour in the k_o plane from $-\infty$ to $+\infty$ going below the singularities $k_o = \pm\sqrt{\mathbf{k}^2 + \mu^2}$, the Peierls prescription implies that

$$[\phi(x_1), \phi(x_2)] = i\hbar[\Delta_A(x_1 - x_2) - \Delta_R(x_1 - x_2)] \\ = i\hbar\Delta(x_1 - x_2) \quad (17)$$

where

$$\Delta(x) = \frac{-1}{(2\pi)^4} \int_C \frac{e^{-ik_\mu x^\mu}}{k^2 - \mu^2} d^4k \quad (18)$$

and C is a contour in the k_o plane enclosing both singularities in the counterclockwise sense.

For half integral spin fields, it is necessary to alter the above prescriptions so as to obtain

anticommutation rules between the field operators. We illustrate the necessary alterations for the case of the free Dirac field, whose Lagrangian is

$$\mathcal{L} = -\frac{1}{2}\bar{\psi}(-i\gamma^\mu\partial_\mu + m)\psi \\ - \frac{1}{2}(i\partial_\mu\gamma^\mu + m)\bar{\psi}\cdot\psi. \quad (19)$$

The addition to the Lagrangian of an infinitesimal term of the form $\lambda\psi(x)\delta(x - x_1)$ would lead to (Bose) commutation rules. Instead one must consider the addition of terms of the type $\lambda\theta\psi(x)\delta(x - x_1)$ where θ anticommutes with ψ . The quantity $\delta_2\psi(x)$ is then determined by the equation

$$(-i\gamma^\mu\partial_\mu + m)\delta_2\psi(x) = \theta_2\delta(x - x_2) \quad (20)$$

$$\delta_2\psi = 0 \quad \text{for } t < t_2 \quad (20a)$$

whose solution is

$$\delta_2\psi = S_R(x - x_2)\theta_2 \quad (21)$$

which

$$S_{R/A}(x) = -(i\gamma^\mu\partial_\mu + m)\Delta_{R/A}(x; m). \quad (22)$$

Combining this solution with the one for $\delta_1\bar{\psi}$ yields the following result for the commutator

$$[\theta_1\psi(x_1), \bar{\psi}(x_2)\theta_2] = -i\theta_1\{S_A(x_1 - x_2) \\ - S_R(x_1 - x_2)\}\theta_2. \quad (23)$$

If now θ_1 and θ_2 are chosen to anti-commute with each other and with all field operators, the commutator in (23) reduces to $\theta_1[\psi(x_1), \bar{\psi}(x_2)]_+\theta_2$, where $[A, B]_+ = AB + BA$; whence

$$[\psi(x_1), \bar{\psi}(x_2)]_+ = iS(x_1 - x_2) \quad (24)$$

where

$$S(x) = S_A(x) - S_R(x) \\ = -(i\gamma^\mu\partial_\mu + m)\Delta(x; m). \quad (25)$$

COVARIANT CURVATURE TENSOR. See Riemann-Christoffel tensor.

COVARIANT DERIVATIVE OF TENSOR FIELD. $t_{pq\dots r}^{ij\dots k}$ are the components in a generic coordinate system x of a tensor field of weight W . We define $t_{pq\dots r, m}^{ij\dots k}$ by

$$t_{pq\dots r, m}^{ij\dots k} = \frac{\partial t_{pq\dots r}^{ij\dots k}}{\partial x^m} - W t_{pq\dots r}^{ij\dots k} \Gamma_{ma}^a \\ + t_{pq\dots r}^{aj\dots k} \Gamma_{ma}^i + \dots + t_{pq\dots r}^{ij\dots a} \Gamma_{ma}^k \\ - t_{aq\dots r}^{ij\dots k} \Gamma_{pm}^a - \dots - t_{pq\dots a}^{ij\dots k} \Gamma_{rm}^a,$$

where Γ_{jk}^i denotes the **Christoffel (3-index) symbol** of the second kind. The aggregate of functions $t_{pq\dots r,m}^{ij\dots k}$ so defined in each coordinate system is a **tensor field** of weight W with covariant order one greater than the original tensor field. It is called the covariant derivative of the tensor field. Since the Christoffel symbols are all zero for a rectangular Cartesian coordinate system, the components of the covariant derivative of a tensor field in a rectangular Cartesian coordinate system are the partial derivatives, with respect to the coordinates, of the components of the tensor field in that coordinate system.

COVARIANT DIFFERENTIATION. The operation of forming the **covariant derivative**.

COVARIANT METRIC TENSOR. See **metric tensor**.

COVARIANT PERTURBATION THEORY. The time displacement operator in the **interaction picture** $U(t, t_0)$, defined by

$$U(t, t_0)\Psi(t_0) = \Psi(t)$$

$$U(t_0, t_0) = 1$$

where $\Psi(t)$ is the state vector of the system in the interaction picture, satisfies the equation

$$U(t, t_0) = 1 - \frac{i}{\hbar} \int_{t_0}^t dt' H_I(t') U(t', t_0)$$

where $H_I(t)$ is the interaction Hamiltonian ($H = H_0 + H_I(t)$). It is unitary

$$U^*(t, t_0) = U^{-1}(t, t_0)$$

for finite times t, t_0 , and in addition satisfies the relation

$$U^{-1}(t, t_0) = U(t_0, t)$$

for finite times t, t_0 . It also obeys the group property

$$U(t, t_1)U(t_1, t_0) = U(t, t_0)$$

which allows us to express a finite transformation as a product of infinitesimal ones

$$U(t, t') = U(t, t_1)U(t_1, t_2) \cdots U(t_{n-1}, t_n)U(t_n, t')$$

where $U(t_j, t_{j+1})$ is an infinitesimal transformation from t_j to t_{j+1} . For the infinitesimal case $U(t_j, t_{j+1})$ can be approximated by

$$U(t_j, t_{j+1}) \approx 1 - \frac{i}{\hbar} \int_{t_{j+1}}^{t_j} dt' H_I(t')$$

so that in the limit as $n \rightarrow \infty$

$$U(t, t') = 1 - \frac{i}{\hbar} \int_{t_0}^t dt_1 H_I(t_1) + \left(-\frac{i}{\hbar}\right)^2 \int_{t_0}^t dt_1 \int_{t_0}^{t_1} dt_2 H_I(t_1) H_I(t_2) + \cdots + \left(-\frac{i}{\hbar}\right)^n \int_{t_0}^t dt_1 \int_{t_0}^{t_1} dt_2 \cdots \int_{t_0}^{t_{n-1}} dt_n H_I(t_1) H_I(t_2) \cdots H_I(t_n).$$

To write this expansion in a more symmetrical form Dyson has introduced the **chronological ordering operator** P defined so as to order any product of time-dependent operators in chronological sequence, with the one with the earliest time label standing furthest to the right

$$P[A_i(t_i)A_j(t_j) \cdots A_k(t_k)] = A_1(t_1) \cdots A_1(t_n)$$

if $t_1 > t_2 > \cdots t_n$.

Consider the expression

$$I_n(t, t_0) = \int_{t_0}^t dt_1 \int_{t_0}^{t_1} dt_2 \cdots \int_{t_0}^{t_{n-1}} dt_n P[H_I(t_1) \cdots H_I(t_n)]$$

since the integrand of I_n is symmetric with respect to $t_1 t_2 \cdots t_n$ the total contribution is $n!$ times a contribution from a particular time ordering of the t 's. If we take the sequence $t_1 > t_2 > \cdots > t_n$ as representative

$$I_n(t, t_0) = n! \int_{t_0}^t dt_1 \int_{t_0}^{t_1} dt_2 \cdots \int_{t_0}^{t_{n-1}} dt_n H_I(t_1) \cdots H_I(t_n)$$

whence

$$U(t, t_0) = \sum_{n=0}^{\infty} \left(-\frac{i}{\hbar}\right)^n \int_{t_0}^t dt_1 \cdots \int_{t_0}^{t_{n-1}} dt_n P(H_I(t_1) \cdots H_I(t_n)).$$

In field theory

$$H_I(t) = \int_{-\infty}^{\infty} \mathcal{H}_I(x) d^3x$$

so that the **S matrix** has the following expansion

The normalization of the one-particle state now demands that

$$\begin{aligned} \langle \mathbf{k}' | \mathbf{k} \rangle &= \langle 0 | a_{\mathbf{k}'} a_{\mathbf{k}}^* | 0 \rangle \\ &= \langle 0 | [a_{\mathbf{k}'}, a_{\mathbf{k}}^*] | 0 \rangle = k_0 \delta(\mathbf{k} - \mathbf{k}'). \end{aligned} \quad (7)$$

If we require the commutator of the a and a^* operators to be a c -number then

$$[a_{\mathbf{k}}, a_{\mathbf{k}'}^*] = \delta(\mathbf{k} - \mathbf{k}') k_0. \quad (8)$$

One verifies that the orthonormality conditions (1c) are in fact generally satisfied with these commutation rules.

A representation of these commutation rules is easily obtained from the defining Equations (3)-(4) and one finds

$$\begin{aligned} a^*(k) | \mathbf{k}_1 \cdots \mathbf{k}_n \rangle &= \sqrt{n+1} | \mathbf{k}, \mathbf{k}_1, \mathbf{k}_2 \cdots \mathbf{k}_n \rangle \\ a(k) | \mathbf{k}_1 \cdots \mathbf{k}_n \rangle &= \frac{1}{\sqrt{n}} \sum_i \delta(\mathbf{k} - \mathbf{k}_i) \\ &\quad | \mathbf{k}_1 \cdots \mathbf{k}_{i-1} \mathbf{k}_{i+1} \cdots \mathbf{k}_n \rangle. \end{aligned}$$

This representation is irreducible.

For an assembly of spin $\frac{1}{2}$ particles (which obey the **Pauli exclusion principle**) the state of a single particle is specified by its momentum (energy) and spin quantum number which can take on two values, say ± 1 . We denote such a one-particle state by $|\mathbf{p}, s\rangle$. An n -particle state is denoted by $|\mathbf{p}_1 s_1, \cdots, \mathbf{p}_n s_n\rangle$ and the no-particle state by $|0\rangle$. The Pauli principle requires that no two particles have the same momenta and spin; more generally, that it be antisymmetric under the interchanges of any two particles. The normalization of these states is

$$\begin{aligned} \langle 0 | 0 \rangle &= 1 \\ \langle \mathbf{p} s | \mathbf{p}' s' \rangle &= p_0 \delta(\mathbf{p} - \mathbf{p}') \delta_{ss'} \\ \langle \mathbf{p}_1 s_1 \cdots \mathbf{p}_n s_n | \mathbf{p}'_1 s'_1 \cdots \mathbf{p}'_m s'_m \rangle \\ &= \delta_{nm} \frac{1}{n!} \det | \delta(\mathbf{p}_i - \mathbf{p}_j) \delta_{s_i s_j} |. \end{aligned}$$

We can again define creation and annihilation operators $a^*(\mathbf{p}s)$ and $a(\mathbf{p}s)$ by

$$\begin{aligned} a^*(\mathbf{p}s) | 0 \rangle &= | \mathbf{p}s \rangle \\ \frac{1}{\sqrt{n!}} a^*(\mathbf{p}_1 s_1) \cdots a^*(\mathbf{p}_n s_n) | 0 \rangle &= | \mathbf{p}_1 s_1 \cdots \mathbf{p}_n s_n \rangle \\ a(\mathbf{p}s) | \mathbf{p}s \rangle &= | 0 \rangle \\ a(\mathbf{p}s) | 0 \rangle &= 0. \end{aligned}$$

The antisymmetry of the vector $|\mathbf{p}_1 s_1 \cdots \mathbf{p}_n s_n\rangle$ under the interchange of any two particles implies that $a^*(\mathbf{p}s)$ and $a^*(\mathbf{p}'s')$ must anticommute

$$\begin{aligned} \{a^*(\mathbf{p}s), a^*(\mathbf{p}'s')\} &= 0 \\ \{a(\mathbf{p}s), a(\mathbf{p}'s')\} &= 0 \end{aligned}$$

where $\{A, B\} = AB + BA$. The normalization of the states now implies that

$$\{a(\mathbf{p}s), a^*(\mathbf{p}'s')\} = \delta(\mathbf{p} - \mathbf{p}') p_0 \delta_{ss'}.$$

CREEP (OR CREEP FUNCTION). The strain variation due to loading by a **step function** of stress. For a linear viscoelastic material this is equal to the creep compliance (see **compliance, creep**) multiplied by the stress.

CREEP COMPLIANCE. See **compliance, creep**.

CREEPING MOTION. Flow in which the viscous forces are much larger than the inertia forces ($Re \ll 1$). In terms of the velocity potential ψ , such that

$$u = \frac{\partial \psi}{\partial y}, \quad v = -\frac{\partial \psi}{\partial x}$$

the motion satisfies the differential equation

$$\nabla^4 \psi = 0$$

whose particular solutions are sometimes called **biharmonic functions**.

CRIPPLING. See **buckling, local**.

CRITICAL ANGLE. See **total reflection**.

CRITICAL ASSEMBLY. An assembly of fissionable material plus moderator which is capable of maintaining a fission chain reaction at very low power level and which is used mainly to study the behavior of the fissionable material under various conditions of geometry, composition, etc.

CRITICAL COEFFICIENT. An additive property of substances which is also a measure of the space actually occupied by the molecules and is proportional to the **critical volume**. It is expressed as the ratio between the critical temperature T_c and the critical pressure P_c , or

$$k = \frac{T_c}{P_c}.$$

(Some writers define the critical coefficient as the product: $RT \frac{T_c}{P_c}$.)

CRITICAL COMPOSITION. See **critical solution phenomena**.

CRITICAL CONSTANTS. The temperature, pressure and density at the **critical point**.

CRITICAL DAMPING. See **damping, critical**.

CRITICAL DENSITY. The density of a substance which is at its **critical temperature** and **critical pressure**.

CRITICAL EQUATION. In nuclear reactor theory, the equation obtained by equating the effective multiplication (see **multiplication, effective**) to unity. When the effective multiplication is given an explicit expression, the critical equation determines the arrangements of material necessary for the maintenance of a chain reaction.

CRITICAL FIELD. The magnetic field H_c below which the **superconducting transition** takes place at a given temperature. Empirically, a relation is observed of the form

$$H_c = H_0 \{1 - (T/T_c)^2\}$$

where H_0 is a parameter characteristic of the material, and T_c is the critical temperature of the superconductor.

CRITICALITY FACTOR. In the theory of neutron chain reactions, criticality factor is synonymous with effective multiplication. (See **multiplication, effective**.)

CRITICAL LOAD, ABSOLUTE. The smallest **critical load** (eigenvalue) for a structure is sometimes called the absolute critical load.

CRITICAL LOAD OR STRESS. A critical load or stress is the solution to an eigenvalue problem for the existence of neighboring configurations (see **buckling**). There may be an infinite number of successively higher critical stresses in any problem, corresponding to more and more complicated buckled configurations generally of shorter and shorter wavelengths.

CRITICAL LOAD, SOUTHWELL METHOD. The experimental determination of the critical load P_{cr} for a geometrically perfect

structure is always obscured by the imperfections of loading and geometry. For simple structures such as columns the magnification factor for the deflections is determined essentially by the reciprocal of $1 - (P/P_{cr})$. Therefore if the deflection δ is plotted against δ/P where P is the load applied, points will fall on a straight line whose slope gives P_{cr} .

$$\delta = (const.) \frac{P}{1 - \frac{P}{P_{cr}}}, \quad \text{or} \quad \frac{\delta}{P} = \frac{\delta}{P_{cr}} + const.$$

(See **beam column**.)

CRITICAL MACH NUMBER. For a body in a uniform stream, the critical Mach number is the **Mach number** of the undisturbed stream for which sonic velocity is just reached at some point on the body. At stream Mach numbers above the critical value, there is a region of supersonic flow near the body, although the flow in the undisturbed stream may still be subsonic.

CRITICAL MASS. The mass of fissionable material in a critical reactor.

CRITICAL MASS PROBLEM, MINIMUM. See **minimum critical mass problem**.

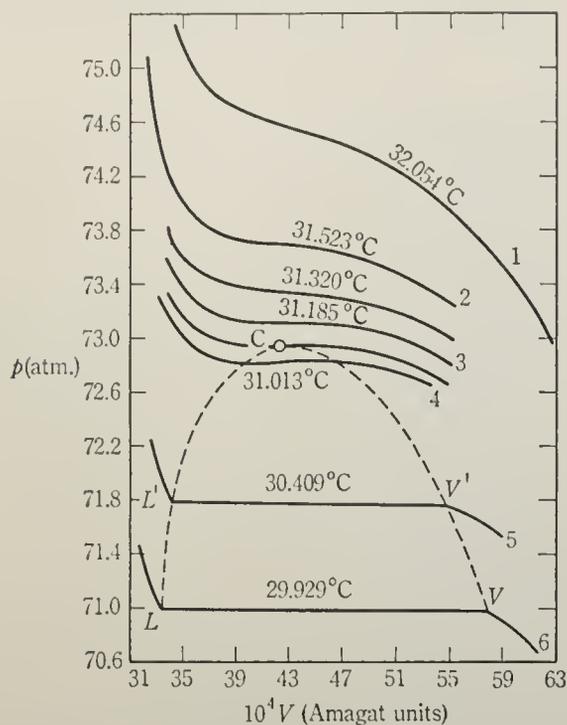

CRITICAL PARAMETERS. The critical temperature, pressure and volume.

CRITICAL PHENOMENA IN THE VAPORIZATION OF MIXTURES. The critical point for a given composition is the point where the liquid and the gaseous phases become identical, as if they were a single component. (See **critical point**.) However, the critical pressure and critical temperature have a different significance for a mixture, than they do in the case of a pure substance. Indeed there may exist a range of pressure and of temperature above the critical point when condensation may still occur.

Closely related to this behavior are the phenomena of *retrograde vaporization* and *retrograde condensation*. In the first case, when we raise the temperature at constant pressure, the vaporization begins, and then is followed by condensation until finally vaporization starts again. The description of retrograde condensation is similar. (See also **binodals**; **spinodal curve**.)

CRITICAL POINT. Consider the family of isotherms of a pure substance in the fluid range (liquid or gas) such for example as shown in the figure for carbon dioxide.

At sufficiently high temperatures each isotherm is a continuous curve, but at low tem-

Isotherms of carbon dioxide in the neighborhood of the critical point.

peratures the isotherm consists of three portions. The first section of the curve at high pressures corresponds to the liquid state, while that at low pressures refers to the gaseous state. These two curves are joined by a horizontal line corresponding to the simultaneous presence of two phases, liquid and gas.

The isotherm between those numbered 3 and 4 in the figure represents the transition between isotherms corresponding to the gas phase only, and those including a horizontal portion corresponding to a liquid-gas equilibrium. In this isotherm the horizontal line has contracted to a single point of inflection C. This is the critical point characterized by the relations

$$\left(\frac{\partial p}{\partial V}\right)_{T_c} = 0; \quad \left(\frac{\partial^2 p}{\partial V^2}\right)_{T_c} = 0; \quad \left(\frac{\partial^3 p}{\partial V^3}\right)_{T_c} < 0. \quad (1)$$

The curve $LL'C$ gives the molar volume of the liquid. Similarly $VV'C$ gives the molar volume of the gas.

At the critical point the molar volumes of the liquid and of the gas become equal. In

general a critical state is characterized by the fact that the two coexistent phases (here the liquid and the vapor) are identical.

The curve $VV'CL'L$ is called the *saturation curve*.

The experimental data do not indicate the existence of a critical point for the liquid-solid transition.

Above the critical point the substance can no longer exist in the liquid state. The critical temperature is thus the highest temperature at which the liquid and vapor can coexist. (See also **critical phenomena in the vaporization of mixtures; critical solution phenomena; continuity of state; Maxwell theorem.**)

CRITICAL POTENTIAL. The minimum electrical potential which has to be supplied to an electron to bring about, on collision with an atom, the emission of a certain spectral line. The critical potential is equal to the energy above the ground state of the upper electronic state taking part in the transition.

CRITICAL PRESSURE. (1) The pressure of a vapor at its **critical point**.

(2) If a compressible fluid flows from a container through an orifice or other constriction, the volume flow depends on the pressure difference across the flow system only if the final pressure exceeds a definite fraction of the initial pressure. If either the initial or the final pressure is held constant, there is a critical pressure separating a regime of flow dependence on pressure difference from one of independence. The fraction depends on the nature of the fluid. (3) See **convergent nozzle; convergent-divergent nozzle**.

CRITICAL PROPERTIES. See **critical parameters**.

CRITICAL REGION. (1) The region in the **diagram of state** of a substance in the neighborhood of the **critical point**. (2) In the statistical theory of testing hypotheses, the space of possible events is divided into two regions, one regarded as concordant with the hypothesis, the other as discordant. If an event, e.g., the outcome of an experiment, falls into the second region the hypothesis is rejected and that region is therefore called critical.

CRITICAL SIZE. In nuclear reactor theory, the value of some geometrical quantity (height, radius, ...) necessary to establish a steady chain reaction. In the case of a bare

reactor, the critical size is closely related to the lowest eigenvalue of the equation

$$(\nabla^2 + B^2)\phi = 0, \quad \phi = 0 \text{ on bounding surface.}$$

CRITICAL SOLUTION PHENOMENA. In addition to critical phenomena in vaporization when the liquid phase becomes identical with the gas phase (see **critical phenomena in the vaporization of mixtures**) there also exist critical solution phenomena in which two liquid phases or two solid phases each of which is a mixture, become identical at the critical point.

For a binary mixture such a critical point is given by the conditions

$$\left(\frac{\partial^2 g}{\partial x_B^2}\right)_c = 0; \quad \left(\frac{\partial^3 g}{\partial x_B^3}\right)_c = 0; \quad \left(\frac{\partial^4 g}{\partial x_B^4}\right)_c > 0 \quad (1)$$

where

$$g = \frac{G}{n} \quad (2)$$

is the molar Gibbs free energy (see **thermodynamics, characteristic functions**) and x_B is the mole fraction.

If the critical temperature is the highest at which the two phases can coexist it is called an *upper critical solution temperature*, if it is the lowest, then the critical point is called a *lower critical solution temperature*.

There are also a few systems which exhibit both an upper and a lower critical solution temperature.

CRITICAL SPEED. See **speed, critical**.

CRITICAL STABILITY (OF SYSTEM). See **stability (of system)**.

CRITICAL TEMPERATURE. (1) The temperature of a substance at its **critical point**. (2) Of a **superconductor**, the temperature T_c at which the **superconducting transition** takes place in zero magnetic field.

CRITICAL VOLUME. The volume occupied by unit mass, commonly one mole, of a substance at its **critical temperature** and **critical pressure**.

CROCCO THEOREM. For an inviscid gas,

$$T \text{ grad } s + \mathbf{v} \times \text{curl } \mathbf{v} = \text{grad } h_o + \frac{\partial \mathbf{v}}{\partial t},$$

where s and h_o are the entropy and stagnation enthalpy per unit mass, T is the temperature and \mathbf{v} is the velocity.

If the flow is steady and adiabatic, the terms on the righthand side vanish and the equation becomes

$$T \text{ grad } s = -\mathbf{v} \times \text{curl } \mathbf{v}.$$

Then, if the flow is irrotational the entropy must be constant throughout. Conversely, if the entropy is not constant the flow cannot be irrotational.

CROSSCORRELATION FUNCTION. A function used in information theory of the form

$$\phi_{12}(\tau) = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T f_1(t)f_2(t - \tau)dt$$

where τ is a time-delay parameter. The function $f(t)$ is considered to be continuous, and it retains phase information, provided either or both the functions, $f_1(t)$ or $f_2(t)$ are periodic. It can be shown by use of the **convolution** integral that the linear response of any network or system is given by the crosscorrelation function between output and input for an input of wide-band random noise.

CROSS-DIFFERENTIATION IDENTITY. Alternative term for the **Euler reciprocity relation**.

CROSS EFFECT. See **normal stress effect**.

CROSS-FLOW. See **heat exchanger**.

CROSS-LINKING. Chemical bonding between the molecular chains of a high polymer, which prevent unrestricted viscous flow.

CROSS METHOD. The method of solving elastic rigid frame problems by a successive approximation technique called **moment distribution** as introduced by Hardy Cross.

CROSS-OVER DESIGN. A class of experimental design in which two treatments to be compared are first applied to two sets of individuals and then "crossed over" so that an individual receiving one treatment on one occasion receives the other treatment on the second. Various elaborations of the idea are possible.

CROSS POLARIZATION. The component of the **electric field vector** normal to the desired polarization component.

CROSS PRODUCT OF VECTORS. See vector multiplication.

CROSS SECTION. From its general meaning of a section at right angles to an axis, the term cross section has been extended to mean a measure of the probability of a particular process. It is expressed in units of area, although it is not usually identical with the geometric cross section across which the process occurs. For a collision reaction between nuclear or atomic particles or systems, the cross section is an area such that the number of reactions occurring is equal to the product of number of target particles or systems multiplied by the number of incident particles which would pass through this area at normal incidence. If n_t is the number of target nuclei or other particles per unit area of a substance exposed to an incident beam consisting of n_o particles, then $\sigma = N/n_o n_t$, where N is the number of reactions of a specified type. (While the cross section per atom of a medium is expressed in dimensions of area, the cross section per unit volume of medium is a reciprocal length.) Nuclear cross sections include the cross section for fission, the cross section for slow neutron capture, and the cross section for elastic scattering. Atomic cross sections include the cross section for Compton collision and the cross section for ionization by electron impact. The total cross section is the sum of the separate cross sections by which a particle can be removed from a beam.

CROSS SECTION, ABSORPTION. The total cross section for removal of an incident particle from a beam, minus the elastic scattering cross section. Sometimes therefore called the total inelastic cross section. In the case of neutrons, for example, it includes the cross sections for inelastic scattering, radiative capture, fission, and such reactions as (n, p) , (n, α) , and $(n, 2n)$.

CROSS SECTION, ACTIVATION. The cross section of formation for a particular radionuclide. It is most commonly used for neutron-induced reactions.

CROSS SECTION, BREIT-WIGNER. In the theory of slow neutron resonance reactions, the cross sections for scattering and x-ray emission due to the formation of a compound nucleus with widely separated energy levels are given by

$$\begin{aligned}\sigma_s(E) &= 4\pi(1-g)R^2 \\ &+ 4\pi\lambda_o^2 g \left| \frac{\Gamma_n/2}{E - E_o + i\Gamma/2} + \frac{R}{\lambda_o} \right|^2 \\ \sigma_\gamma(E) &= \pi\lambda_o^2 g \left(\frac{E_o}{E} \right)^{1/2} \frac{\Gamma_n \Gamma_\gamma}{(E - E_o)^2 + (\Gamma/2)^2} \\ g &= \frac{1}{2} \left(\frac{2J + 1}{2I + 1} \right), \\ J &= I + \frac{1}{2} \text{ (for slow neutrons)}\end{aligned}$$

when the neutron energy, E is in the vicinity of E_o , the energy required for the formation of a level. Here R , the nuclear "radius" is defined through the requirement that $\sigma_s(E) = 4\pi R^2$ far from E_o . $2\pi\lambda_o$ is the neutron wavelength at resonance, Γ_n and Γ_γ are the scattering and x-ray widths, and Γ is the total width, all evaluated at resonance. I is the spin of the target nucleus.

CROSS SECTION, DIFFERENTIAL. The cross section for a nuclear process whereby an angle is specified (relative to the direction of incidence) for the emission of particles or photons per unit angle or per unit solid angle.

CROSS SECTION, DOPPLER BROADENED. In the theory of neutron reactions, thermal motion of the target atoms causes the effective cross sections encountered by neutrons to deviate from the Breit-Wigner values. Averaging over these motions gives a Doppler broadened cross section. $\sigma_\gamma(E)$ for example, becomes:

$$\begin{aligned}\sigma_\gamma(x, \theta) &= 4\pi\lambda_o^2 \frac{\Gamma_n \Gamma_\gamma}{\Gamma^2} \\ &\times \int_{-\infty}^{\infty} \frac{dy}{1 + y^2} \exp \left\{ -\frac{(x - y)^2}{4\theta} \right\}\end{aligned}$$

where

$$x = \frac{E - E_o}{\Gamma/2} \quad \theta = \frac{4E_o k T}{A \Gamma^2}$$

A is the mass number of the target nucleus. (For other notation, see **cross section, Breit-Wigner.**)

CROSS SECTION, ELASTIC SCATTERING. The cross section for a scattering process in which, in the center of mass system, no energy is transferred to the scattering center, nor is there any change in the spin motions of particle and scatterer.

CROSS SECTION, INELASTIC SCATTERING. The cross section for the scattering of an incident particle accompanied by excitation of the scattering center. The scattered particle loses an amount of energy equal to the amount needed to raise the scattering center (nucleus, atom, or molecule) to one of its excited states. Inelastic scattering is an important process of energy loss for neutrons passing through a medium of high mass number.

CROSS SECTION, INTERACTION. See **interaction cross section**.

CROSS SECTION, IONIZATION. In general, the probability that a particle or photon traversing a gas, or other form of matter, will undergo an ionizing collision while passing through unit length of a volume just sufficient to contain one atom. The term is used especially in radiation counter technology, where it is a measure of the probability that an electron traversing a radiation counter will make an ionizing collision with one of the counter gas atoms. In the low voltage region the ionization cross section increases linearly with the electron energy.

CROSS SECTION, MACROSCOPIC. Symbolized by Σ , the product of the number of scatterers per unit volume and the appropriate cross section. Given a mixture of scattering materials,

$$\Sigma = \sum_i N_i \sigma_i.$$

When the number of scatterers per unit volume is unknown, the macroscopic cross section is sometimes expressed per unit weight of scattering material.

CROSS SECTION, MICROSCOPIC. Cross section per atom or molecule.

CROSS SECTION OF BAR. The area cut by a plane perpendicular to the axes of the bar.

CROSS SECTION, PARTIAL. A cross section for a particular process among several competing processes. (See **cross section, total**.)

CROSS SECTION, RADIATIVE CAPTURE. The cross section for a process in which the incident particle is captured by the target nucleus to form a compound nucleus which rids itself of excess energy through emission of photons. In the case of neutrons, radiative

capture is the chief absorption process for most elements for neutrons of low energies. The cross section is often inversely proportional to neutron velocity for sufficiently low energies.

CROSS SECTION, REMOVAL. In the study of the penetration of radiation through matter, consider a shielding system composed of a layer of water of thickness w into which a slab of heavier material of thickness, t , is inserted. The removal cross section, Σ_r , characteristic of the heavy material and type of radiation involved, is defined by the assertion that attenuation of radiation by the water shield is augmented by the factor $\exp(-\Sigma_r t)$ when the slab is inserted.

CROSS SECTION, RUTHERFORD. The cross section for elastic scattering of two electrically charged particles through their mutual Coulomb force. The total cross section is infinite owing to the infinite range of the Coulomb potential which gives rise to an infinite cross section for scattering into infinitely small angles. However, the differential cross section is given by

$$\frac{d\sigma}{d\Omega} = \left(\frac{z_1 z_2 e^2}{2\mu v^2} \right)^2 \text{cosec}^4 \frac{1}{2}\theta$$

where θ is the scattering angle in the center of mass system, $z_1 e$ and $z_2 e$ are the charges, and μ the reduced mass, of the two particles, and v is their relative velocity. This celebrated result, true only in the non-relativistic limit, was first given by Rutherford in his work on the scattering of α -particles by matter. The differential scattering cross section for charged particles by nuclei are often expressed in units of the Rutherford cross section to show clearly the departures in scattering due to true nuclear scattering.

CROSS SECTION, SCATTERING. The cross section for scattering of a particle or a photon out of a beam. It is the integral over the total solid angle of the differential scattering cross section. (See **cross section, differential scattering**, and the various entries under scattering.)

CROSS SECTION, STOPPING. The same as atomic stopping power. (See **stopping power**.)

CROSS SECTION, TOTAL. The cross section effective for removing an incident particle from a beam. It is the sum of the separate cross sections for all processes by which the particle can be removed from the beam. For example, the total cross section of an atom for a nuclear particle is essentially the total of the absorption and scattering cross sections; for a photon it is essentially the sum of the Compton scattering, photoelectric and pair production cross sections.

CROUT METHOD. A method of triangularization for matrix inversion.

CRYOSCOPIC CONSTANT. Let us consider the **crystallization curve** of a dilute solution. We define the depression of the freezing point θ of the solvent by

$$\theta = T_1^\circ - T. \quad (1)$$

T_1° is the freezing point of the solvent and T of the solution.

If a solution is both very dilute and ideal one has

$$\theta = \frac{R(T_1^\circ)^2}{\Delta_f h_1^\circ} \frac{M_1}{1000} \sum_s m_s = \theta_c \sum_s m_s. \quad (2)$$

$\Delta_f h_1^\circ$ is the latent heat of fusion of the pure solvent at temperature T_1° , M_1 the molar mass of the solvent, m_s the **molality** of the solute s .

The quantity θ_c is called the cryoscopic constant (or freezing point constant). Its value depends only on the nature of the solvent. For water one has

$$\theta_c = 1.86 \text{ }^\circ\text{C/mole in 1000 g}$$

and for cyclohexanol

$$\theta_c = 41.6 \text{ }^\circ\text{C/mole in 1000 g.}$$

This wide range of values is related to the fact that θ_c contains the entropy of fusion

$$\Delta_f h_1^\circ / T_1^\circ \quad (3)$$

which varies considerably from substance to substance.

CRYSTAL ANGLES. The characteristic constant angles between the faces of any given crystal form.

CRYSTAL ELEMENTS. The angles, plus the **axial ratios** or **intercept ratios**, in terms of which the position of any crystal face may be described.

CRYSTAL INDICES, MILLER. Three indices used to represent any crystal face in terms of the **crystallographic axes** and the **crystallographic axial ratios**. These integers give the ratio of the intercepts of the unit plane to those of the particular face.

CRYSTAL INTERCEPTS. See **crystallographic parameters**.

CRYSTAL LATTICE. See **space lattice**.

CRYSTALLIZATION CURVE. Consider a system of c components and suppose first that these components are completely miscible in the liquid state, but completely immiscible in the solid state. On freezing, the solution yields various crystals, each variety of which consists of a single component, since the formation of mixed crystals is excluded. The coexistence curve of the solution with crystals of component l is given by the equation

$$\ln x_1^l \gamma_1^l = \int_{T_1^\circ}^T \frac{\Delta_f h_1^\circ}{RT^2} dT \quad (1)$$

where x_1^l and γ_1^l are respectively the mole fraction and activity coefficient of component 1 in the solution, $\Delta_f h_1^\circ$ the latent heat of fusion at temperature T_1 and T_1° the melting point of pure component 1.

If the solution is ideal and the latent heat of fusion may be considered as independent of temperature this equation becomes

$$-\ln x_1^l = \frac{\Delta_f h_1^\circ}{R} \left(\frac{1}{T} - \frac{1}{T_1^\circ} \right). \quad (2)$$

This equation is due to Schröder and Van Laar.

If we apply (1) or (2) to a binary mixture we obtain two crystallization curves which intersect at the *eutectic point*. At the eutectic point crystals of both 1 and 2 and the solution coexist in equilibrium.

If the components are miscible in the solid phase, one has **mixed crystals**.

CRYSTALLIZATION RATE EQUATIONS. Attempts have been made from time to time to establish equations for the linear velocity of crystallization (v) of substances. Empirical relationships of the form

$$v = \text{const. } \Delta t / \eta$$

have been used, where Δt is the degree of supercooling and η is the viscosity of the liquid. Theoretical equations have expressed v as exponential functions of the work of formation of a nucleus, w , and activation energy q , e.g.,

$$v = Ae^{-\frac{w}{kT}}e^{-\frac{q}{kT}}$$

where A is a constant, T is the absolute temperature, and k is the Boltzmann constant.

CRYSTALLOGRAM. The x-ray diffraction pattern of a crystal, whence the **crystal structure** may be obtained.

CRYSTALLOGRAPHIC AXES. Usually three, sometimes four, lines meeting at a point which are so chosen as to bear a definite relationship to the characteristic features of the crystallographic **symmetry**. They may, for example, be normal to the plane of symmetry, or parallel to, or coincident with, the edge between principal faces or the axes of symmetry. Although the choice of axes is to some extent arbitrary, some sets produce a simpler representation than others. Whenever possible, the three axes are chosen to be at right angles to each other.

CRYSTALLOGRAPHIC AXIAL RATIOS. The ratios of the crystal intercepts, i.e., the ratios of distances from the origin of the **crystallographic axes** to the points where they are intercepted by the faces of the **unit cell**.

CRYSTALLOGRAPHIC GROUP. Any **subgroup** of the three-dimensional real orthogonal group which leaves invariant (as a whole) the set of lattice-points (i.e., with integral coordinates) in Euclidean 3-space. There are 32 such groups, 11 being crystallographic groups of the first kind (i.e., subgroups of the rotation group), 11 being extended groups of the first kind (i.e., rotations followed by reflection through the origin) and 10 others.

CRYSTALLOGRAPHY. The branch of physical science which deals with the external shapes of crystals and with the geometrical relations between the **atomic planes** within them. If a solid crystal is broken, it is found to have separated along certain cleavage planes into polyhedral fragments, and measurements show that these planes were all originally parallel to one or another of a few standard planes. In most **crystal systems**, each of the more prominent crystal faces be-

longs to one of three plane-families, intersecting along the **crystal axes** (in hexagonal crystals there are four). It is observed (**Haüy law**) that if the ratio of the intercepts of two crystal planes on one of these axes is a simple fraction, the ratios of the intercepts on the other axes are also simple fractions, and in this way it is established that the intercepts on any one axis must be multiples of a common unit. A given family of planes is then labeled by its Miller indices or Bravais-Miller indices, the reciprocals of the ratios of its intercepts with each axis, expressed in terms of the common unit for that axis, and reduced to lowest integral terms. Study of the **axial ratios**, indices, and angles shows that all crystals may be classified into seven **crystal systems**. All the above properties are satisfied if a crystal consists of a regular array of atoms, molecules, ions, etc., in a space lattice, and this is verified by the x-ray analysis of crystal structure.

CRYSTAL MOMENTUM. An expression sometimes used for the quantity obtained by multiplying a **wave vector** by **Planck's constant**, h . It has the dimensions of momentum, but when it refers to an excitation or electron wave in a crystal there is no real momentum associated with it, and it is not necessarily conserved in a collision.

CRYSTAL, NORMAL MODES OF. See **normal modes of a crystal**.

CRYSTAL PARAMETERS. The lengths of the intercepts on the **crystallographic axes** of the standard plane—that is, the lengths of the sides of the **unit cell** of the lattice. In general, only the **crystallographic axial ratios** can be determined directly.

CRYSTAL PHASES (α , β , γ , \dots ϵ , etc.). Phases resulting from the ability of some alloys to crystallize in more than one form, depending on the relative quantities of the constituents. Alloys of different metals may nevertheless give the same crystal lattices, so that a term such as the α -phase shows that there is a structural connection between them. (See **Hume-Rothery rules**.)

CRYSTAL, RESONANCE FREQUENCY OF. The frequency at which a piezoid has either a maximum or minimum impedance, depending upon whether parallel or series resonance is employed.

CRYSTAL SATURATION MAGNETO-STRICTION. When a cubic crystal such as iron is magnetized to saturation in a direction defined by the direction cosines $\alpha_1, \alpha_2, \alpha_3$, the fraction changes in length in a direction $\beta_1, \beta_2, \beta_3$, is given to a first approximation by the expression

$$\frac{\Delta l}{l} = \frac{3}{2}\lambda_1(\alpha_1^2\beta_1^2 + \alpha_2^2\beta_2^2 + \alpha_3^2\beta_3^2 - \frac{1}{3}) + 3\lambda_2(\alpha_1\alpha_2\beta_1\beta_2 + \alpha_2\alpha_3\beta_2\beta_3 + \alpha_3\alpha_1\beta_3\beta_1)$$

where λ_1 and λ_2 are material properties. For the polycrystalline material with random orientation

$$\frac{\Delta l}{l} = \frac{2\lambda_1 + 3\lambda_2}{5}$$

CRYSTALS, EQUATION OF STATE FOR. See **Mie-Grüneisen equation of state.**

CRYSTAL STRUCTURE. It was early suggested that the regular structure of crystals, embodied in the laws of crystallography could be explained if they were thought of as built up by the repetition of equal polyhedral cells, fitting together to fill space, each cell representing a characteristic group of particles, perhaps the atoms and molecules of the compound. A rough calculation showed that the spacing of these units in many ionic crystals might be of the same order of magnitude as the wavelengths of x-rays, as deduced from quantum theory. Von Laue suggested, and verified, that diffraction of the x-rays occurs when they are passed through a crystal, suitably oriented. This diffraction effect is characteristic of the type of crystal, and by observing the relative magnitudes and orientations of the various diffracted beams one has clues to the crystal structure.

Although it is easy to calculate the diffraction pattern for a given crystal structure, it is quite another matter to deduce the crystal structure directly from the diffraction pattern. The first step is to determine the spacing of the atomic planes from the Bragg equation, and hence the dimensions of the unit cell. Any special symmetry of the space group of the structure will be apparent from space group extinction. A trial analysis may then solve the structure, or it may be necessary to measure the structure factors and try to find the phases for a Fourier synthesis. Various techniques can be used, such as the

F² series, the heavy atom, the isomorphous series, anomalous atomic scattering, expansion of the crystal and other methods. (See also **x-ray analysis.**)

CRYSTAL SYMMETRY. It is an obvious characteristic of a crystal that it possesses the property of appearing unchanged after the performance of some simple geometrical operation, such as rotation about an axis, or reflection in a plane. This **symmetry** (see the various classifications under the term **symmetry**) is a consequence of the identical property of the underlying crystal **lattice.**

CRYSTAL SYSTEMS. It can be shown by geometry that there exist 32 different classes of crystal symmetry, or point groups. These are conveniently classified into seven (by some authors, six) systems, characterized by their axial angles and ratios. (See **crystallography**, see table on page 199.)

CUBATURE FORMULAS. See **multivariate interpolation.**

CUBICAL DILATATION. The ratio between the change of volume of an element of a body in passing from an unstrained to a strained state (see **state of strain**) and the volume of the element in the unstrained state.

CUBIC SYSTEM. One of the seven **crystal systems.** In this system, the axes are of equal length and intersect at right angles.

CUMULANTS. The eumulants $\kappa_1, \kappa_2 \dots$ of a probability distribution function are defined by the identity

$$\begin{aligned} \exp \left[it\kappa_1 + \frac{(it)^2}{2!} \kappa_2 + \frac{(it)^3}{3!} \kappa_3 + \dots \right] \\ \equiv \left[1 + it\mu'_1 + \frac{(it)^2}{2!} \mu'_2 + \frac{(it)^3}{3!} \mu'_3 + \dots \right] \\ = \phi(t) \end{aligned}$$

where $\mu'_1, \mu'_2 \dots$ are the moments of the distribution about the origin and $\phi(t)$ is the **characteristic function.** $\Psi(t) = \log \phi(t)$ is called the **cumulant generating function.** κ_1 is equal to the mean μ'_1 and the other cumulants can be expressed in terms of the moments about the mean; the first four can be given by $\kappa_1 = \mu'_1, \kappa_2 = \mu_2, \kappa_3 = \mu_3, \kappa_4 = \mu_4 - 3\mu_2^2$.

The cumulants other than the first are invariant under a change of origin and semi-

invariant under a change of scale. For the **normal distribution** all cumulants after the second are equal to 0; for the **Poisson distribution** all the cumulants are equal to μ . $\gamma_1 = \kappa_3/\kappa_2^{3/2}$ and $\gamma_2 = \kappa_4/\kappa_2^2$ provide measures of **skewness** and **kurtosis**.

CUMULATIVE DISTRIBUTION FUNCTION. See **distribution function**.

CUMULATIVE FREQUENCY FUNCTION. See **distribution**.

CUMULATIVE PROBABILITY FUNCTION. See **distribution**.

CURIE. A unit of radioactivity which was originally defined as the amount of emanation (radon) from or in equilibrium with one gram

of radium. Because of experimental uncertainties this unit has been redefined by the revised recommendations of the International Commission on Radiological Units (July, 1953) as follows: "The curie is a unit of radioactivity defined as the quantity of any radioactive nuclide in which the number of disintegrations per second is 3.700×10^{10} ."

CURIE EQUATION. See **Curie-Weiss law**.

CURIE LAW. See **Curie-Weiss law**.

CURIE POINT. The temperature of the ferromagnetic-paramagnetic change defined in the Curie-Weiss law. By analogy, the term is also used for the **transition temperature** of any **cooperative phenomenon**, such as that exhibited by ferroelectric substances.

CRYSTAL SYSTEMS

Systems	Crystallographic Elements	Essential Symmetry	Number of Point Groups
Cubic, or regular	Three axes at right angles: all equal. $\alpha = \beta = \gamma = 90^\circ$ $a:b:c = 1:1:1$	4 triad axes; 3 diad, or 3 tetrad axes	5
Tetragonal	Three axes at right angles: two equal. $\alpha = \beta = \gamma = 90^\circ$ $a:b:c = 1:1:y$	1 tetrad axis	7
Orthorhombic or Rhombic	Three axes at right angles: unequal. $\alpha = \beta = \gamma = 90^\circ$ $a:b:c = x:1:y$	3 diad axes, or 1 diad axis and 2 perpendicular planes intersecting in a diad axis	3
Monoclinic	Three axes, one pair not at right angles: unequal. $\alpha = \gamma = 90^\circ$ $\beta \neq 90^\circ$ $a:b:c = x:1:y$	1 diad axis, or 1 plane	3
Triclinic or Anorthic	Three axes not at right angles: unequal. $\alpha, \beta, \gamma \neq 90^\circ$ $a:b:c = x:1:y$	No axes or planes	2
Hexagonal	Three axes coplanar at 60° : equal. Fourth axis at right angles to other three. $a_1:a_2:a_3:b = 1:1:1:x$	1 hexad axis	7
Rhombohedral or Trigonal	Three axes equally inclined, not at right angles: all equal. $\alpha = \beta = \gamma \neq 90^\circ$ $a:b:c = 1:1:1$	1 triad axis	5

CURIE SYMMETRY PRINCIPLES. See symmetry requirements in coupling of irreversible processes.

CURIE TEMPERATURE. See Curie point.

CURIE-WEISS LAW. The Curie law states that, above the Curie point θ the magnetic susceptibility of a paramagnetic substance is inversely proportional to the absolute temperature, the constant of proportionality being the Curie constant C' .

The Curie law was modified by Weiss to state that the susceptibility (χ) of a paramagnetic substance above the Curie point is inversely proportional to the temperature excess above that point, i.e.,

$$\chi = C'/(T - \theta).$$

The law does not hold near the melting point of a substance.

CURL. A vector resulting from the action of the operator **del** on a vector, **V**. It can be written in Cartesian coordinates in the following forms:

$$\begin{aligned} \text{curl } \mathbf{V} &= \nabla \times \mathbf{V} \\ &= \mathbf{i} \left\{ \frac{\partial V_z}{\partial y} - \frac{\partial V_y}{\partial z} \right\} + \mathbf{j} \left\{ \frac{\partial V_x}{\partial z} - \frac{\partial V_z}{\partial x} \right\} \\ &\quad + \mathbf{k} \left\{ \frac{\partial V_y}{\partial x} - \frac{\partial V_x}{\partial y} \right\} \\ &= \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ \partial/\partial x & \partial/\partial y & \partial/\partial z \\ V_x & V_y & V_z \end{vmatrix}. \end{aligned}$$

The curl of a position vector is $\mathbf{3}$, $\mathbf{R} = \mathbf{i}x + \mathbf{j}y + \mathbf{k}z$, $\nabla \times \mathbf{R} = \mathbf{3}$.

If the curl of a vector function vanishes everywhere in a certain region, the function is said to be an irrotational vector (or a lamellar vector), in this region. It follows that if \mathbf{V} is an irrotational vector so that $\nabla \times \mathbf{V} = 0$, then $\mathbf{V} = \nabla\phi$ (\mathbf{V} is the gradient of ϕ), where ϕ is some scalar function.

European writers often use the word rotation instead of curl and the symbol **rot V**.

CURRENT. (1) The term usually refers to an electric current, which is the time rate of flow of electric charge across a surface (see **current, electric**). (2) The term is also used for the time rate of flow of other physical quantities such as mass, quantum mechanical

probability, etc. (See **continuity equations; current density**.)

CURRENT, AVERAGE. The average value of a current (I) over a time interval (t_1, t_2) is

$$\langle I \rangle = \frac{1}{t_2 - t_1} \int_{t_1}^{t_2} I dt.$$

CURRENT, BEAM. The current carried by a beam of charged particles such as positive ions or electrons, e.g., the proton current in a high energy accelerator. The beam current I is given by $I = zNe$ where z is the number of electronic charges (e) carried by the ion and N is the number of ions crossing a plane, perpendicular to the direction of flow, per unit time. The beam current density, the time rate at which charges cross a unit area perpendicular to their velocity is $znev$, where n is the number of particles per unit volume and v is their velocity.

CURRENT, CONDUCTION. Electric current consisting of the flow of free charges, as distinct from **displacement current**.

CURRENT DENSITY. (1) A vector representing the time rate of flow of electric charge per unit area. The direction of the vector is the direction of positive charge flow; the magnitude is the limit of the flow rate per unit area as the area approaches zero. The area considered is perpendicular to the direction of flow. (2) In nuclear physics, a vector such that its component along the normal to a surface equals the net number of particles crossing that surface per unit area and unit time. Commonly referred to simply as current, as in neutron current. (3) By analogy with electric current, a vector representing the time rate of flow of any quantity such as mass or momentum, per unit area in a transport process.

CURRENT DENSITY, DISPLACEMENT.

In a volume distribution of steady current in space, the **current density j** is everywhere solenoidal, i.e., $\nabla \cdot \mathbf{j} = 0$. For time-varying phenomena, the **conduction current density, j**, must satisfy the **continuity equation**, $\nabla \cdot \mathbf{j} + \frac{\partial \rho}{\partial t} = 0$, where ρ is the **electric charge density**. ρ is related to the **electric displacement vector, D**, by the equation

$\nabla \cdot \mathbf{D} = \rho$ (see **Maxwell equations**). The continuity equation then becomes

$$\nabla \cdot \left(\mathbf{j} + \frac{\partial \mathbf{D}}{\partial t} \right) = 0$$

where $\frac{\partial \mathbf{D}}{\partial t}$ is called the **displacement current density**. The sum of the conduction current density and the displacement current density is therefore everywhere solenoidal even when currents and fields vary with time.

In a dielectric \mathbf{D} may be written $\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P}$, where \mathbf{P} is the **polarization** (see **electric displacement vector**). The displacement current density can therefore be written in two parts

$$\frac{\partial \mathbf{D}}{\partial t} = \epsilon_0 \frac{\partial \mathbf{E}}{\partial t} + \frac{\partial \mathbf{P}}{\partial t}.$$

The first member is called the *vacuum displacement current density* and does not have the significance of a current in the sense of being the motion of charges. The second term is called the *polarization current density* and corresponds to the actual motion of charge within the dielectric.

CURRENT DENSITY, POLARIZATION. See discussion under **current density, displacement**.

CURRENT, EDDY. Any change of magnetic flux in a conducting medium induces an **electromotive force** which causes currents to flow in the medium. (See **Faraday law of electromagnetic induction**.) Currents generated in this way are called eddy currents, and contribute to the power losses in conductors, conductive shields and magnetic cores.

CURRENT, ELECTRIC. Broadly, the flow of electric charge. More specifically, the time rate at which charge crosses a given surface is the current across the surface. There are actually three types of current: conduction current, convection current, and displacement current. Conduction current is due to the motion of charges in a neutral system (as electrons in a conductor, or the motion of electrons and "holes," which contribute largely to the current in semiconductors); convection current is due to the motion of unneutralized charge, as the motion of electrons in a vacuum tube; displacement current is an effect of a changing electric flux. Current is a scalar.

The current through a specified surface is given by the integral over that surface of the normal component of **current density**. In loose usage, we often speak of the direction of a current; actually, being a scalar, current has a sense (plus or minus) but not a direction. The positive sense of a current is conventionally taken as the direction in which positive charges would move if they were the carriers of the current. In metals, where the current is actually carried by negative electrons, the flow of electrons is opposite to the positive direction of the current. E.g., one coulomb of negative charge passing to the left per second is one ampere of (positive) current to the right.

CURRENT (OR STREAM) FUNCTION.

The stream or current function is a scalar function of position used to describe steady two-dimensional flow of an incompressible fluid. The current function, ψ , is defined by

$$u = \frac{\partial \psi}{\partial y}, \quad v = -\frac{\partial \psi}{\partial x}$$

where u, v are the components of the velocity parallel to Ox, Oy . It will be noticed that the flow across any line from the point A to the point B is

$$\begin{aligned} \int_A^B (udy - vdx) &= \int_A^B \nabla \psi \cdot d\mathbf{s} \\ &= \psi_B - \psi_A. \end{aligned}$$

CURRENT, NEUTRON. The total neutron current is the vector quantity:

$$\mathbf{J}(r, t) = \int_0^\infty dE \int d\hat{\Omega} \hat{\Omega} N(r, E, \hat{\Omega}, t) v,$$

where the quantities appearing in the integral are defined under **flux, neutron, angular**. The current of neutrons of energy E is:

$$\mathbf{J}(r, E, t) = \int d\hat{\Omega} \hat{\Omega} N(r, E, \hat{\Omega}, t) v.$$

CURRENT, NOISE, EQUIVALENT. A quantitative representation in current units of the spectral density of a noise-current generator at a specified frequency. The relation between the equivalent noise current I_n and the spectral density W_i of the noise-current generator is

$$I_n = (2\pi W_i)/e$$

where e is the magnitude of the electronic charge. The equivalent noise current in terms of the mean square noise-generator current \bar{i}^2 within a frequency increment Δf is

$$I_n = \bar{i}^2 / (2e\Delta f).$$

CURRENT, PROBABILITY. In wave mechanics, the probability of finding a particle at a given point is given by a **probability density**. The change in time of this probability density is given by the divergence of a current. In the case of a single particle described by a Schrödinger wave function $\psi(x,y,z)$, the probability density is $|\psi(x,y,z)|^2$, and the expression of the probability current is given by

$$\frac{\hbar}{2mi} (\psi^* \text{grad } \psi - \psi \text{grad } \psi^*),$$

where ψ^* is the conjugate complex of ψ , m is the mass of the particle, and $\hbar = h/2\pi$, h being Planck's constant.

CURRENT SHEET. An infinitely thin sheet carrying finite current per unit length normal to the lines of flow. This current may be either electric or magnetic. (See **magnetic current**.)

CURRENT SOURCE, IDEAL. An energy source that provides at a given terminal-pair (port), a current function that is independent of the voltage at that terminal-pair (port). An ideal current source is idle when its environment is a short circuit.

CURVATURE. The curvature κ of a plane curve $y = f(x)$ at a point x_0, y_0 on the curve is defined as the rate of change of the inclination of the tangent to the curve with respect to arc length. Thus

$$\kappa = \frac{d}{ds} \text{arc tan } y',$$

or in Cartesian coordinates

$$\kappa = y''(1 + y'^2)^{-3/2}.$$

The reciprocal $1/\kappa$ of the curvature is called the *radius of curvature*. The circle with this radius, with center on the normal, and passing through x_0, y_0 is called the *circle of curvature*, or the *osculating circle*, and its center is the *center of curvature*, while the plane in which it lies is called the *plane of curvature* or the

osculating plane. The curvature of a curve in three dimensional space is the rate of change of direction of the tangent with respect to arc length, and the *torsion* (also called second curvature) is the corresponding rate of change of direction of the **binormal**. The *principal curvatures of a surface* are the maximum and the minimum of the normal curvatures (i.e., curvatures of normal sections of the surface). The product and the sum of the principal curvatures are called the *total curvature* and the *mean curvature*, respectively, of the surface at the given point. The mean value of the principle curvatures is the *mean normal curvature* at the point. The total curvature is also called the *specific curvature* or the *Gauss curvature*. The mean curvature is also called the *first curvature* or the *circular curvature*. The *amplitude of normal curvature* is half the difference between the two principal curvatures. (See also **curvature of surface, center of**.)

CURVATURE, ANTICLASTIC. Longitudinal strain in a beam is accompanied by strain of opposite sign. Therefore curvature of longitudinal fibers produces transverse curvature of opposite sign (saddle surface) known as anticlastic curvature. The ratio of the curvatures is the ratio of the strains when the beam is narrow and is given by **Poisson's ratio**. When the beam is wide, the anticlastic curvature is constrained and the beam is stiffer.

CURVATURE, EULER THEOREM ON NORMAL. See **Euler theorem on normal curvature**.

CURVATURE, GEODESIC. See **geodesic curvature**.

CURVATURE, INFLUENCE OF. See **chemical potential, influence of curvature on**; and **vapor pressure, influence of curvature on**.

CURVATURE, NORMAL. See **normal curvature**.

CURVATURE OF BEAM. The curvature of the line of centroids of the cross section of the beam. When bending is in a single plane x,y and the beam is initially straight, the curvature usually is approximated by

$$\frac{d^2y}{dx^2}$$

as the square of the slope generally is small compared with unity.

CURVATURE OF FIELD. One of the five **Seidel geometrical aberrations** of lenses. If a system is corrected so that there is no spherical aberration, no coma, and no astigmatism, the third order theory images of off-axis points will lie on a curved surface called the **Petzval surface**.

CURVATURE OF LENS, TOTAL. A lens with spherical surfaces of radii r_1, r_2 has total curvature

$$K = \frac{1}{r_1} - \frac{1}{r_2}$$

where an appropriate sign convention is used, such as $r_1 > 0$ if the center of curvature is to the right of the vertex (axial intersection of the surface). Thus for a thin lens, the power is

$$\frac{1}{f} = (n - 1)K$$

where n is the relative index of refraction and f the focal length.

CURVATURE (GAUSSIAN) OF SPACE-TIME. $G = g^{\mu\nu}G_{\mu\nu}$ where $g^{\mu\nu}$ are the contravariant metric components and $G_{\mu\nu}$ is the **contracted Riemann-Christoffel tensor**. The vanishing of G does not imply that space-time is flat.

CURVATURE OF SURFACE, CENTER OF (FOR A POINT). Let P and Q be two points on a line of curvature on the surface. As Q approaches P , the normal to the surface at Q intersects that at P and the point of intersection is called a *center of curvature of the surface* for the point P . For each point on the surface there are, in general, two centers of curvature, corresponding to the two lines of curvature through the point. The distance of a center of curvature from P , measured in the direction of the unit normal at P , is called a (*principal*) *radius of curvature* of the surface at P . There are, in general, two radii of curvature to a surface at each point. The inverse of a radius of curvature of the surface at P is called a *principal curvature of the surface* at P .

CURVATURE, PRINCIPAL DIRECTIONS OF. See **principal directions of curvature**.

CURVATURE, RELATIVE. See **relative curvature**.

CURVATURE, SCALAR. See **scalar curvature**.

CURVATURE, SCREW (OF A CURVE AT A POINT). The magnitude of $d\mathbf{n}/ds$, where \mathbf{n} denotes the unit normal and s the distance measured along the curve from a fixed point.

$$d\mathbf{n}/ds = \sqrt{\kappa^2 + \tau^2},$$

where κ and τ are the **curvature** and **torsion** of the curve at the point.

CURVATURE, SPHERE OF. See **sphere of curvature**.

CURVATURE, SPHERICAL. See **sphere of curvature**.

CURVATURE, SURFACE OF NEGATIVE TOTAL. See **anticlasic surface**.

CURVATURE, TANGENTIAL. See **geodesic curvature**.

CURVATURE TENSOR. In each coordinate system x we define B^i_{ajk} by

$$B^i_{ajk} = \frac{\partial \Gamma^i_{aj}}{\partial x^k} - \frac{\partial \Gamma^i_{ak}}{\partial x^j} + \Gamma^b_{aj}\Gamma^i_{bk} - \Gamma^b_{ak}\Gamma^i_{bj},$$

where Γ^i_{jk} is the **Christoffel three-index symbol** of the second kind. The aggregate of quantities B^i_{ajk} so defined form a **tensor field**, contravariant of order one and covariant of order two, which is called the **curvature tensor**. Also sometimes referred to as the *Riemann-Christoffel tensor*, or *Riemann-Christoffel tensor of the second kind*, or *mixed Riemann-Christoffel tensor*.

CURVATURE, VECTOR. See **vector curvature**.

CURVE. For the purposes of applied mathematics, a curve in n -dimensional Euclidean space may be most conveniently defined as the locus of a point moving with one degree of freedom; that is, its path is defined with the aid of one parameter, $x_1 = x_1(t)$, $x_2 = x_2(t)$, \dots , $x_n = x_n(t)$, with $a \leq t \leq b$. If $x_1(a) = x_1(b)$, $x_2(a) = x_2(b)$, \dots , $x_n(a) = x_n(b)$, the curve is *closed*. If, with this possible exception, distinct values of t produce distinct points, the curve is *simple*. If the total length of an inscribed polygonal line approaches a finite limit as the length of each side approaches zero, the curve is *rectifiable*.

CURVE, CENTER OF. See **centroid** (of a geometrical figure).

CURVED BEAM. See **beam, curved**.

CURVED TUBES. See **tubes, curved**.

CURVE FITTING. Suppose that a physical variable y is known to bear a particular functional relation to another variable x :

$$y = f(x; \alpha, \beta, \dots),$$

where the form of f is known, but where f contains certain parameters α, β, \dots , that are unknown. Thus in radioactive decay the amount of a constituent is known to be an exponential function of time, $y = \alpha \exp(-\beta t)$, where t takes the place of the above x . If it is possible to measure the y associated with any x , one can make a series of measurements, x_i, y_i , and hope to solve the equations

$$y_i = f(x_i; \alpha, \beta, \dots)$$

for the parameters. Since, in general, the measurements will be subject to error one must make more measurements than there are parameters, and since the equations will then be inconsistent, in general, it is necessary to establish some criterion for making the "best" selection of the parameters so that, in some sense, all equations are satisfied as nearly as possible, even though possibly none is satisfied exactly.

A possible criterion is the **minimax approximation**: to select the parameters so as to minimize the greatest of the quantities

$$|y_i - f(x_i; \alpha, \beta, \dots)|.$$

This is sometimes used, but is very difficult computationally in most cases. Sometimes one resorts to trial and error, with visual inspection of the graphs. The method of **least squares** can often be justified on grounds of probability, and usually leads to the simplest computations.

The same mathematical problem arises when a known function $\phi(x)$ is to be approximated in some fashion by a simpler one. For this purpose **interpolation** is the most usual method of procedure.

Sometimes one has only the empirical measurements x_i, y_i , but no theory to prescribe a particular functional form $f(x, \dots)$. In that case one can only apply intuition, and possibly trial and error, in selecting a convenient form.

(See **smoothing**.) (See Leo Nielsen Kaj, *Methods in Numerical Analysis*, Macmillan, 1956.)

CURVE, INTRINSIC EQUATIONS OF. A curve can be completely specified, apart from a rigid motion, by specifying the dependence of the **curvature** and **torsion** on the distance measured along the curve from a fixed point. The equations expressing this dependence are called the *intrinsic equations of the curve*.

CURVE, LOXODROMIC. See **loxodrome**.

CURVE, SKEW. See **twisted curve**.

CURVE, SPACE. See **space curve**.

CURVES, SYSTEM OF CONJUGATE. See **conjugate system of curves on a surface**.

CURVE, TWISTED. See **twisted curve**.

CURVILINEAR CONGRUENCE. See **congruence of curves**.

CURVILINEAR MOTION. Unless the resultant force \mathbf{F} on a particle of mass m is constant in direction and the velocity of the particle is initially in the same direction, curvilinear motion results. Sometimes it is convenient to write Newton's second law (as for the motion of a particle of mass m in a plane) $\mathbf{F} = m\mathbf{a} = m\ddot{\mathbf{r}}$ in Cartesian form $F_x = m\ddot{x}$, $F_y = m\ddot{y}$, $F_z = m\ddot{z}$, where the two dots denote the second derivative with respect to time. Often it is better to use intrinsic coordinates (see **acceleration**) and write $\mathbf{F} = m\mathbf{a}_t + m\mathbf{a}_n = m \frac{dv}{dt} \mathbf{T} + m \frac{v^2}{r} \mathbf{N}$, where \mathbf{T} and \mathbf{N} are unit vectors along the tangent and inward normal, respectively.

CURVILINEAR ORTHOGONAL COORDINATES. A curvilinear system of coordinates α, β, γ is generated by a system of three mutually orthogonal families of surfaces $\alpha = \text{constant}$, $\beta = \text{constant}$, $\gamma = \text{constant}$. It is assumed that the unit tangent vectors $\mathbf{a}, \mathbf{b}, \mathbf{c}$ along the coordinate curves form everywhere a right-handed system, i.e., $\mathbf{a} \times \mathbf{b} = \mathbf{c}$.

An infinitesimal line vector $d\mathbf{l}$ is given by the expression

$$d\mathbf{l} = \mathbf{a}M d\alpha + \mathbf{b}N d\beta + \mathbf{c}P d\gamma.$$

A volume element dV is given by

$$dV = MNP d\alpha d\beta d\gamma.$$

A vector surface element whose normal is along the \mathbf{a} direction is given by

$$d\mathbf{S} = \mathbf{a}NPd\beta d\gamma.$$

The unit vectors \mathbf{a} , \mathbf{b} , \mathbf{c} are, of course, not constant. Their derivatives are:

$$\frac{\partial \mathbf{a}}{\partial \alpha} = -\frac{\mathbf{b}}{N} \frac{\partial M}{\partial \beta} - \frac{\mathbf{c}}{P} \frac{\partial M}{\partial \gamma}; \quad \frac{\partial \mathbf{b}}{\partial \alpha} = \frac{\mathbf{a}}{N} \frac{\partial M}{\partial \beta};$$

$$\frac{\partial \mathbf{c}}{\partial \alpha} = \frac{\mathbf{a}}{P} \frac{\partial M}{\partial \gamma};$$

$$\frac{\partial \mathbf{a}}{\partial \beta} = \frac{\mathbf{b}}{M} \frac{\partial N}{\partial \alpha}; \quad \frac{\partial \mathbf{b}}{\partial \beta} = -\frac{\mathbf{a}}{M} \frac{\partial N}{\partial \alpha} - \frac{\mathbf{c}}{P} \frac{\partial N}{\partial \gamma};$$

$$\frac{\partial \mathbf{c}}{\partial \beta} = \frac{\mathbf{b}}{P} \frac{\partial N}{\partial \gamma};$$

$$\frac{\partial \mathbf{a}}{\partial \gamma} = \frac{\mathbf{c}}{M} \frac{\partial P}{\partial \alpha}; \quad \frac{\partial \mathbf{b}}{\partial \gamma} = \frac{\mathbf{c}}{N} \frac{\partial P}{\partial \beta};$$

$$\frac{\partial \mathbf{c}}{\partial \gamma} = -\frac{\mathbf{a}}{M} \frac{\partial P}{\partial \alpha} - \frac{\mathbf{b}}{N} \frac{\partial P}{\partial \beta}.$$

The vector differential operator is defined by

$$\nabla = \frac{\mathbf{a}}{M} \frac{\partial}{\partial \alpha} + \frac{\mathbf{b}}{N} \frac{\partial}{\partial \beta} + \frac{\mathbf{c}}{P} \frac{\partial}{\partial \gamma}$$

$$\nabla \cdot \mathbf{A} = \text{div } \mathbf{A} = \frac{1}{MNP} \left\{ \frac{\partial(A_1NP)}{\partial \alpha} + \frac{\partial(A_2PM)}{\partial \beta} + \frac{\partial(A_3MN)}{\partial \gamma} \right\}$$

$$\nabla \times \mathbf{A} = \text{curl } \mathbf{A} = \frac{\mathbf{a}}{NP} \left\{ \frac{\partial(PA_3)}{\partial \beta} - \frac{\partial(NA_2)}{\partial \gamma} \right\}$$

$$+ \frac{\mathbf{b}}{PM} \left\{ \frac{\partial(MA_1)}{\partial \gamma} - \frac{\partial(PA_3)}{\partial \alpha} \right\}$$

$$+ \frac{\mathbf{c}}{MN} \left\{ \frac{\partial(NA_2)}{\partial \alpha} - \frac{\partial(MA_1)}{\partial \beta} \right\}$$

$$\nabla f = \text{grad } f = \frac{\mathbf{a}}{M} \frac{\partial f}{\partial \alpha} + \frac{\mathbf{b}}{N} \frac{\partial f}{\partial \beta} + \frac{\mathbf{c}}{P} \frac{\partial f}{\partial \gamma}$$

$$\nabla^2 f = \frac{1}{MNP} \left\{ \frac{\partial \left(\frac{NP}{M} \frac{\partial f}{\partial \alpha} \right)}{\partial \alpha} + \frac{\partial \left(\frac{PM}{N} \frac{\partial f}{\partial \beta} \right)}{\partial \beta} \right.$$

$$\left. + \frac{\partial \left(\frac{MN}{P} \frac{\partial f}{\partial \gamma} \right)}{\partial \gamma} \right\}.$$

The operator $\mathbf{A} \cdot \nabla$ is defined by

$$\mathbf{A} \cdot \nabla = \frac{A_1}{M} \frac{\partial}{\partial \alpha} + \frac{A_2}{N} \frac{\partial}{\partial \beta} + \frac{A_3}{P} \frac{\partial}{\partial \gamma}.$$

Examples:

(1) Cartesian coordinates $M = N = P = 1$;
 $\alpha = x$; $\beta = y$; $\gamma = z$.

(2) Cylindrical coordinates $\alpha = r$; $\beta = \phi$;

$\gamma = z$; $M = 1$; $N = r$; $P = 1$; $\frac{\partial \mathbf{a}}{\partial \phi} = \mathbf{b}$;

$$\frac{\partial \mathbf{b}}{\partial \phi} = -\mathbf{a}.$$

(3) Spherical coordinates $\alpha = \phi$; $\beta = \theta$; $\gamma = r$;

$M = r$; $N = r \sin \phi$; $P = 1$; $\frac{\partial \mathbf{a}}{\partial \phi} = -\mathbf{c}$;

$$\frac{\partial \mathbf{c}}{\partial \phi} = \mathbf{a}; \quad \frac{\partial \mathbf{a}}{\partial \theta} = \mathbf{b} \cos \phi; \quad \frac{\partial \mathbf{b}}{\partial \theta} = -\mathbf{c} \sin \phi - \mathbf{a}$$

$$\cos \phi; \quad \frac{\partial \mathbf{c}}{\partial \theta} = \mathbf{b} \sin \phi.$$

If a vector field \mathbf{A} satisfies the condition

$$\mathbf{A} \cdot \text{curl } \mathbf{A} \equiv 0,$$

it is possible to construct a family of surfaces that is everywhere perpendicular to the vector lines \mathbf{A} . It is therefore possible to choose these surfaces as the family $\gamma = \text{constant}$ and the \mathbf{A} lines themselves as the coordinate lines perpendicular to this family, i.e., $\mathbf{A} \equiv \mathbf{c}A_3$ ($|\mathbf{A}| = |A_3|$)

$$A_1 = A_2 \equiv 0.$$

Let an element of arc length along the \mathbf{A} -lines be denoted by dl and R_1 and R_2 be the principal radii of curvature of a surface element perpendicular to \mathbf{c} . Then

$$\text{div } \mathbf{A} = \frac{\partial A_3}{\partial l} + A_3 \left(\frac{1}{R_1} + \frac{1}{R_2} \right).$$

If $\mathbf{A} = \text{grad } f$, then

$$A_3 = \frac{\partial f}{\partial l}$$

and

$$\text{div } \mathbf{A} = \nabla^2 f = \frac{\partial^2 f}{\partial l^2} + \frac{\partial f}{\partial l} \left(\frac{1}{R_1} + \frac{1}{R_2} \right)$$

and

$$\text{curl } \mathbf{A} = |\mathbf{A}|k\mathbf{B} - [\mathbf{T} \times \text{grad } |\mathbf{A}|]$$

where k is the curvature of \mathbf{A} lines

\mathbf{T} is the unit tangent vector along \mathbf{A} lines

\mathbf{B} is the binormal-unit vector of the \mathbf{A} lines.

CUSP. A **singular point** on a curve where there are two coincident tangents. If there is a branch of the curve on each side of the double tangent, the cusp is of the first kind (e.g., the **semicubical parabola**); if the two branches lie on the same side of the double tangent, the cusp is of the second kind. If the curve is represented by $f(x,y) = 0$, the condition for a cusp, and also for a point of osculation, is

$$\left(\frac{\partial^2 f}{\partial x \partial y}\right)^2 - \frac{\partial^2 f}{\partial x^2} \frac{\partial^2 f}{\partial y^2} = 0.$$

CUT-OFF. (1) In a reciprocating steam engine, the point at which the supply of steam to the cylinder is arrested. (2) In a **diesel engine**, the point at which fuel injection ceases. Ideally, combustion also ceases at this point. It is measured by the *cut-off ratio*

$$\rho = \frac{V_c + V_i}{V_c}$$

where V_c is the volume at the end of compression, V_i the volume increase due to combustion, and hence $V_c + V_i$ is the volume at fuel cut-off.

CUT-OFF FREQUENCY. (1) Of a wave filter, the frequency at which the attenuation begins to increase sharply. (2) For a given characteristic field configuration (mode) in a non-dissipative waveguide, the frequency below which the **propagation constant** becomes real.

CUT-OFF RATIO. See *cut-off*; **diesel engine**.

CUT SET. In the theory of **linear graphs** the concept of a cut set is almost as important as that of a **tree**. A cut set of a connected graph G is a set of **edges** such that the deletion of these edges reduces the **rank** of G by one. Moreover, no proper subset of this set possesses this property.

Clearly, the removal of the cut set of edges must yield an unconnected graph (see **graph, connected**) since the number of vertices v is invariant and $\text{rank } G = v - 1$. Thus by "cutting" this set of edges the graph is separated into two pieces. One of the pieces can be an isolated vertex. This latter case occurs for example if all the edges incident at a vertex are removed. As a matter of fact, the totality of edges incident at a given vertex is a cut set if and only if the vertex is not a **cut vertex**.

Another and deeper characterization of a cut set is as a minimal set of **elements** which contains at least one **branch** from every **tree**. Again, a single non-circuit element constitutes a cut set whereas a single **circuit** element does not.

CUT SET MATRIX. The cut set matrix $Q_a = (q_{ij})$ of a *directed graph* G is defined in the following manner:

- (a) Q_a has one row for each cut set of the graph and one column for each **edge**;
- (b) $q_{ij} = 1$ if edge j is in cut set i and the orientations agree (see **cut set, oriented**);
- (c) $q_{ij} = -1$ if edge j is in cut set i and the orientations disagree;
- (d) $q_{ij} = 0$ if edge j is not in cut set i .

The rank of Q_a is $v - 1$, v denoting the number of vertices in G .

The cut set matrix Q_a and **vertex matrix** A_a are rather intimately related. For example:

- (1) If G is **non-separable**, Q_a contains A_a (with some rows possibly multiplied by -1) as a submatrix.
- (2) If Q is a cut set matrix of $v - 1$ rows and rank $v - 1$ of a connected directed graph G of v vertices and A the vertex matrix of G ,

$$Q = DA$$

where D is non-singular.

- (3) Under the same restrictions as in 2, the non-singular submatrices of Q of order $v - 1$ are in one-to-one correspondence with the **trees** of G . That is to say, each such submatrix is the *fundamental cut set matrix* of some tree. Conversely, any fundamental cut set matrix appears as a submatrix of Q .

CUT SET, ORIENTED. Let G be a linear connected graph. (See **graph, connected**.) The removal of a **cut set** of edges decomposes G into two connected pieces A and B . The cut set is oriented by ordering A and B either as (A, B) or (B, A) . Each **element** of the cut set must have one vertex in A and one vertex in B . Suppose the cut set is oriented as (A, B) . Then, an oriented element of the cut set is said to have the same orientation as the cut set if it is directed away from its vertex in A and toward its vertex in B .

CUT SETS, FUNDAMENTAL. Suppose G is a linear connected graph (see **graph, connected**) possessing v vertices and T is one of its trees. Each cut set of G must contain at least one branch of T . Those $v - 1$ cut sets of G which include exactly one branch of T are said to be fundamental with respect to T . The orientation of a fundamental cut set of a directed graph (see **digraph**) is usually chosen to agree with that of the defining branch.

CUT VERTEX. See **vertex, cut**.

CYCLE. (1) The complete sequence of values of a periodic quantity which occur during a period. (2) A series of changes or processes executed in orderly sequence, by means of which a mechanism, a working substance, or a system is caused periodically to return to the same initial state. In particular consider a (closed) thermodynamic system, represented by the cycle

$$\oint dQ = \oint dW.$$

A cycle is represented by a closed (but not necessarily continuous) curve in a thermodynamic diagram. When $\oint dW$ is positive, the cycle produces work at the expense of heat. It is then called a *forward* or *power cycle*. When $\oint dW$ is negative, the cycle consumes work; it can then be used as a refrigerator or a heat pump; it is called a *reversed cycle*.

The *thermal efficiency* of a power cycle is defined as the ratio of the work produced $W =$

$\oint dW$ to the positive heat added to the cycle,

$Q \neq \oint dQ$ but $Q = \int (dQ)_{pos}$. Hence

$$\eta = \frac{W}{Q}.$$

If the total amount of heat $\oint dQ$ is represented as

$$\oint dQ = Q - Q_o, \quad Q_o > 0, \text{ is the sum of negative heats,}$$

we have

$$W = Q - Q_o$$

and

$$\eta = 1 - \frac{Q_o}{Q}.$$

The operation of a reversed cycle is described by the coefficient of performance

$$e = \frac{Q_o}{W}$$

when it is used for refrigeration. The quantity of heat Q_o absorbed by the reversed (refrigerating) cycle is known as the *refrigerating effect*. In the case of a heat pump no generally accepted single coefficient describing its efficiency is available.

CYCLE, MAJOR. In a storage device which provides serial access to storage positions, the time interval between successive appearances of a given storage position.

CYCLE, MINOR. In a storage device which provides serial access to storage positions, the time interval between the appearance of corresponding parts of successive words.

CYCLE OF STRESS. The stress variation on a particular plane through a specific point in a body which is subjected to a repeated load is called a cycle of stress. If the stress varies alternately between **tension** and **compression**, the variation is known as reversal of stress. The reversal is complete when the alternate stresses are equal in magnitude.

The algebraic difference between the maximum and minimum stresses of a cycle is the range of stress. The endurance limit depends on the range of stress.

CYCLE, THERMAL EFFICIENCY OF. See **thermal efficiency of cycle**.

CYCLIC. See **permutation; group**.

CYCLING. A periodic change of the controlled variable in an automatic controller.

CYCLOID. A cycloid is the plane curve traced by the motion of a point fixed on the circumference of a rolling wheel. If the wheel turns at the rate of one radian per minute, then the equations of the cycloid, using the time t as a parameter, are

$$x = a(t - \sin t), \quad y = a(1 - \cos t),$$

where a is the radius of the wheel. (See also **brachistochrone**.)

The teeth of gears are often cut with faces which are arcs of cycloids, so that there is rolling contact where the gears are in mesh.

CYCLOMATIC NUMBER. The same as the nullity of a graph.

CYCLONIC MOTION. Circulatory motion relative to the earth in the direction of the vertical component of the earth's rotation; anticlockwise when viewed from above in the northern hemisphere. Such motion is produced in the atmosphere by horizontal convergence in air at rest, the vortex lines being stretched vertically.

CYCLONIC VORTICITY. Vorticity relative to the earth in a cyclonic direction, i.e., in the direction of the vertical component of the earth's rotation.

CYCLOSTROPHIC FLOW. A form of gradient flow in which the centripetal acceleration exactly balances the horizontal pressure force. (See **cyclostrophic wind**.)

CYCLOSTROPHIC FORCE. The centrifugal force due to the curvature of the path of the air over the earth's surface. (See **gradient wind**.)

CYCLOSTROPHIC WIND. That horizontal wind velocity for which the centripetal acceleration exactly balances the horizontal pressure force:

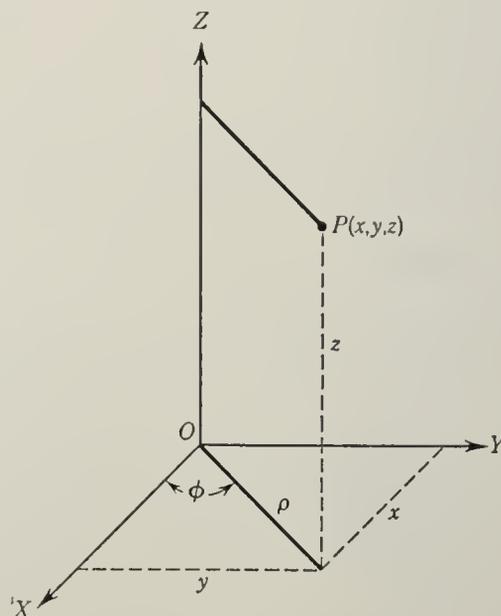

$$\frac{V_c^2}{R} = -\alpha \frac{\partial p}{\partial n}$$

where V_c is the cyclostrophic wind speed, R the radius of curvature of the path, α the specific volume, p the pressure, and n the direction normal to the streamlines toward the center of curvature of the path.

The cyclostrophic wind can be an approximation to the real wind in the atmosphere only near the equator, where the Coriolis acceleration is small; or in cases of very great wind speed and curvature of the path, so that the centripetal acceleration is the dominant one. (See **Eulerian wind**.)

CYLINDRICAL COORDINATES. A curvilinear system ρ, ϕ, z , whose coordinate surfaces

consist of: right-circular cylindrical surfaces based on circles about the origin in the XY -plane ($\rho = \text{const.}$); half-planes from the Z -

Cylindrical coordinates.

axis ($\phi = \text{const.}$); planes parallel to the XY -plane ($z = \text{const.}$). The position of a point in this system is given by (ρ, ϕ, z) where

$$x = \rho \cos \phi; \quad y = \rho \sin \phi; \quad z = z.$$

More precisely the system should be called circular cylindrical, because *elliptic* and *parabolic* cylindrical coordinates are also used. For example, elliptic cylindrical coordinates are defined as follows. Consider the equations

$$\frac{x^2}{a^2 \cosh^2 u} + \frac{y^2}{a^2 \sinh^2 u} = 1$$

$$\frac{x}{a^2 \cos^2 v} - \frac{y^2}{a^2 \sin^2 v} = 1.$$

Elliptic cylindrical coordinates are then defined by the three systems of coordinate surfaces: elliptic cylinders, given by $u = \text{const.}$; hyperbolic cylinders, given by $v = \text{const.}$; planes parallel to the xy -plane.

CYLINDRICAL FUNCTION. Synonym of **Bessel function**.

D

D'ALEMBERTIAN. Analogous to the differential operator del in ordinary **vector** analysis, a four-dimensional operator called **quad**, and denoted by the symbol \square , has components $\partial/\partial x_i$. The contracted second-order **derivative** of a scalar function ϕ can then be written $\square^2\phi$. It is known as the d'Alembertian operator

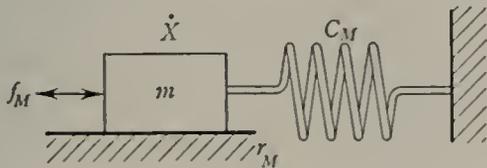

$$\square^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} - \frac{1}{c^2} \frac{\partial^2}{\partial t^2}$$

and it is thus similar to the **Laplacian** operator in three dimensions. The equation $\square^2\phi = 0$ is a wave equation for waves traveling with the velocity of light, c . The d'Alembertian is Lorentz invariant. (See also Minkowski's world in **relativity, special theory of**.)

D'ALEMBERT PARADOX. A hydrodynamical paradox arising from the neglect of viscosity. This paradox may be traced to the neglect of viscous forces, which are those responsible for fluid resistance by modifying the velocity field close to a solid body.

D'ALEMBERT PRINCIPLE. The equations of motion of the form $\mathbf{F} = m\mathbf{a}$, $M = I\alpha$, etc., may be written $\mathbf{F} - m\mathbf{a} = 0$, etc. If $-m\mathbf{a}$ is called an **inertia** or reversed **effective force**, the sum of the forces is zero. Dynamics is thus reduced to statics by the d'Alembert principle. The equal and opposite internal forces which appear in a system of particles need not be considered. (See **inertia forces**.)

D'ALEMBERT PRINCIPLE APPLIED TO A MECHANICAL RECTILINEAL SYSTEM OF ONE DEGREE OF FREEDOM. The differential equations for mechanical systems

may be set up employing the d'Alembert principle; namely, the algebraic sum of the forces applied to a body is zero. The mechan-

ical forces due to the elements in a mechanical rectilinear system are

Mechanomotive force of mass reaction

$$= -m \frac{d^2x}{dt^2} \quad (1)$$

Mechanomotive force of mechanical

$$\text{rectilinear resistance} = -r_M \frac{dx}{dt} \quad (2)$$

Mechanomotive force of mechanical

$$\text{compliance} = -\frac{x}{C_M} \quad (3)$$

In addition to the above mechanomotive forces are the mechanomotive forces applied externally.

The above principle may be used to derive the differential equation of the mechanical rectilinear system of the figure. From the d'Alembert principle the algebraic sum of the forces applied to a body is zero. The equation may be written

$$m \frac{d^2x}{dt^2} + r_M \frac{dx}{dt} + \frac{x}{C_M} = F_M e^{j\omega t} \quad (4)$$

where $f_M = F_M e^{j\omega t}$ is the external applied mechanical force.

Equation 4 is the same as Equation 8 of **mechanical system of one degree of freedom**.

D'ALEMBERT PRINCIPLE APPLIED TO A MECHANICAL ROTATIONAL SYSTEM OF ONE DEGREE OF FREEDOM. The differential equations for mechanical rotational systems may be set up by employing the **d'Alembert principle**; namely, the algebraic sum of the applied torques applied to a body is zero. The rotational mechanical forces due to the elements in a mechanical rotational system are

Rotatomotive force of moment

$$\text{of inertia reaction} = -I \frac{d^2\phi}{dt^2} \quad (1)$$

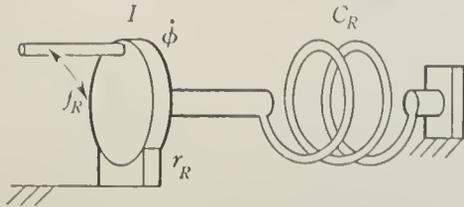

Rotatomotive force of mechanical

$$\text{rotational resistance} = -r_R \frac{d\phi}{dt} \quad (2)$$

Rotatomotive force of rotational compliance

$$= -\frac{\phi}{C_R} \quad (3)$$

In addition to the above rotatomotive forces are the rotatomotive forces applied externally.

Applying the d'Alembert principle the equation for the rotational system of the figure may be written

$$I \frac{d^2\phi}{dt^2} + r_R \frac{d\phi}{dt} + \frac{\phi}{C_R} = f_R \epsilon^{j\omega t} \quad (4)$$

where $f_R = f_R \epsilon^{j\omega t}$ is the external applied torque.

Equation 4 is the same as Equation 8 of mechanical rotational system of one degree of freedom.

D'ALEMBERT PRINCIPLE APPLIED TO AN ACOUSTICAL SYSTEM OF ONE DEGREE OF FREEDOM.

The differential equations for acoustical systems may be set up by employing the d'Alembert principle; namely, the algebraic sum of the applied pressures is zero. The acoustical pressures due to the elements in an acoustical system are

Acoustomotive force of inertive reaction

$$= -M \frac{d^2X}{dt^2} \quad (1)$$

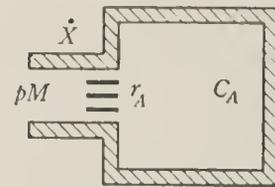

Acoustomotive force of acoustical resistance

$$= -r_A \frac{dX}{dt} \quad (2)$$

Acoustomotive force of acoustical capacitance

$$= -\frac{X}{C_A} \quad (3)$$

In addition to the above acoustomotive forces are the acoustomotive forces applied externally.

Applying the d'Alembert principle, the equation for the acoustical system of the figure may be written

$$M \frac{d^2X}{dt^2} + r_A \frac{dX}{dt} + \frac{X}{C_A} = P \epsilon^{j\omega t} \quad (4)$$

where $p = P \epsilon^{j\omega t}$ is the external applied pressure.

Equation 4 is the same as Equation 7 of acoustical system of one degree of freedom.

D'ALEMBERT TEST. If

$$\lim_{n \rightarrow \infty} |a_{n+1}/a_n| = r$$

and $r < 1$, the series

$$\sum_{n=1}^{\infty} a_n$$

converges; if $r > 1$, it diverges; if $r = 1$, the test fails and the series must be investigated in some other way (see convergence).

This test is often known as Cauchy's convergence test of the second kind but it was published by d'Alembert in 1768, seems to have been known to Waring in 1781, and was not given by Cauchy until 1821. It is essentially the same as the ratio test.

DALTON LAW. (Also known as the Gibbs-Dalton law.)

If a number of chemically inert gases are contained in the same space, each of them expands into the whole volume as if the other component were not present. The total pressure of the mixture is equal to the sum of the partial pressures of the individual gases. The partial pressure of an individual gas is that pressure which would prevail if it alone occupied the total volume.

The Dalton law has only asymptotic validity ($p \rightarrow 0$). Macroscopically, it can be considered an empirical law. Microscopically, it can be derived on the assumption that gases consist of point-like molecules which undergo perfectly elastic collisions but otherwise exert no force on each other.

In spite of its limited validity, the Dalton law forms the basis of all engineering calcula-

tions concerning gaseous mixtures, because more exact formulations are still lacking.

DAMPED VIBRATIONS. See **vibrations, damped.**

DAMPING. This term usually refers to the checking of a motion due to resistance, as by friction or similar cause. It is of especial significance in connection with the diminishing amplitude of an **oscillation**, as that of a pendulum swinging in the air, or that of the electricity vibrating in an oscillating circuit. Unless energy is supplied during each cycle, the amplitude of such a vibrator falls off at each successive oscillation by an amount commonly expressed in terms of the decrement, or *damping factor*, which is the ratio of any one amplitude to that next succeeding it in the same sense or direction.

In so-called *logarithmic damping*, this decrement is constant; in a simple oscillating electric circuit, the amplitude decays as $e^{-\delta t}$, where t is the time and δ , the logarithmic decrement, is a constant depending upon the effective resistance, inductance, and capacitance of the circuit. (See **electric oscillations and waves.**) An important instance of damping is found in the reading of an oscillating index, like a balance pointer, on a scale. If one may assume that the amplitude falls off by equal amounts at each swing (*linear damping*), in order to find the equilibrium position, one has only to average an even number of readings at one extreme and an odd number at the other, and then find the mean of the two averages. This linear damping assumption is an approximation to the relationship $e^{-\delta t} \doteq 1 - \delta t$ for small damping. (See **time-constant.**)

DAMPING, ACOUSTIC. When a sound wave travels through a medium it is attenuated by a number of different mechanisms. The four principal causes of attenuation are heat conduction, scattering, viscous friction, and elastic hysteresis. It is often difficult to separate the effects of viscous friction and elastic hysteresis, and the term internal friction is used to describe them jointly. (See **friction, internal.**)

DAMPING CAPACITY, SPECIFIC. See **specific damping capacity.**

DAMPING COEFFICIENT. See **oscillation, damped harmonic.**

DAMPING, CRITICAL. The value of **damping** of a single degree of freedom system above which free oscillatory motion ceases and the system has an asymptotic approach to equilibrium. In a system in which the variable x obeys the differential equation

$$a \frac{d^2x}{dt^2} + b \frac{dx}{dt} + cx = 0$$

the condition for critical damping is that

$$b = 2\sqrt{ac}.$$

DAMPING FACTOR. Defined in entry on **damping.**

DAMPING, LINEAR. Defined in entry on **damping.**

DAMPING, LOGARITHMIC. Defined in entry on **damping.**

DAMPING, OPTIMAL. That value of **damping**, with the damping ratio slightly less than unity, at which an indicating system such as a galvanometer will overshoot its final deflection by less than the desired uncertainty in reading the instrument. In general, optional damping results in faster readings than does critical damping, with no real loss in accuracy.

DAMPING RATIO. The ratio of the actual **damping** to the critical damping. (See **damping, critical.**)

DAMPING, STRUCTURAL. Damping caused by structural **impedance** in an oscillating mechanical system. It is expressed by the relationship:

$$C = \frac{F}{e_F} \left(\frac{X_F}{X_o} \right)^2 = 2 \frac{c}{c_c}$$

where c is the damping coefficient, c_c is the critical damping coefficient, F is the force, e_F is the velocity of the force, X_F is the displacement of the force, X_o is the zero frequency deflection, and $2 \frac{c}{c_c}$ is the structural damping.

DAMPING, VISCOUS. The damping in a mechanical system in which the force varies in proportion to the velocity. The viscous-damping coefficient is equal to the ratio of the viscous-damping force to the velocity.

DANCOFF CORRECTIONS. In nuclear reactor theory, quantities which enable one to estimate interaction effects among the fuel rods comprising a lattice. The Dancoff correction may be written as $1 - T_1$ where T_1 a *moderator transmission factor*, expresses the probability that a neutron emerging from one fuel rod will be transmitted through the intervening moderator, without colliding, to impinge upon a nearest neighbor rod.

DANDELIN METHOD. A **root-squaring method** for solving **algebraic equations** in which the equation $\phi(x) = 0$ is replaced by

$$\phi(\sqrt{x})\phi(-\sqrt{x}) = 0,$$

differing only mildly from the later **Graeffe method**. Dandelin applied this first in conjunction with the **Newton method** for accelerating convergence, but also proposed repeated application as a method in itself.

DANGER COEFFICIENT. The danger coefficient of a substance for a particular nuclear reactor is the change in reactivity caused by inserting that substance in the reactor. The danger coefficient depends on the amount and distribution of the substance inserted and is usually quoted as reactivity change per unit mass for a standard position in the reactor.

DARBOUX VECTOR. The Darboux vector δ of a curve is defined as the vector

$$\delta = \tau\mathbf{T} + \kappa\mathbf{B}$$

where τ is the torsion, κ is the curvature, \mathbf{T} is the unit tangent vector along the positive sense of the curve, and \mathbf{B} is the unit binormal vector.

If ds denotes an element of arc length along the curves then

$$\frac{d\mathbf{T}}{ds} = \delta \times \mathbf{T}$$

$$\frac{d\mathbf{N}}{ds} = \delta \times \mathbf{N}$$

$$\frac{d\mathbf{B}}{ds} = \delta \times \mathbf{B}$$

where \mathbf{N} is the unit normal vector, i.e., $\mathbf{T} \times \mathbf{N} = \mathbf{B}$.

The Darboux vector can be interpreted kinematically. If a rigid body moves freely in space, its most general motion can be de-

scribed as a screw motion, i.e., the center of mass moves along a space curve and at the same time the "moving trihedron" $\mathbf{T}, \mathbf{N}, \mathbf{B}$ which is rigidly anchored to the center of mass, rotates about the Darboux vector. (The function of the curve must be continuously differentiable for the relations to apply.) In other words, the Darboux vector coincides with the instantaneous axis of rotation. If ω denotes the instantaneous angular velocity vector and v the instantaneous speed of the center of mass, then

$$\omega = v\delta.$$

DARCY. A unit, the permeability of a medium through which a liquid of one centipoise viscosity will flow at a rate of one cubic centimeter per square centimeter of area when the pressure gradient is one atmosphere per centimeter.

DARCY'S LAW. A law which governs the flow of a viscous fluid through a porous medium. The flow is supposed sufficiently slow for the inertia forces to be negligible (i.e., **Stokes flow**, with low **Reynolds number**), and is therefore in the direction towards decreasing pressure and proportional to the pressure gradient. Thus

$$\mathbf{v} = -\frac{k}{\mu} \text{grad } p$$

where k is a constant of the medium. In a medium of constant k and fluid of constant viscosity μ , there is a **velocity potential** given by

$$\phi = -\frac{k}{\mu} p.$$

DARK-LINE SPECTRUM. See **spectrum**, **dark-line**.

DARWIN-FOWLER METHOD. See **method of steepest descents**.

DAVISSON CHART. A chart expressing thermionic-emission current density in terms of cathode power dissipation. The coordinates are skewed in a manner which causes the log of current density as a function of the log of power to be a straight line.

DAY, JULIAN. See **Julian Day**.

DBA. Abbreviation for *dbRN adjusted*. This is a unit used to show the relationship between the interfering effect of a noise fre-

quency or band of noise frequencies, and a fixed amount of noise power commonly called *reference noise*. (See **dbRN**.)

DBRN. Abbreviation for *decibels above reference noise*. This is a unit used to show the relationship between the interfering effect of a noise frequency, or a band of noise frequencies, and a fixed amount of noise power commonly called *reference noise*. A tone of 1000 cycles per second, having a power level of -90 dbm, was selected as the reference noise power because it appeared to have negligible interfering effect, and would permit measurement of interfering effect in positive numbers. By way of explanation, dbRN was originally determined by measuring the interfering effect of noise in telephone circuits which used Type 144 handsets. Later, an improved type of handset (Western Electric Type F1A) came into general use. This required an adjustment of the reference noise level and a different unit. The reference level was changed to -85 dbm and the new unit was called **dba**.

DBX. Abbreviation for *decibels above reference coupling*. *Reference coupling* is defined as the coupling between two circuits that would be required to give a reading of 0 **dba** on a 2-type noise measuring set connected to the disturbed circuit when a test tone of 90 **dba** (using the same weighting as that used on the disturbed circuit) is impressed on the disturbing circuit.

DEAD LOAD. The load due to the weight of the permanent parts of a structure, the immovable part of the **total load**.

DEAD RECKONING (NAVIGATION). The determination of the position of a ship by advancing a known, or assumed, position by any of the methods of the sailings, for the courses and distances traversed by the ship in a given interval of time. In the determination of a dead reckoning position (*DR*), the true headings (i.e., corrected magnetic or corrected gyro) and speed through the water are used.

If the navigator can estimate the effects of the current and winds on the direction and distance of travel of the ship in the given interval, these may be applied to the *DR* position to obtain what is called an *estimated position* (*EP*).

Within recent years several types of dead reckoning equipment have been devised that

receive information from the compass and from the patent log and transform that to a tracing that shows the *DR* position continuously. However, such devices are seldom as accurate as the plot kept by the navigator. (Cf. the sailings.)

DE BROGLIE HYPOTHESIS. The hypothesis that a wave is associated with material particles, with the wavelength, λ , and momentum $p = mv$, of the particle related by $\lambda = h/p$. At high energies the relativistic mass

$$m = m_0/\sqrt{1 - v^2/c^2}$$

must be used.

DE BROGLIE WAVELENGTH. See **de Broglie hypothesis**.

DEBYE EFFECT. A selective absorption of electromagnetic waves in a dielectric medium, due to molecular dipoles. (See **Debye energy**; **induction forces**.)

DEBYE ENERGY. This correction to the dipole-dipole (Keesom) interaction energy results from the interaction of the permanent dipole μ of one molecule with the induced dipole of another molecule with a **polarizability** α .

The electrical field strength ϕ at a distance r from the dipole is proportional to μ/r^3 . It induces in the other molecule an induced dipole moment

$$u_i \approx \alpha\phi \approx \alpha\mu/r^3.$$

The total interaction energy due to this induction effect is

$$\epsilon_D = \mu_i\phi \approx \alpha\mu^2/r^6.$$

The *Debye*, or *induction energy*, is practically independent of temperature. It is, however, usually smaller than the **Keesom energy**. Neither the Keesom nor the Debye energy is capable of interpreting the attractive forces between non-polar molecules. (See **dispersion forces**, **induction forces**.)

DEBYE EQUATION FOR THE DISPERSION OF THE DIELECTRIC CONSTANT. Whereas for static fields the dielectric constant is a real number, for periodic fields it is usually a complex quantity (see **dielectric constant**; **electrical displacement in dielectrics**). Debye has shown that, if in a static

field, equilibrium is reached exponentially in time, then

$$\epsilon(\omega) - \epsilon_\infty = \frac{(\epsilon_s - \epsilon_\infty)}{1 - i\omega\tau}. \quad (1)$$

$\epsilon(\omega)$ is the dielectric constant in a periodic electric field $\mathbf{E} = \mathbf{E}_0 \cos \omega t$. ϵ_∞ and ϵ_s are the limiting values of $\epsilon(\omega)$ for very large and zero frequencies, respectively. τ is the relaxation time of the dielectric.

The real and imaginary parts of the dielectric constant are respectively:

$$\epsilon_1(\omega) - \epsilon_\infty = \frac{\epsilon_s - \epsilon_\infty}{1 + \omega^2\tau^2}$$

and

$$\epsilon_2(\omega) = \frac{(\epsilon_s - \epsilon_\infty)\omega\tau}{1 + \omega^2\tau^2}.$$

The last equation shows that the dielectric losses (proportional to ϵ_2) vanish for very high and very low frequencies, and present a maximum value $\epsilon_2(\omega_m) = (\epsilon_s - \epsilon_\infty)/2$ for an angular frequency $\omega_m = 1/\tau$.

The condition that equilibrium be reached exponentially in time is in general valid only for dilute solutions of dipolar molecules.

DEBYE EQUATION OF STATE (OF SOLIDS). The relation between pressure p , and volume V ,

$$p = \frac{\partial U_0}{\partial V} + \gamma \frac{U_D}{V}$$

where γ is Grüneisen's constant, U_0 is the internal energy at 0°K, and U_D is the contribution to the internal energy due to the lattice vibrations.

DEBYE FREQUENCY. In his derivation of an equation for specific heat, Debye treated a crystalline material as an homogeneous isotropic solid to which classical vibration laws applied. He was then able to calculate the number of vibrations with frequencies between ν and $\nu + d\nu$. The atomic nature of the structure was then accounted for by the postulate of a maximum frequency, ν_0 , of the order of the atomic frequency. ν_0 is the Debye frequency, and is characteristic of a given solid. (See Debye temperature.)

DEBYE HEAT CAPACITY EQUATION. The Debye theory considers the specific heat of a solid as due to thermal vibrations of the crystal lattice, and the molar heat capacity

C_v is given by this theory in terms of the Debye temperature Θ , the relation being

$$C_v = 3Nkf(\Theta/T)$$

where

$$f(x) = 3x^{-3} \int_0^x \frac{e^y y^4}{(e^y - 1)^2} dy$$

(the Debye function).

N is Avogadro's number and k , the Boltzmann constant.

At high temperatures, this relation leads to the Dulong and Petit law $C \rightarrow 3Nk$, and at low temperatures to the Debye T^3 law.

DEBYE-HÜCKEL THEORY. Debye and Hückel have developed a semi-phenomenological theory to take account of the effect of electrostatic forces in such media as solutions of strong electrolytes or plasmas.

It is based on a combination with the Boltzmann formula, of the Poisson equation

$$\nabla^2 \Psi = -\frac{4\pi}{\epsilon} \rho \quad (1)$$

where ρ is the charge density, Ψ , the electrostatic potential, ϵ , the dielectric constant. If one combines these two relations, assumes the electrical potential energy to be small in respect to thermal energy and uses the electro-neutrality condition, one obtains the basic equation of the Debye-Hückel theory

$$\nabla^2 \Psi = \kappa^2 \Psi(r). \quad (2)$$

$\Psi(r)$ is the electric potential at a distance r around some central ion, $1/\kappa$ is a characteristic length, called the Debye length; it is the distance at which the field of the central ion is screened by the other charges to $1/e$ of its value. It is also often called the mean thickness of the ionic atmosphere.

$$\kappa^2 = \frac{4\pi \sum_i N_i z_i^2 e^2}{\epsilon k T}. \quad (3)$$

N_i is the number of ions of species i , z_i is the charge number, and e , the charge of a proton.

The spherically symmetrical solution of (2) which is finite at $r = \infty$ is

$$\Psi(r) = \frac{A}{r} e^{-\kappa r} \quad (4)$$

where A is a constant.

From (4) all thermodynamic properties can easily be deduced, as well as the main trans-

port properties in solutions of strong electrolytes. The main success of the Debye-Hückel theory is the calculating of the **limiting law** for strong electrolytes.

DEBYE LENGTH. See Debye-Hückel theory.

DEBYE TEMPERATURE. A parameter Θ having the dimensions of temperature appearing in the Debye theory of specific heats. It is defined by the equation

$$\Theta = \frac{h\nu_0}{k}$$

where h is Planck's constant, k is the Boltzmann constant, and ν_0 is the **Debye frequency** and is characteristic of a given solid. In the Debye treatment, atomic vibrations are treated as elastic waves, so that ν_0 can be related to the velocities of these waves in the solid. Thus,

$$\nu_0^3 = \frac{9N}{4\pi V} \left/ \left(\frac{2}{c_2^3} + \frac{1}{c_1^3} \right) \right.$$

where c_1 and c_2 are the velocities of longitudinal and transverse elastic waves respectively, V is the volume of the crystal, and N the total number of atoms in the crystal.

DEBYE T^3 LAW. According to the Debye theory of specific heat, the molar specific heat of a solid C_v should tend to be proportional to the cube of the absolute temperature at temperatures below about $\Theta/10$ where Θ is the **Debye temperature**. The expression for C_v is then

$$C_v = \frac{12\pi^4 Nk}{5} (T/\Theta)^3$$

where N is Avogadro's number and k is the Boltzmann constant.

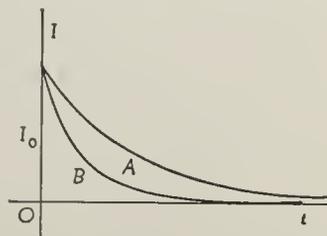

DEBYE THEORY OF CRYSTAL VIBRATIONS. A theory which assumes a spectrum for lattice vibrations similar to that of an elastic continuum, except that it is cut off at a maximum frequency in such a way that the total number of degrees of vibrational modes is equal to the total number of **degrees of freedom** of the lattice.

DEBYE UNIT. A unit of electrical dipole moment equal to 10^{-18} electrostatic units. It is of the order of magnitude of the electronic charge multiplied by the interatomic distance

of chemical compounds. (See **dipole, electrical**.)

DEBYE-WALLER EQUATION. See **thermal motions in a lattice**.

DECAY COEFFICIENT. Certain processes found in nature progress at a rate diminishing in accordance with an exponential function of the time; such, for example, as phosphorescence and radioactive emission. The falling

Typical exponential decay curves. The decay coefficient in *B* is greater than in *A*.

off or "decay" of such a process may be represented by an equation giving the intensity at time t as $I = I_0 e^{-Ct}$, in which I_0 is the intensity at the beginning of the time t and C is the "decay coefficient." Closely related to C is the half-value period, which is the time required for I to fall to $1/2$ its original value I_0 ; it is equal to $0.69315/C$. Thus, if the half-value period of radium B is 1608 sec, its decay coefficient C is

$$\frac{0.69315}{1608 \text{ sec}} = 0.000431/\text{sec.}$$

This means that approximately 0.000431 of the substance existing at any instant disintegrates during the ensuing second. The reciprocal of C , called the "decay modulus," represents the time required for I to diminish to $1/e$ or 0.3697 of its original value I_0 . It is equal to 1.4427 times the half-value period; for the decay of radium B its value is therefore 2320 sec.

This relationship may also be written in terms of the number of atoms present of a particular species, as

$$N = N_0 e^{-\lambda t}.$$

Thus, the decay law is a statistical law, so that if N is the number of radioactive atoms present, the number of which will disintegrate on the average in unit time is λN . The number which will disintegrate in any particular unit of time may not be exactly λN , but if a

large number of measurements of the number of disintegrations per unit time is made, the values will show a **Poisson distribution** with λN as the average value.

DECAY CONSTANT. See **decay coefficient**; **decay constant**, **acoustic**.

DECAY CONSTANT, ACOUSTIC. The exponential power by which the sound decays after the source is stopped.

DECAY MODULUS. In a damped harmonic oscillator, the time for the amplitude of oscillation to diminish to $1/e$ of its initial value is called the decay modulus. For an oscillator with the equation of motion

$$m\ddot{x} + R\dot{x} + fx = 0$$

the decay modulus is $2m/R$. (See **oscillation**, **damped**.)

DECAY TIME OF A MAGNETIC FIELD. The characteristic time of decay of a **magnetic field** due to **Joule** heating in a conductor or a plasma is given by

$$\tau = \frac{4\pi L^2 \sigma / C}{c},$$

where σ is the electrical conductivity in Gaussian units, L is a length such that $L = H/|\nabla H|$, H being the magnitude of the magnetic field, and c is the speed of light. (See **relaxation**.)

DECIBEL. See **gain ratio**.

DECIBELS ABOVE REFERENCE COUPLING. See **DBX**.

DECIBELS ABOVE REFERENCE NOISE. See **DBRN**.

DECIMAL. Characterized by ten; compounded of ten parts. The decimal system of number representation is the ordinary one using the **radix** 10.

DECISION FUNCTION. In statistics, a function of observations determining which way a decision should go according to the values which the function attains.

DECLINATION (ASTRONOMIC). The declination of a heavenly body is the angle measured north or south from the celestial equator along the hour circle through the object to the object. Declination is sometimes referred to as $+$ for north declination and $-$ for south

declination. In using this coordinate, care must be exercised to indicate the proper side of the equator, e.g., N 35° , 35° N, $+35^\circ$.

Star catalogues give the declination of the star for the epoch of the catalogue. Due to **precession** and **nutation**, the declinations are continually changing. Constants to facilitate the reduction of position given in the catalogue to those of another date are published for every star.

DECODER. In computer terminology, a network or system in which a combination of inputs is excited at one time to produce a single output. Sometimes called *matrix*.

DECOMPOSITION OF A VECTOR. Every **vector field** $\mathbf{B}(x,y,z)$ can be decomposed into a sum of a **gradient** and a **curl**, i.e., $\mathbf{B} = \mathbf{N} + \mathbf{E}$, where $\mathbf{N} = \text{grad } f$ and $\mathbf{E} = \text{curl } \mathbf{D}$.

The scalar field f and the vector field \mathbf{D} satisfy the following equations:

$$f = -\frac{1}{4\pi} \iiint_V \frac{\text{div } \mathbf{B}}{r} dV + \frac{1}{4\pi} \oiint_S \frac{\mathbf{B} \cdot \mathbf{n}}{r} dS$$

$$\mathbf{D} = \frac{1}{4\pi} \iiint_V \frac{\text{curl } \mathbf{B}}{r} dV + \frac{1}{4\pi} \oiint_S \frac{\mathbf{B} \times \mathbf{n}}{r} dS$$

r is the distance from the point at which \mathbf{B} is computed to a surface element dS or volume element dV . S is the surface boundary of the volume V ; \mathbf{n} is the outward normal of S .

DEDEKIND CUT. A Dedekind cut in the rational numbers is any division of the set of rational numbers into two subsets A and B such that: (1) neither A nor B is empty; (2) every rational number is either in A or in B ; (3) every number in B is greater than any number in A ; (4) A contains no largest number.

If B contains no smallest number, the cut defines an irrational number.

DE DONDER AFFINITY. See **chemical affinity**.

DE DONDER INEQUALITY. See **chemical affinity**.

DEEP BEAM. See **beam**, **deep**.

DEFECT. A term used to denote various types of point imperfections in solids, such as vacancies, interstitial atoms, etc., as distinct from extended imperfections such as dislocations. Lattice defects are particularly im-

portant in ionic crystals, where they may be created by heating in the vapor of one constituent, thus creating a stoichiometric excess, by bombardment with **x-rays** and energetic particles, etc. Any crystal must contain a certain equilibrium concentration of defects, as a function of the temperature, purely as a result of thermal agitation (see **Frenkel defect**, **Schottky defect**). Defects are responsible for the **diffusion** of ions, ionic conductivity, and the complex phenomena related to color centers.

DEFERRED APPROACH TO THE LIMIT.

Let ϕ represent a quantity to be calculated by a finite difference method (e.g., an integral); let ϕ_h represent the approximation obtained when $\Delta x = h$. Often it is approximately true that

$$\phi_h = \phi_0 + \phi_1 h^2 + \phi_2 h^4 + \dots$$

Let ϕ_{h_1} and ϕ_{h_2} represent similarly values obtained with $h = h_1$ and $h = h_2$. If h_1 and h_2 are small enough so that terms beyond h^2 can be neglected, then

$$\phi_{h_1, h_2} \equiv |h_1^2 \phi_{h_2} - h_2^2 \phi_{h_1}| / |h_1^2 - h_2^2|$$

is a much better approximation to ϕ than is either ϕ_{h_1} or ϕ_{h_2} . Commonly one takes $h_2 = h_1/2$.

DEFINITE. See **form**, **integral**.

DEFINITION CIRCLE. In **impedance matching**, a circle of constant standing-wave ratio surrounding a desired impedance on a complex impedance plane.

DEFLAGRATION. Slowly progressing mode of **combustion** in a flame.

DEFLATION. A transformation applied to a **matrix A** when one **eigenvalue and eigenvector** are known, for the purpose of reducing the computations required for finding the others. The general theorem is, if eigenvalues of **A** are $\lambda_1, \lambda_2, \dots, \lambda_n$, and if $\mathbf{A}\mathbf{v}_1 = \lambda_1\mathbf{v}_1$, then eigenvalues of

$$\mathbf{A}_1 = \mathbf{A} - \mathbf{v}_1 \mathbf{k}^T$$

are $\lambda_1 - \mathbf{k}^T \mathbf{v}_1, \lambda_2, \dots, \lambda_n$, whatever the vector **k**. By choosing \mathbf{k}^T to be a multiple of the first row of **A**, and scaled so that

$$\mathbf{k}^T \mathbf{v}_1 \equiv \lambda_1,$$

the first row of **A**₁ is null.

DEFLECTION. Loads acting on a structure cause displacement of the structure from its original position. The term deflection is used for the displacement of joint and supports, and for the line of centroids of bars of which structures are composed. Deflection rather than strength sometimes governs design.

DEFLECTION, ANGLE OF. See **angle of deflection**.

DEFLECTION, BENDING. The motion or displacement of the line of centroids of a beam or plate in a transverse direction.

DEFLECTION CURVE. The deflection curve of a beam is the position of the line of centroids (axis) of the beam which results from transverse loading.

DEFLECTION, LARGE. The term large deflection is a relative one. Deflections are large if the non-linear effects they produce must be taken into account in the **strain-displacement relations**. In the case of a beam the exact expression for curvature would be required rather than d^2y/dx^2 . The need to take deflection into account in the equations of equilibrium alone, as in buckling of columns, is not considered to make the problem one of large deflection.

DEFLECTION, LATERAL. See **lateral deflection**.

DEFLECTION, SHEAR. The deformations of a beam, frame or arch are in part produced by transverse shear. Energy methods or their equivalent give close approximations to the deflection associated with the shearing stress. Except for specially designed beams with thin or open webs, the shear deflection is small compared with the bending deflection. (See **deep beams**.)

DEFLECTION THEORY. A name given to a successive approximation analysis technique for obtaining consistent deflections of cable and stiffening truss in a suspension bridge.

DEFORMATION. (1) A transformation $f_1(p)$ between two sets *A, B* of elements of a **topological space** is called a deformation of *A* into *B* if $f_1(p)$ is such that, letting $f_0(p)$ denote the identical transformation of *A* into itself, it is possible for all $0 \leq t \leq 1$ and all the points *p* of *A*, to define transformations $f_t(p)$ which are continuous in *t* and in *p*. Two

point sets which can be deformed into each other are said to be *homotopic*. Thus a torus is homotopic to a section of a pipe, but not to a sphere. (2) The change in the shape or size of a body which accompanies a stressed condition is called deformation or *strain*.

DEFORMATION POTENTIAL. The effective electric potential acting on a free electron in a metal or semiconductor as a result of a local deformation of the crystal lattice. The scattering of electrons by lattice vibrations may be analyzed in terms of the deformations produced by the vibrations, and hence the corresponding potentials.

DEFORMATION, PURE HOMOGENEOUS. See pure homogeneous deformation.

DEFORMATION THEORY OF PLASTICITY. A plastic flow law which expresses total plastic strain components in terms of the applied stress, and possibly stress increments. This type of law has been discredited for plastic flow with varying principal stress ratios or rotating principal stress directions in favor of **incremental theories**.

DEGENERACY. (1) The term used to describe the situation in which a quantum mechanical system has more than one **eigenstate** characteristic of the same **eigenvalue(s)** of the operators corresponding to a given set of dynamical variables. The existence of degeneracy is an indication that one has not specified values for as many dynamical variables as quantum mechanics requires for a unique determination of the state of the system. The additional dynamical variables that must be specified can be found by finding all of the additional operators which will commute with the set chosen and with themselves. Specifying eigenvalues for all of the dynamical variables found in this way will eliminate the degeneracy. (2) Sometimes the term degeneracy is used in the more limited sense of describing the ease in which there is more than one energy eigenfunction of the **Hamiltonian** corresponding to the same eigenvalue. The removal of degeneracy in this more limited sense can often be accomplished by the application of a perturbing field leading to a different energy shift for each one of the eigenfunctions involved in the degeneracy. (3) The term degeneracy is also used in certain classical problems, such as those of vibrat-

ing systems in which different modes have the same frequency.

DEGENERACY, EXCHANGE. See exchange degeneracy.

DEGENERACY TEMPERATURE. A temperature usually defined as the temperature for which the de Broglie wavelength of a particle with kinetic energy kT (k is Boltzmann's constant, T is absolute temperature) is equal to the mean separation of the particles in the gas. (See also **degenerate gas**.)

DEGENERATE CONDUCTION BAND. A band in which two or more orthogonal quantum states exist which have the same energy and spin, and zero mean velocity.

DEGENERATE ELECTRON GAS. An electron gas which is far below its **Fermi temperature**, that is, which must be described by the **Fermi distribution**. The essential characteristic of this state is that a very large proportion of the electrons completely fill the lower energy levels, and are unable to take part in any physical processes until excited out of these levels.

DEGENERATE GAS. A gas for which the condition

$$n \frac{h^3}{(2\pi mkT)^{3/2}} \ll 1$$

(n is number of gas particles per unit volume, h is the Planck constant, m is the mass of a gas particle, k is the Boltzmann constant, T is absolute temperature) is not satisfied. This condition is equivalent to

$$e^{\nu} \ll 1,$$

where $\nu = \mu/kT$ (μ is **thermal potential**). (See also **quantum statistics**.)

DEGENERATE LEVELS. Two or more energy levels of a molecule or atom are degenerate when their wave functions are equivalent, and yet independent. The degeneracy is usually split in an external electrical or magnetic field.

DEGENERATE OSCILLATING SYSTEM. A vibrating system with several **degrees of freedom** in which the frequencies associated with two or more degrees of freedom may be equal in magnitude. (See **degeneracy (3)**.)

DEGENERATE STATE. In quantum mechanics, when different states of motion correspond to the same **energy level**, the states are said to be degenerate. The degeneracy can often be removed by the application of a perturbing field with the effective introduction of a new quantum condition, i.e., the breakup of one **eigenvalue** into several. (See **degeneracy** (1) and (2).)

DEGRADATION OF ENERGY. When a quantity of heat Q is allowed to pass from a source at temperature T to the surroundings at temperature $T_o < T$, it is possible to convert some, but not all, of it into mechanical work W . The maximum amount which can be converted into work is that obtainable from a **Carnot cycle** operating between the sources at T and T_o , that is

$$W = \frac{T - T_o}{T} Q.$$

The quantity of heat

$$Q_o = Q - W = \frac{T_o}{T} Q$$

cannot be converted into work, as is expressed by the second law of **thermodynamics**, and becomes *unavailable* or *degraded*. When a real engine operates between the sources at T and T_o it will produce less work than W , say W' , owing to the irreversibility of real processes. The quantity

$$Q'_o = Q - W'$$

becomes then *unavailable* or *degraded*.

DEGREE MATRIX. See **matrix**, **degree**.

DEGREE OF ADVANCEMENT IN CHEMICAL REACTIONS (EXTENT OF REACTIONS). See **conservation of mass in closed systems**.

DEGREE OF A VERTEX. See **vertex**, **degree of**.

DEGREE OF COHERENCE. See **partial coherence**.

DEGREE OF SUPERHEAT. See **superheated vapor**.

DEGREES OF FREEDOM. (1) The number of independent coordinates necessary for the unique determination of the position of every particle in a dynamical system is the number

of degrees of freedom. Each degree of freedom is represented by a coordinate which can vary with time independently of all the rest. A particle constrained to move on a surface has two degrees of freedom. A single particle which may move anywhere in three-dimensional space has three degrees of freedom. A system composed of three particles has 9 degrees of freedom; for it takes nine independent coordinates to specify the positions of the particles in space, and their arrangement may therefore be changed in nine different ways. A single rigid body, on the other hand, has 6 degrees of freedom, since it may have motions of translation in three coordinate directions and it may also rotate about any one of the three coordinate axes through its center of mass. Any actual motion of the body is in general made up of all six, its linear motion being the resultant of three linear components and its rotation the resultant of three angular components. Each molecule of a diatomic gas has 7 degrees of freedom; viz., the six just mentioned for the molecule as a whole (regarded as a rigid body), and, in addition, one corresponding to the possible vibration of the two atoms toward and from each other. If the body is not rigid, the number of degrees of freedom may be virtually infinite. It should, however, be added that, because of restrictions imposed by the **quantum theory**, not all of the possible degrees of freedom can in general be expected to participate in changes of molecular energy. (See **equipartition of energy**.)

(2) The number of independent variables in a thermodynamic system. Thus, in the statement of the **phase rule**, that number of variable factors such as pressure, temperature or concentration, which must be fixed to define completely the state of the system.

(3) The number of independent **meshes**, or the number of independent **cut-sets** that may be selected in a **network**.

(4) A statistic which can (by linear transformation if necessary) be regarded as the sum of squares of ν independent variates is said to have ν degrees of freedom. Thus a sample sum of squares $\sum_{i=1}^n (x_i - \bar{x})^2$, where \bar{x} is the mean, has $n - 1$ degrees of freedom. By extension, a statistic which depends on several such quadratic forms is said to have the degrees of freedom appropriate to the forms; e.g., the **F-ratio**, which is the ratio of two forms with ν_1

and ν_2 degrees of freedom respectively, is spoken of as possessing ν_1 and ν_2 degrees of freedom.

DEGREES OF FREEDOM, FREEZING IN OF. See **freezing in of degrees of freedom.**

DEL. The differential operator used in **vector** analysis and sometimes also called nabla, since its usual symbol ∇ is thought to resemble an Assyrian harp with the latter name. In Cartesian coordinates it is $(i\partial/\partial x + j\partial/\partial y + k\partial/\partial z)$. When applied to a scalar function it gives the **gradient**; to vectors, it can give the **divergence** or the **curl**.

In the following relations ϕ is a scalar; \mathbf{U} , \mathbf{V} are vectors; the asterisk (*) can be either a dot or a cross and, depending on that choice, A , B are either scalars or vectors. $\nabla * (A + B) = \nabla * A + \nabla * B$; $\nabla * (\phi A) = \nabla \phi * A + \phi \nabla * A$; $\nabla(\mathbf{U} \cdot \mathbf{V}) = (\mathbf{V} \cdot \nabla)\mathbf{U} + (\mathbf{U} \cdot \nabla)\mathbf{V} + \mathbf{V} \times (\nabla \times \mathbf{U}) + \mathbf{U} \times (\nabla \times \mathbf{V})$; $\nabla \cdot (\mathbf{U} \times \mathbf{V}) = \mathbf{V} \cdot \nabla \times \mathbf{U} - \mathbf{U} \cdot \nabla \times \mathbf{V}$; $\nabla \times (\mathbf{U} \times \mathbf{V}) = (\mathbf{V} \cdot \nabla)\mathbf{U} - \mathbf{V}(\nabla \cdot \mathbf{U}) - (\mathbf{U} \cdot \nabla)\mathbf{V} + \mathbf{U}(\nabla \cdot \mathbf{V})$. If $\mathbf{R} = ix + jy + kz$, a position vector, $\nabla \cdot \mathbf{R} = 3$; $\nabla \times \mathbf{R} = 0$; $\mathbf{U} \cdot \nabla \mathbf{R} = \mathbf{U}$.

There are six possible combinations where the operator is applied twice, although two of them equal zero identically. They are: (1) $\nabla^2 \phi$, the **Laplacian**; (2) $\nabla^2 \mathbf{V}$; (3) $\nabla(\nabla \cdot \mathbf{V})$; (4) $\nabla \times (\nabla \times \mathbf{V}) = \nabla(\nabla \cdot \mathbf{V}) - \nabla \cdot \nabla \mathbf{V}$; (5) $\nabla \times \nabla \phi = 0$; (6) $\nabla \cdot \nabla \times \mathbf{V} = 0$.

DE LAVAL TURBINE. A single-stage impulse turbine. In order to have a reasonable efficiency a dc Laval turbine must operate at a very high rotational speed (of order of 15,000 rpm).

DELAYED ELASTICITY. See **elasticity, delayed.**

DELAYED NEUTRONS. See **neutrons, delayed.**

DELAY LINE. An electrical **network** used to hold back for a definite time the passage of a signal applied to the input terminals, but which thereafter transmits the delayed signal without distorting it.

DELAY TIME. The response of a **Kelvin material** to a **step function** of stress, of amplitude σ_0 , is a strain which varies with time according to

$$\epsilon(t) = \frac{\sigma_0}{m} (1 - e^{-t/\tau})$$

where m is the modulus and τ is a constant known as the delay time. When a more general material is represented by a sequence of Kelvin elements in series, the associated sequence of delay times, τ_i , gives the discrete delay time spectrum. For such a material, step function stressing gives the response:

$$\epsilon = \sigma_0 \sum_i \frac{1}{m_i} (1 - e^{-t/\tau_i}).$$

General linear viscoelastic behavior corresponds to the continuous generalization of this:

$$\epsilon = \sigma_0 \int_0^\infty L(\tau)(1 - e^{-t/\tau})d\tau.$$

$L(\tau)$ is then the retardation spectrum, sometimes expressed in terms of the variable $\ln \tau$ instead of τ .

DELOCALIZATION ENERGY. The removal of the wall separating two identical boxes containing equal numbers of electrons lowers the **zero point energy** of the system. In the simplest one-dimensional case, the kinetic energy levels, which were given for each box by the sequence $k^2(h^2/8ml^2)$, become $k'^2(h^2/8m(2l)^2)$ for the united box. k and k' are whole numbers, l is the length of the primitive box, h , the Planck constant and m , the mass of the electron. Each level can be occupied by two electrons. The respective zero point energies, before and after the removal of the box, are therefore

$$2 \cdot (2^2 + 4^2 + 6^2 + \dots)(h^2/4m(2l)^2)$$

and

$$(1^2 + 2^2 + 3^2 + 4^2 + \dots)(h^2/4m(2l)^2).$$

The increased mobility of the π -electrons along a skeleton molecule with **conjugated double bonds** leads to an analogous lowering of the heat of formation, i.e., to an increased stability of these molecules. This effect is usually called the *delocalization effect*, and the corresponding decrease in energy is called the *delocalization*, or *enlargement energy*.

DELTA (Δ). In the theory of the slowing down of fast neutrons through collisions with matter, the parameter

$$\Delta = 2 \frac{\sigma_a(kT)}{\mu\sigma_s}$$

gives the relative importance of capture to moderating power. σ_s is the high-energy scattering cross-section of the material, $\sigma_a(kT)$ is the value of the capture cross-section at $E = kT$, k being Boltzmann's constant and T the moderator temperature, and μ is the ratio of neutron mass to atom mass.

DELTA FUNCTION. Commonly written as $\delta(x)$, it lies outside the usual scope of function theory. It can be defined by the relation

$$\int_a^b \phi(x)\delta(x - x_o)dx = \phi(x_o)$$

where $\phi(x)$ is continuous and $a \leq x_o \leq b$. It can thus be thought of as a function which is zero for every value of x except the origin, where it is infinite in such a way that

$$\int_a^b \delta(x)dx = 1, \quad a < 0 < b.$$

The delta function has played an important role in mathematical physics and applied mathematics since it can be used to represent idealizations such as point charge, or point load, which lead to **Green's functions** of the differential equations representing various field theories. Analysis using delta functions has been put on a sound mathematical basis by L. Schwartz in his theory of distributions (see **distribution theory**). $\delta(x)$ can be considered as the derivative of the **Heaviside step function** $H(x)$.

DELTA OPERATOR. See **delta function**.

DELTA-SQUARE PROCESS. Let a_i, a_{i+1}, a_{i+2} represent three consecutive terms in a sequence, possibly three consecutive approximations to a root of an equation obtained by Newton's method, Bernoulli's method, or some other. In many situations, when the sequence has a limit, then $a_i - (\Delta a_i)^2/\Delta^2 a_i$ will be much closer to this limit than will a_{i+3} . Here Δ represents the **difference operator**. If the approach is geometric, that is, if $a_i = a + \alpha\rho^i$, then this gives the limit a exactly.

The formula can be derived by assuming the above form for a_i and solving for a . A somewhat more general formula in terms of $a_i, a_{i+1}, a_{i+2}, a_{i+3}, a_{i+4}$ can be obtained on the assumption that $a_i = a + \alpha_1\rho_1^i + \alpha_2\rho_2^i$. The result has a meaning even when $|\rho| \geq 1$, hence the method is sometimes effective for summing

divergent series. Generalizations have been developed by Shanks and by Wynn.

DELTA WING. A wing whose plan form is an isosceles triangle with its line of symmetry parallel to the direction of flight. If the apex angle is small, the pressure distribution and lift may be estimated from the theory of **wings of small aspect ratio**. For larger apex angles it is necessary to use the more general **lifting surface theory**. In their usual forms, however, both these theories neglect the effects of separation at the leading edges. These separations often have important effects on the real flow.

DEMAGNETIZING FIELD. A body of magnetic material subject to an **applied magnetizing force** \mathbf{H}_a is acted upon by a net magnetizing force,

$$\mathbf{H} = \mathbf{H}_a - \Delta\mathbf{H}$$

where the demagnetizing field $\Delta\mathbf{H}$ is interpreted as being due to the poles induced on the surface of the body. In the case of a permanent magnet with $\mathbf{H}_a = 0$, the demagnetizing field is readily seen to be the field of the magnet itself, which always has such a direction as to oppose the magnetization. The existence of a demagnetizing field is a necessary consequence of the fact that energy is stored in the field external to the magnetized body, and that the sum of this energy and the internal energy must be minimized at equilibrium. The demagnetizing field is approximately proportional to the magnetization, \mathbf{M} .

$$\Delta\mathbf{H} = N\mathbf{M}.$$

The proportionality factor N is called the demagnetizing factor, and depends primarily on the shape of the body.

DEMAGNETIZATION, ADIABATIC. See **adiabatic demagnetization**.

DEMAGNETIZATION CURVE. The portion of the **hysteresis loop** that lies in the second quadrant.

DEMAGNETIZATION FACTOR. See **depolarization factor; demagnetizing field**.

DE MOIVRE IDENTITY. A useful and easily proved rule (see **complex number**) for

raising a complex number to an integral power, namely,

$$\{r(\cos \theta + i \sin \theta)\}^n = r^n(\cos n\theta + i \sin n\theta);$$

in other words, $re^{i\theta} = r^n e^{in\theta}$.

DE MOIVRE-LAPLACE THEOREM. A particular case of the **central limit theorem** applied to the **binomial distribution**. If π is the probability of success the observed proportion p of successes in n independent trials tends, for large n , to be distributed in the normal (Gaussian) form with **mean** and **variance** $\pi(1 - \pi)/n$.

DENSE. A subset T of a **metric space** S is dense in S if every element of S is the limit of a sequence of elements in T .

DENSITY. (1) The ratio of mass m to volume V in a homogeneous system:

$$\rho = m/V.$$

In an inhomogeneous system, the density at a point is given by

$$\rho = \lim dm/dV$$

if the system can be treated as a continuum. (2) In length-force-time systems of units, the term density is sometimes used to denote weight per unit volume, rather than mass per unit volume. (3) By analogy, the ratio of the number of particles or total amount of such a quantity as energy or momentum, carried by or contained in a volume to that volume. Thus one speaks of energy density, luminous density, electron density, charge density, etc. (See entries following.)

DENSITY, DIFFUSE. A quantity defined as the logarithm of the reciprocal of the diffuse transmittance. (See **transmittance**, **diffuse**.)

DENSITY, ENSEMBLE. See **ensemble density**.

DENSITY, LUMINOUS. The luminous energy found in a unit volume of space.

DENSITY MATRIX. If a system can be described by the quantum mechanical wave function

$$\psi = \sum_{\alpha jm} A_m^{\alpha j} U_m^{\alpha j},$$

where the $U_m^{\alpha j}$ constitute a complete, orthogonal set of eigenfunctions of the total angular

momentum with eigenvalue $j(j+1)\hbar^2$, the z -component of the total angular momentum with **eigenvalue** $m\hbar$, and any other operators whose eigenvalues are designated by α ; then the matrix having as its elements

$$\rho_{\alpha jm, \alpha' j' m'} = A_m^{\alpha j} A_{m'}^{\alpha' j'}$$

is known as the density matrix. It is the quantum mechanical counterpart of the classical **ensemble density**.

DENSITY, NEUTRON. The neutron density, $N(r, t)$ is generally defined as:

$$N(r, t) = \int_0^\infty dE \int d\Omega N(r, E, \hat{\Omega}, t)$$

where the angular density $N(r, E, \hat{\Omega}, t)$ is defined under **flux, neutron, angular**.

DENSITY OF MOBILE CHARGES IN SEMICONDUCTOR. If the density of conduction electrons in a non-degenerate conduction band (see **degenerate conduction band**) of a crystal is sufficiently low for mutual interactions to be neglected, the equilibrium value of this density, n_e , can be obtained by integration of the expression for the **density of quantum states** over the **Fermi-Dirac distribution**. This gives

$$n_e = \frac{2(2\pi m_e^* kT)^{3/2}}{h^3} \exp [(\epsilon_F - \epsilon_C)/kT]$$

where ϵ_F is the **Fermi level**, ϵ_C is the energy at the bottom of the conduction band, m_e^* is the effective mass of the electron, T is the absolute temperature, and h and k are the Planck and Boltzmann constants. In obtaining this expression, it is assumed that $\epsilon_F - \epsilon_C \gg kT$.

The same relation may be used for obtaining the density of electron "holes" in a crystal, except that $(\epsilon_v - \epsilon_F)$ must now be substituted for $(\epsilon_F - \epsilon_C)$. (ϵ_v is the energy at the top of the valence band; m_e^* represents the effective mass of the hole.)

DENSITY OF QUANTUM STATES IN CONDUCTION BAND. If, in a non-degenerate conduction band (see **degenerate conduction band**), a crystal of volume Ω_N contains $\nu(\epsilon) d\epsilon$ quantum states with energies between $\epsilon_C + \epsilon$ and $\epsilon_C + \epsilon + d\epsilon$ (ϵ_C is the energy of the bottom of the conduction band), then, for small ϵ , the following asymptotic relation holds

$$\nu(\epsilon) = \frac{2^{1/2}\pi(m_e^*)^{3/2}\Omega_N}{h^3} \epsilon^{1/2}$$

where m_e^* is the effective mass of the electron, and h is Planck's constant.

DENSITY, SCALAR. See **scalar density**.

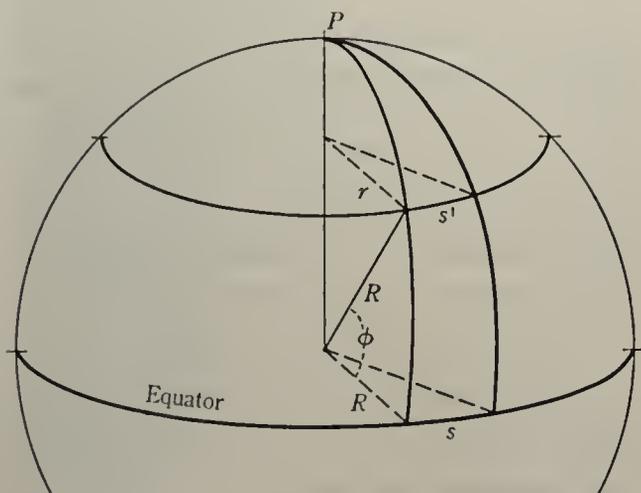

DENSITY, SPECULAR. The logarithm of the reciprocal of the specular transmittance. (See **transmittance, specular**.)

DENUMERABLE. A synonym of **countable**.

DENUMERABLE SET. See **cardinal**.

DEPARTURE. Any course and distance made good by a ship in a given time may be resolved into two components at right angle to each other, one in the north-south direction, known as the difference of latitude, and the other in the east-west direction, known as the departure. Because of errors in the methods available for determining the course and distance made good by the ship, one may assume in most calculations that the earth is a sphere. With this assumption, and with the distance expressed in nautical miles, the north-south component is the difference of latitude in minutes of arc.

Departure cannot be directly expressed as a difference of longitude, for it is measured along a small circle parallel to the equator. In the figure s' is a departure measured in

nautical miles along a parallel of latitude ϕ . The arc s , on the equator, represents the difference of longitude, measured in minutes of arc on the equator, or in nautical miles. Referring to the figure, it is seen that s' is shorter in length than s . If r is the radius of the small circle in latitude ϕ , and R is the equatorial

radius of the earth, then $r/R = \cos \phi$. The length of an arc, in units of linear measure, is proportional to the radius of the arc. Hence $s'/s = r/R = \cos \phi$. s' is referred to as the departure, expressed in nautical miles. Also $s' = s \cos \phi$.

DEPOLARIZATION FACTOR OR DEMAGNETIZATION FACTOR. The factor N relating the **depolarization field** \mathbf{E} to the **polarization** \mathbf{P} of the specimen, by the relation $\mathbf{E} = -N\mathbf{P}$. For example, the depolarization factor for a sphere is $4\pi/3$ about any axis. For a circular cylinder (long) it is 2π about a transverse axis, and 0 about a longitudinal axis. For a thin slab, it is 4π about a normal axis, and 0 about an axis in a plane of the slab, etc. All the factors are given in unratinalized units.

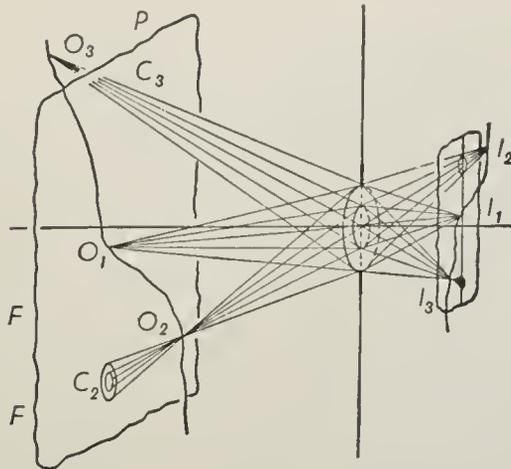

DEPOLARIZATION FIELD. When an electric or magnetic field is applied to a macroscopic specimen, the field acting on a given atom contains a contribution due to the charges or poles induced on the surface of the specimen. This field opposes the external applied field, and hence tends to reduce the **polarization** of the material.

DEPTH, EFFECTIVE. The distance between centroids of the top and bottom flanges of a beam. When the web is designed to carry the shear so that the flanges must carry the entire bending moment, the effective depth multiplied by the area of one flange and by the yield stress gives the moment carrying-capacity for a symmetric beam.

DEPTH OF FIELD. In photography the term depth of field refers to the distance over which satisfactory definition is obtained when the lens is in focus for a certain distance. If, for example, a lens is in focus for an object at a distance of 25' and the definition is satisfactory on objects from 20–40', the depth of field extends from 20–40'. Depth of field is frequently but incorrectly termed depth of focus, which is the range of image distances corresponding to the range of object distances covered by the depth of field.

The depth of field depends upon: 1. The standard adopted for "satisfactory" definition. 2. The distance of the plane on which the lens is in focus. 3. The foetal length of the lens. 4. The relative aperture (f /number). So far as the last three are concerned we may note

(1) that the depth of field increases with the distance of the plane on which the lens is in focus and (2) that it becomes less as the focal length or (3) as the aperture increases.

Let O_3, O_2, O_1 represent an object, parts of which are at different distances from the lens L . Suppose the lens to be focused on O_1 , a point image I_1 will be formed on the focusing screen, or sensitive plate. With the focusing screen, or the sensitive plate, at this point it is clear that the image of O_2 is formed at I_2 behind the screen and that of O_3 at I_3 in front of the screen. In other words, the position of the image point varies with the distance of the object point and the lens cannot produce a point for point image upon a plane surface, such as the sensitive film, unless the subject itself is a plane. When this is not the case, the image of points nearer or further from the lens is a circular disk rather than a point.

Any disk, however, will appear to the eye as a point if the viewing distance is sufficiently great. At a distance of 10", for example, a circle with a diameter of $\frac{1}{100}$ " appears as a point to the average eye. On an angular basis this corresponds to about 2 minutes of an arc.

Since any unsharpness in any part of the negative is increased when an enlargement is made, the disk, or circle of confusion, in an enlargement is equal to the diameter of the disk in the negative multiplied by the degree (times) of enlargement. Thus, if the largest circle allowable for sharp definition is assumed to be $\frac{1}{100}$ " and the print is a $5\times$ enlargement, the maximum diameter of the circle of confusion in the negative is $\frac{1}{100} \times 5$ or $\frac{1}{500}$ " and the depth of field should be calculated accordingly.

If it is assumed that the viewing distance is the distance at which the proper perspective is

obtained, i.e., a distance equal to the focal length of the lens, then the circle of confusion can be expressed as a fraction of the focal length of the lens. The value generally used is 0.00058 or $\frac{1}{1720}$ of the focal length.

If u is the distance focused on, θ is the angular size of circle of confusion ($\frac{1}{1720}$ of the focal length), and τ is the effective diameter of lens or the focal length divided by the f/number , then the nearest point sharply defined in front of the plane in focus is

$$\frac{u^2 \tan \theta}{\tau + u \tan \theta}$$

and the greatest distance beyond the plane in focus is

$$\frac{u^2 \tan \theta}{\tau - u \tan \theta}$$

Tables of depth of field are included in most camera manuals and in reference books.

DERIVATIVE. The derivative $f'(z)$ of a function $f(z)$ of a **complex variable** is the limit, provided it exists and is independent, of the path by which z approaches z_0 , of the difference-quotient, thus,

$$f'(z) = \lim_{z \rightarrow z_0} \frac{f(z) - f(z_0)}{z - z_0},$$

the derivative of a real function being defined analogously.

If $u = f(x, y, z, \dots)$ is a function of several variables, the derivative of u calculated with respect to one of the variables, the others being kept constant, is called a **partial derivative** of u . The partial derivative of u with respect to x

is written in the forms $\frac{\partial u}{\partial x}, u_x$. In case each of the variables x, y, z, \dots on which u depends is itself a function of a single variable t , then

$$\frac{du}{dt} = \frac{\partial u}{\partial x} \frac{dx}{dt} + \frac{\partial u}{\partial y} \frac{dy}{dt} + \frac{\partial u}{\partial z} \frac{dz}{dt} + \dots,$$

which is called a **total derivative** of u . (See also **directional derivative**.)

DERIVATIVE CONTROL. See **control proportional, derivative and integral**.

DERIVATIVE, COVARIANT. See **covariant derivative**.

DERIVATIVE, DIRECTIONAL. If u is a **unit vector**, the quantity $u \cdot \nabla \phi$, its **scalar**

product with the gradient of a scalar function, is the rate of change of ϕ in the direction of \mathbf{u} or the directional derivative of ϕ .

DERIVATIVE, HELMHOLTZ. See Helmholtz derivative.

DERIVATIVE OF TENSOR FIELD, COVARIANT. See covariant derivative of tensor field.

DERIVATIVE, PARTIAL. See partial derivative.

DERIVATIVE, TOTAL. See derivative.

DERIVED SET. The derived set of a given point set is the set of its limit points.

DESCARTES RULE OF SIGNS. The number of positive real roots of the algebraic equation $a_0x^n + a_1x^{n-1} + \cdots + a_{n-1}x + a_n = 0$ is equal to the number of changes of sign in the sequence of coefficients $a_0, a_1, \cdots, a_{n-1}, a_n$ or is less by an even number. The number of negative real roots is equal to the number of changes of sign in $a_0, -a_1, a_2, -a_3, \cdots$, or less by an even number. A special case of the Budan theorem.

DESCRIPTIVE GEOMETRY. The representation on the two-dimensional Euclidean plane of three-dimensional objects. The subject was essentially invented and much developed by Gaspard Monge about 1795.

DESIGN DIAMETER. See blade, twisted.

DESIGN LIFT COEFFICIENT. See thin-airfoil theory.

DESIGN OF EXPERIMENTS. The design of experiments is the science of obtaining unambiguous results of the highest possible accuracy from experiments on variable material. The variability is taken account of in the results by assessing standard errors and fiducial or confidence limits for the estimates derived from an experiment. Three main principles of experimental design may be distinguished:

1. *Replication.* Any treatment must normally be applied to more than one experimental unit. This provides greater accuracy than can be obtained from a single observation, since the experimental errors tend to cancel each other; it also provides a measure of the experimental error derived from the variability between replicates.

2. *Randomization.* The decision as to which experimental unit shall receive which treatment should include a random element. This is designed to ensure that every treatment shall have its fair share of the particularly favorable and the particularly unfavorable experimental units.

3. *Local Control.* Any structure in the properties of the experimental units should be utilized fully. Thus if the units fall into relatively homogeneous groups (neighboring plots in a field, animals from the same litter, etc.) comparisons between treatments should be made as far as possible between units in the same group.

(For particular designs embodying these principles, see randomized blocks, latin squares, lattice designs, balanced incomplete blocks, partially balanced incomplete blocks, Youden squares; see also factorial experiments.)

DESLANDRES TABLE (OF A BAND SYSTEM). See band system.

DESTRUCTION OPERATOR. See creation and annihilation operators.

DETAILED BALANCING, PRINCIPLE OF. A principle which states that in equilibrium the number of processes which destroy a situation A and produce a situation B is equal to the number of processes which destroy B and produce A . This principle is often valid, but not always; in the presence of a magnetic field, for instance, it does not hold for all processes A and B . It was called by Tolman the principle of microscopic reversibility and plays an important role in the derivation of the Onsager relations.

DETECTION OF TABULAR ERRORS (BY MEANS OF DIFFERENCES). This method is based upon the following table, readily verified and extended:

y	δy	$\delta^2 y$	$\delta^3 y$
0		0	
	0		ϵ
0	ϵ	ϵ	-3ϵ
ϵ	$-\epsilon$	-2ϵ	3ϵ
0	0	ϵ	
			$-\epsilon$
0		0	

This shows that the effect of small errors becomes accentuated progressively in the columns of differences.

DETERMINANT. The determinant $|A|$ of an n -rowed square matrix $A = \{a_{ij}\}$ is the sum

$$|A| = \Sigma(\pm)a_{1i_1}a_{2i_2} \cdots a_{ni_n}$$

of the $n!$ products $a_{1i_1}a_{2i_2} \cdots a_{ni_n}$ where $i_1, i_2 \cdots i_n$ is a permutation of the integers $1, 2, \cdots n$, the plus sign being taken if the permutation is even, and the minus sign if it is odd (see **permutation, even or odd**). Thus, if $n = 2$,

$$A = \begin{Bmatrix} a_{11}, & a_{12} \\ a_{21}, & a_{22} \end{Bmatrix}, \text{ then } |A| = a_{11}a_{22} - a_{12}a_{21}.$$

(For various special determinants, **Fredholm, Gram**, etc.: see under the respective names. See also **Laplace expansion**.)

DETERMINANTAL EQUATION. The equation obtained by setting the value of a determinant equal to zero.

DETERMINANTAL WAVE FUNCTION. For a system of N non-interacting particles a **wave function** which is antisymmetric with respect to interchange of any two particles is given in terms of the one particle wave functions by the determinant:

$$\psi = \frac{1}{N!} |\phi_i(r_j)|,$$

where $\phi_i(r_j)$ is the ij entry in the determinant, and represents the j th particle in the i th one particle wave function. For a system of identical particles of half-integral **spin (fermions)** the total wave function of the system (space and spin) must be antisymmetric with respect to interchange of the particles.

DETERMINANT, SLATER. See **Slater determinant**.

DETERMINATE STRUCTURE. A static structure is said to be determinate or statically determinate when the support reactions and the forces and moments at each section of each bar are uniquely determined from the applied loads by statics alone. Forces and moments therefore are independent of the properties of the materials employed. Also, once the load carrying capacity of any member is reached, the structure will fail. (See **indeterminate structure**.)

DETERMINATION, COEFFICIENT OF. The square of the (product-moment) **correlation coefficient** between two variables. More generally, the square of the multiple correlation coefficient between one variate and a set of others.

DETONATION. The process of propagating the reaction front in a combustible mixture which occurs at a very high velocity and during which heating and ignition are done by a shock wave which is created ahead of the combustion front. Detonation is the characteristic mode of combustion which occurs, among others, in explosives.

DEVELOPABLE (SURFACE). A surface that can be rolled out, without stretching or shrinking, onto a plane; it may be defined as a surface whose total **curvature** vanishes everywhere; it is the **envelope** of a one-parameter family of planes. It is also called a *torse*.

DEVELOPABLE, OSCULATING (OF A TWISTED CURVE). The envelope of the **osculating planes** of the curve.

DEVELOPABLE, POLAR (OF A TWISTED CURVE). The envelope of the normal planes of the curve.

DEVELOPABLE, RECTIFYING (OF A TWISTED CURVE). The envelope of the **rectifying planes** of the curve.

DEVIATE, DEVIATION. The deviation of x from a is defined as $x - a$.

If a is the mean, $x - a$ is the deviation from the mean (not the **mean deviation**). The absolute value of the deviation of x from a is $|x - a|$.

If x is a **variate**, the value $x - a$ is often described as a deviate, especially if a is the **mean**.

If P is a probability and $F(x)$ the **distribution function** of a variate x , the variate y defined by

$$P = \int_{-\infty}^y dF(x)$$

is called the *equivalent deviate* of x . y may be regarded as a transformed variate. In particular, if $F(x)$ is the distribution function of a *normal variable*, y is called the *normal equivalent deviate* (N.E.D.).

DEVIATING FORCE. See **geostrophic forc.**

DEVIATION. (1) See **deviate, deviation.**
(2) The angle through which a ray or beam of radiation is bent by diffraction or refraction. (See **angle of deviation.**)

DEVIATION, ANGLE OF. See **angle of deviation.**

DEVIATION LOSS, ANGULAR. Of a **transducer** used for sound emission or reception, an expression, in **decibels**, of the ratio of the reference **response** observed on the principal axis to the transducer response at a specified angle from the principal axis. (See also **directivity pattern.**)

DEVIATION, MINIMUM ANGLE OF. The angle of deviation of a prism (not necessarily triangular) is a minimum if the entrant and exit rays make equal angles with the entrant and exit surfaces of the prism. This angle is of particular interest in prism spectroscopes because it can be easily determined and a simple formula connects the angle A between the planes of the entrant and exit surfaces, the angle of minimum deviation D , and the index of refraction n of the prism,

$$n \sin \frac{1}{2}A = \sin \frac{1}{2}(A + D).$$

If A is small then $D = (n - 1)A$. At the angle of minimum deviation the **resolving power** is independent of A .

DEVIATOR. See **stress deviator; strain deviator.**

DEWAR STRUCTURES. See **benzene, structures of.**

DEW POINT. The temperature at which the actual content of water vapor in an atmosphere is sufficient to saturate the air with water vapor. If the atmosphere contains much water vapor the dew point is higher than in the case of drier air, so that the dew point is an indication of the humidity of the atmosphere. (See also **combustion.**)

DIACAUSTIC. A **caustic** produced by refraction.

DIAGONAL. Any inclined web member of a **truss** other than the end post is known as a diagonal. Under various live load conditions certain web members of a bridge truss may

be subjected to a reversal of stress. Stiff diagonals are web members designed to carry either **tension** or **compression**. Tension diagonals are assumed to be incapable of resisting any appreciable amount of compression.

When the diagonals are designed to take tension only (are not stiff) two are required, sloping in opposite directions, in a panel where either one, acting alone, would have its stress reversed. When one of these diagonals is acting the other is out of action for all practical purposes. The one which carries the **dead load** stress when no other loads are on the bridge is called the main diagonal. The other which comes into play when the main diagonal goes out of action is the counter.

DIAGONAL MATRIX. See **matrix.**

DIAGONAL TENSION. The shear stresses in the web of a beam are equivalent to tension in one 45-degree direction and compression in the other. Concrete must be reinforced to carry this tension. Thin webs of metal may buckle in compression unless they are stiffened by horizontal, vertical or diagonal stiffeners. (See **tension field.**)

DIAGRAM EFFICIENCY. See **blade efficiency.**

DIAGRAM FACTOR. Ratio of area of the real indicator diagram of a reciprocating engine to its ideal value obtained from an idealized diagram. It is equal to the efficiency ratio, η_r .

DIALYTIC. Given two equations for one unknown, namely $f(x) = a_0x^n + a_1x^{n-1} + \dots + a_n = 0$, and $g(x) = b_0x^m + b_1x^{m-1} + \dots + b_m = 0$, let it be required to find the condition on the coefficients a_i, b_j that these equations may be consistent, i.e., may have a common root. The *Sylvester dialytic method* consists of regarding them as linear homogeneous equations in the various powers, including the zeroth, of x . Then multiplying both equations by x gives two new equations with only one new unknown. This process is continued until the number of equations is equal to the number of unknowns. Setting the **determinant** of this system of equations equal to zero gives the desired result.

DIAMAGNETISM. In diamagnetic materials the magnetic susceptibility, χ , is negative and the relative permeability, μ , is less than 1.

Unlike **paramagnetic materials**, whose atoms or molecules have a net magnetic moment, the atoms or molecules of a diamagnetic material have zero magnetic moment in the absence of an external applied field. With the application of an external magnetic field a net **dipole moment**, opposing the field, is induced in the atoms or molecules. In paramagnetic materials there is also a diamagnetic effect but it is much weaker than that of the paramagnetism.

DIAMAGNETISM, LANGEVIN - PAULI FORMULA. The equation for the diamagnetic susceptibility for an assembly of N atoms per unit volume is

$$\chi = - \frac{Ze^2N}{6mc^2} \overline{r^2}$$

where $\overline{r^2}$ is the mean square radial distance of the electrons from their nuclei, and Z is the atomic number. e and m are the electronic charge and mass respectively, and c is the velocity of light. This formula was originally derived classically by Langevin, and corrected quantum-mechanically by Pauli. (See also **Langevin theory of diamagnetism**.)

DIAMAGNETISM OF CONDUCTION ELECTRONS, ORBITAL. See **orbital diamagnetism of conduction electrons**.

DIAPPOINT. The diapoint of a ray in an axially symmetrical optical system is defined as the intersection of the image ray with the plane that passes through an object point and the axis; in the case of a meridional ray, the diapoint is the **sagittal focus**. M. Herzberger has shown that this is a unifying conception in geometric optics, and in particular leads to a simple development of Gullstrand's first-order theory for a **normal congruence**.

DIATHERMAL WALL (ALSO ADIATHERMAL, DIATHERMANEOUS). A perfect heat conductor; assuring equality of temperature on both sides of it. Since in a rigorous development of the principles of thermodynamics it is necessary to introduce the concept of a diathermal wall before the concept of heat, it is necessary to adopt the following alternative definition. If two closed systems are placed in contact (i.e., interact) through a diathermal wall, their states cannot be varied independently of one another. If the state of one system is changed, then in general, the

state of the other system will also change; the systems are coupled. If the state of one system is described by k properties x_i and the state of the other system is described by l properties y_i , then coupling the two systems with the aid of a diathermal wall implies a functional relationship

$$f(x_1, x_2, \dots, x_i, \dots, x_k; y_1, y_2, \dots, y_i, \dots, y_l) = 0.$$

The number of degrees of freedom (independent properties) of the combined system is now $k + l - 1$. (See **adiabatic wall**.)

DIATHERMANEOUS WALL. See **diathermal wall**.

DIATOMIC GAS, DISSOCIATION OF. See **Saha equilibrium formula**.

DIATOMIC MOLECULES, NON-CROSSING RULE. See **non-crossing rule for the potential curves of diatomic molecules**.

DIATOMIC MOLECULES, PARTITION FUNCTION OF. A function which consists to a fair approximation of four factors, relating respectively to the translational, vibrational, rotational, and electronic degrees of freedom. (See **partition function**.)

DIATOMIC ROTATOR, ENERGY LEVELS OF. See **rigid diatomic rotator, energy levels of**.

DICHROIC. (1) A medium is dichroic if it transmits light of different colors depending on either the thickness traversed or on the concentration of the coloring matter in the medium. (2) A medium is dichroic if the reflected light is of a different color than the transmitted light. (3) A crystal is dichroic if it is **pleochroic** with respect to exactly two axes.

DICHROISM, CIRCULAR. See **circular dichroism**.

DIDO'S PROBLEM. The original problem of Dido appears to have been that of finding the curve of given length which encloses a maximum area, the answer being a circle. The problem which is important in the calculus of variations (see **variations, calculus of**), has been generalized in various ways; e.g., by asking that the curve enclose a field of maxi-

imum value, where the fertility varies from point to point.

DIELECTRIC. A material characterized by its relatively poor electrical conductivity, hence an insulator.

DIELECTRIC, ANISOTROPIC. A dielectric medium in which the dielectric constant depends upon the direction along which the electric field is applied. This property is displayed by various crystalline substances and by an ionized gas in a magnetic field.

DIELECTRIC BOUNDARY FORMULAS. Let two different dielectric media, numbered 1 and 2 respectively, meet at a surface S with unit normal \hat{n} drawn from medium 1 into medium 2. If \mathbf{E}_1 and \mathbf{E}_2 are the respective electric vectors and \mathbf{D}_1 and \mathbf{D}_2 the respective electric displacement vectors in these media, then the following relations are satisfied at S :

$$\hat{n} \times (\mathbf{E}_2 - \mathbf{E}_1) = 0, \quad \hat{n} \cdot (\mathbf{D}_2 - \mathbf{D}_1) = \omega$$

where ω is the surface density of free charge distributed over S .

DIELECTRIC CAVITY FIELD. See cavity field in a dielectric.

DIELECTRIC CONSTANT. (1) The absolute dielectric constant is identical with the permittivity ϵ , and is the ratio of the electric field strength \mathbf{E} to the electric displacement \mathbf{D} . In isotropic media ϵ is a scalar, in anisotropic media ϵ is a tensor (see **constitutive equations**). The absolute dielectric constant may also be defined through the Coulomb law for two charges (q_1 and q_2) immersed in a homogenous and isotropic dielectric medium that extends in all directions to distances much greater than r , the distance between the charges: $F = q_1 q_2 / 4\pi\epsilon r^2$ in rationalized units. In non-rationalized units, the corresponding expression is $F = q_1 q_2 / \epsilon r^2$.

(2) The relative dielectric constant is the ratio of the absolute dielectric constant for a medium to that for free space (ϵ/ϵ_0). In the esu system of units the relative and absolute dielectric constants are the same.

Whereas for static fields the dielectric constant is a real number, for periodic fields, it is usually a complex quantity (see **dielectric constant; electrical displacement in dielectrics**). Debye has shown that, if in a static field, equilibrium is reached exponentially in

time, then

$$\epsilon(\omega) - \epsilon_\infty = \frac{(\epsilon_s - \epsilon_\infty)}{1 - i\omega\tau}$$

$\epsilon(\omega)$ is the dielectric constant in a periodic electric field $\mathbf{E} = \mathbf{E}_0 \cos \omega t$. ϵ_∞ and ϵ_s are the limiting values of $\epsilon(\omega)$ for very large and zero frequencies, respectively. τ is the relaxation time of the dielectric. (See also **Kirkwood formula for the static dielectric constant; Debye equation for the dispersion of the dielectric constant**.)

DIELECTRIC CONSTANT, COMPLEX. The ratio of the static capacitance C of a capacitor filled with a dielectric medium to its geometrical or vacuum capacitance is $C/C_0 = \epsilon/\epsilon_0 = k$, where ϵ and ϵ_0 are the permittivities of the medium and of free space, respectively, and k is the relative dielectric constant. If the medium is dissipative (either because it is not a perfect insulator, so that real currents can flow through it, or because there is frictional resistance to induced polarization currents), the a-c behavior of the capacitance is equivalent to that of a resistance in parallel with a capacitance. The effect of this resistance can be incorporated into the dielectric constant, which then becomes a complex quantity denoted by $k^* = \epsilon^*/\epsilon_0$, which can be written as $k^* = k' - jk''$. The imaginary coefficient (k'') is called the *loss factor*, $\tan \delta = k''/k'$ is called the *loss tangent*, and δ is called the *loss angle*.

DIELECTRIC CONSTANT, PLASMA. A plasma in a magnetic field of magnitude \mathbf{B} , can be considered to have a dielectric constant ϵ given by

$$\epsilon = 1 + \frac{4\pi\rho c^2}{\mathbf{B}^2}$$

where ρ is the mass density and c is the velocity of light.

DIELECTRIC CONSTANT, RELATION TO INDEX OF REFRACTION. See Maxwell relation between dielectric constant and refractive index.

DIELECTRIC DISSIPATION FACTOR. The cotangent of the dielectric phase angle of a dielectric material.

DIELECTRIC HYSTERESIS. An effect in a dielectric material analogous to the hysteresis found in magnetic materials. (See **ferroelectricity**.)

DIELECTRIC, INVERSION FIELDS IN. See **inversion fields in dielectrics**.

DIELECTRIC, ISOTROPIC. A dielectric medium in which the **dielectric constant** is independent of the direction of the applied field.

DIELECTRIC LOSS ANGLE. See **dielectric constant, complex**.

DIELECTRIC PHASE ANGLE. The angular difference in phase between the sinusoidal alternating voltage applied to a dielectric and the component of the resulting alternating current having the same period as the voltage.

DIELECTRIC POWER FACTOR. The cosine of the **dielectric phase angle**.

DIELECTRIC, REACTION FIELD IN. See **reaction field in a dielectric**.

DIELECTRIC RELAXATION. That part of the **dielectric constant** of a solid which depends on the orientation of the **dipole moments** of the molecules is subject to the phenomenon of relaxation. A certain time is required for the assembly of dipoles to come into equilibrium with the applied field. (See **relaxation** and related entries.)

DIELECTRIC, SELF ENERGY IN. See **self energy in a dielectric**.

DIELECTRIC STRENGTH. The maximum potential gradient (**electric field strength**) that a material can withstand without rupture.

DIESEL CYCLE. See **diesel engine**.

DIESEL ENGINE. (Also known as a compression-ignition engine.) A type of reciprocating internal combustion engine in which air is induced into, and then compressed nearly adiabatically in a cylinder by a piston moving in it. The compression raises the temperature of the air to a point where the subsequent, timed injection of a spray of liquid fuel causes the latter to ignite and to burn, thus producing useful mechanical work.

A diesel engine can operate either as a two-stroke or as a four-stroke engine. The operation of a diesel engine is illustrated by the

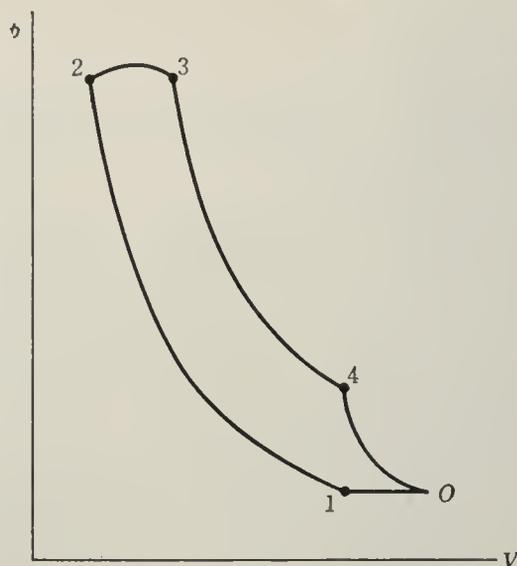

Fig. 1. p,V diagram of two-stroke diesel cycle.

two-stroke cycle shown in Figure 1. In this case, one working stroke occurs for every one revolution, and the sequence of operations is as follows:

- 0-1. Scavenging and introduction of fresh intake of air.
- 1-2. Compression to a temperature higher than ignition temperature of fuel.
- 2-3. Combustion, which occurs in some diesel-engine types nearly at constant pressure.
- 3-4. Expansion; working stroke.
- 4-0. Release.

In a four-stroke engine, the intake of air and release of the burnt gases is governed by valves

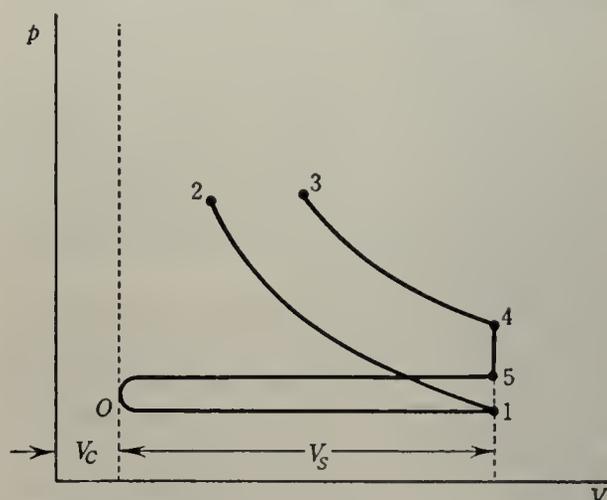

Fig. 2. p,V diagram of four-stroke diesel cycle.

and affects only the lower portion of the diagram, Figure 2. Here the following operations occur:

- 0-1. Introduction of air. Inlet valve open.
- 1-2. Compression of air. Valves closed.
- 2-3. Combustion as before; not shown.
- 3-4. Expansion. Working stroke; valves closed.
- 4-5. Release. Exhaust valve open.
- 5-0. Expulsion of burnt gases. Exhaust valve open.

It is customary to analyze diesel engines by making the following assumptions:

During the entire cycle the gas contained in the cylinder remains unchanged both in quantity and in composition. The addition of heat is effected by transfer from an outside source, instead of by combustion. The rejection of heat is effected by transfer to an outside sink instead of by expulsion of exhaust gases (during this cooling, the volume of the gas in the cylinder remains constant). It is further assumed that the gas in the cylinder obeys the **ideal gas law** (i.e., is a perfect gas) and that its specific heat does not vary, but is constant throughout the cycle.

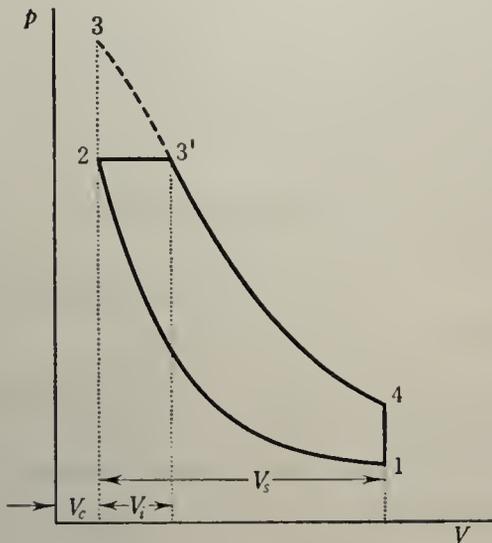

Fig. 3.

In this manner the efficiency of the engine is judged in relation to the diesel cycle shown in Figure 3. In it

$$r = \frac{V_1}{V_2} = \frac{V_c + V_s}{V_c}$$

denotes the compression ratio (which is a ratio of volumes, not pressures), and

$$\rho = \frac{V_c + V_i}{V_c}$$

is the cut-off ratio, which is a measure of the length of injection cycle. Then, the thermal efficiency of the cycle is given by

$$\eta_{th} = 1 - \frac{1}{\gamma r^{\gamma-1}} \frac{\rho^\gamma - 1}{\rho - 1}$$

where γ is the ratio of specific heats c_p/c_v , on the assumption that compression and expansion are isentropic.

The combustion process in a modern high-speed diesel engine does occur not even approximately at constant pressure. In order

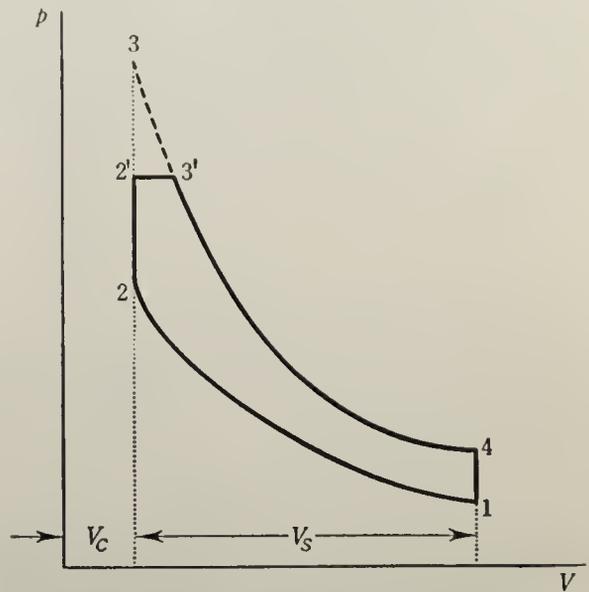

Fig. 4. p, V diagram of dual (combustion) diesel cycle.

to analyze such engines it is assumed that some combustion occurs at constant volume, which is followed by some combustion at constant pressure. The resulting cycle is called a *dual (combustion) cycle*, Figure 4. Its efficiency is

$$\eta_{th} = 1 - \frac{\beta \rho^\gamma - 1}{r^{\gamma-1} [\beta - 1 + \gamma^\beta (\rho - 1)]}$$

Here $\beta = P_{2'}/P_2$ is a measure of the length of time during which the fuel burned at constant volume.

Modern engines operate on compression ratios in the range $r = 10$ to 16 or 18. There exist many varieties of diesel engines which differ from each other in their details of design. At the present time the diesel engine has the highest overall efficiency.

DIETERICI EQUATION. An equation of state relating pressure, volume, and temperature of gas, and the gas constant. The

Dieterici equation applies a correction to the **van der Waals equation** to allow for variation in density throughout a gas, due to the higher potential energies of molecules on or near the boundaries. One form of this equation is

$$P = \frac{RT}{V - b} e^{-a/RTV}$$

in which P is the pressure of the gas, T is the absolute temperature, V is the volume, R is the gas constant, e is the natural log base 2.718 . . . , and a and b are constants.

DIFFERENCE, CENTRAL. If h is the interval between equally spaced values of the **argument** in a **difference table** constructed from $y = f(x)$, it is convenient to define

$$\delta f(x) = f\left(x + \frac{h}{2}\right) - f\left(x - \frac{h}{2}\right);$$

$$\mu f(x) = \frac{1}{2} \left[f\left(x + \frac{h}{2}\right) + f\left(x - \frac{h}{2}\right) \right]$$

A central difference, formed by the first of these operators, is related to a **finite difference** by the equation

$$\delta^m y_{n/2} = \Delta^m y_{(n-m)/2}$$

where m and n are integers, both even or both odd. These quantities are used near the middle of a difference table, as in the **Bessel** and **Stirling formulas for interpolation**.

DIFFERENCE, DIVIDED. If y_0, y_1, y_2, \dots are values of $y = f(x)$, corresponding to x_0, x_1, x_2, \dots , not necessarily evenly spaced, then

$$[x_i x_j] = \frac{y_i - y_j}{x_i - x_j}$$

is a first-order **divided difference** of $f(x)$. Second-order differences, third-order differences, etc., are defined in a similar way, thus the n th order divided difference is

$$[x_0 x_1 \dots x_n] = \frac{[x_0 x_1 \dots x_{n-1}] - [x_1 x_2 \dots x_n]}{x_0 - x_n}$$

These quantities are used for **interpolation** of tabulated functions when the given data are unequally spaced.

DIFFERENCE EQUATION. Any equation involving finite differences. The usual methods for solving **differential equations** reduce to the solution of difference equations, with either

the derivatives or the integrals expressed approximately in terms of finite differences. (See **differentiation formulas, quadrature formulas, ordinary differential equations, and partial differential equations.**)

DIFFERENCE LIMEN (DIFFERENTIAL THRESHOLD) (JUST NOTICEABLE DIFFERENCE). The increment in a stimulus which is just detected in a specified fraction of the trials. The relative difference limen is the ratio of the difference limen to the absolute magnitude of the stimulus to which it is related. According to the Weber law, the relative difference limen is a constant. This law is only approximately true.

DIFFERENCE NUMBER. The same as **neutron excess**.

DIFFERENCE OPERATORS. For interpolation based upon equally spaced points, most standard formulas, as well as others, can be developed and expressed easily in terms of a few difference operators which can be manipulated formally as algebraic quantities. In their definition given below it is to be understood that they have no existence independent of the functions upon which they operate. Understanding that $\Delta x = h$ is fixed, the operators are defined as follows:

$$E^u f(x) = f(x + uh)$$

[displacement operator];

$$\Delta f(x) = f(x + h) - f(x)$$

[forward difference operator];

$$\nabla f(x) = f(x) - f(x - h)$$

[backward difference operator];

$$\delta f(x) = f(x + h/2) - f(x - h/2)$$

[central difference operator];

$$2\mu f(x) = f(x + h/2) + f(x - h/2)$$

[central mean operator];

$$Df(x) = df(x)/dx$$

[differential operator];

$$\theta f(x) = hdf(x)/dx.$$

The last operator is not in common use, but simplifies the writing of some formulas and may be called the *logarithmic displacement operator*. For functions of several variables, subscripts can be used to specify the variable with respect to which the operator acts. Thus

$$E_x f(x, y, \dots) = f(x + h, y, \dots).$$

All operators can be defined formally in terms of one of them. Thus

$$\Delta = E - 1, \quad \nabla = 1 - E^{-1}, \quad E = \exp \theta,$$

the last being the operational expression of the Taylor series.

Examples of the application of these relations are to be found under appropriate headings, but the following illustration may be in order here. Let

$$x = x_0 + uh, \quad u = (x - x_0)/h, \\ f(x) = E^u f(x_0).$$

Since $E = 1 + \Delta$, therefore, by the binomial theorem,

$$E^u = 1 + \binom{u}{1} \Delta + \binom{u}{2} \Delta^2 + \binom{u}{3} \Delta^3 + \dots$$

and therefore, formally, taking $x_i = x_0 + ih$, one has

$$f(x) = f(x_0) + \frac{x - x_0}{h} \Delta f(x_0) \\ + \frac{(x - x_0)(x - x_1)}{2!h^2} \Delta^2 f(x_0) + \dots$$

Unless u is a non-negative integer this is an infinite series, but for purposes of interpolation the series is truncated by dropping all but the first several terms. If all terms are dropped beyond that containing $\Delta^n f(x_0)$, then there is retained on the right that n th degree polynomial that passes through the $n + 1$ points whose coordinates are

$$x_i, f(x_i), \quad i = 0, 1, \dots, n,$$

and the formula is *Newton's interpolation formula* with forward differences. If one writes $E = (1 - \nabla)^{-1}$ and proceeds similarly one obtains *Newton's interpolation formula* with backward differences:

$$f(x) = f(x_0) + \frac{x - x_0}{h} \nabla f(x_0) \\ + \frac{(x - x_0)(x - x_{-1})}{2!h^2} \nabla^2 f(x_0) + \dots$$

It is to be noted that the binomial coefficients

$$\binom{u}{r} = \frac{u(u-1) \cdots (u-r+1)}{r!}$$

are defined even when u is not a positive integer, and they are polynomials in u . Some-

times the symbol $u_{(r)}$ is used, and related to these polynomials are the factorial polynomials

$$u^{(r)} = u(u-1) \cdots (u-r+1) = r! u_{(r)}.$$

Note that

$$\Delta u^{(r)} = r u^{(r-1)}, \quad \Delta u_{(r)} = u_{(r-1)}.$$

DIFFERENTIAL. The differential dx of an independent variable x is itself an independent variable (the increment of x may be taken at will). The differential dy of a dependent variable $y = f(x)$ is defined as the product $dy = f'(x)dx$. The differential dy is a useful approximation to the actual increment of y . Similarly, if $z = f(x, y)$, then the differential dz of z (also called the total or exact differential) is defined by $dz = f_x(x, y)dx + f_y(x, y)dy$, where f_x, f_y are partial derivatives (see **derivative**). The differential may also be defined for more general cases.

DIFFERENTIAL ANALYZER. A computer, generally an **analog computer**, designed for the purpose of solving **differential equations**.

DIFFERENTIAL EQUATION. An equation which relates, for each choice of the independent variable(s), the values of one or more dependent variables and one or more **derivatives** of each. It is an **ordinary differential equation** in case only a single independent variable occurs; a **partial differential equation** when there are two or more. For a dependent variable to be uniquely defined as a function of the independent variable(s), there must be associated a sufficient number of initial or boundary conditions, or a combination of both. (For specific differential equations, Bessel, Laplace, etc., see respective names. For methods of numerical solution see **ordinary differential equations**, **partial differential equations**, **elliptic equations**, **parabolic equations**, and **hyperbolic equations**.)

DIFFERENTIAL EQUATIONS, BOUNDARY VALUE PROBLEM IN. See **boundary value problem**.

DIFFERENTIAL EQUATIONS, HOLO-NOMIC. See **conservative force**.

DIFFERENTIAL EQUATIONS, NON-HOLONOMIC. See **conservative force**.

DIFFERENTIAL EQUATIONS, RHEONOMIC. See **conservative force**.

DIFFERENTIAL EQUATIONS, SCLERONOMIC. See conservative force.

DIFFERENTIAL FORM (OF DEGREE r IN n -DIMENSIONS). A homogeneous polynomial of degree r in n differentials, e.g., dx^i or dx_i ($i = 1, 2, \dots, n$), the coefficients in which are functions of x^i or x_i .

DIFFERENTIAL HEAT OF MIXING. See heat of dilution.

DIFFERENTIAL OPERATOR. See operator; difference operators.

DIFFERENTIAL OPERATORS, SPINOR. See spinor calculus.

DIFFERENTIAL PARAMETERS, BELTAMI. See Beltami differential parameters.

DIFFERENTIAL PROCESS. In statistics, a synonymous term for additive process.

DIFFERENTIAL THEOREM. See Laplace transform theorems.

DIFFERENTIATION. The process of finding a derivative. *Logarithmic differentiation* consists of finding the derivative of a function by first differentiating its logarithm.

DIFFERENTIATION FORMULAS (NUMERICAL). A quite general procedure for carrying out numerical differentiation is to use interpolation, or least squares, or some other method for approximating the function of interest, and then to differentiate the approximating function. When the points of interpolation are unequally spaced one can use divided differences to form an interpolation polynomial.

When the points are uniformly spaced, a number of convenient formulas can be derived by means of difference operators. Since

$$hD = \theta = \log(1 + \Delta) = -\log(1 - \nabla),$$

one obtains

$$\begin{aligned} \theta &= \Delta - \Delta^2/2 + \Delta^3/3 - \dots \\ &= \nabla + \nabla^2/2 + \nabla^3/3 + \dots, \end{aligned}$$

in terms of forward and backward differences, respectively. Derivatives of higher order can be obtained by raising to higher powers the expressions for θ .

Expressions in terms of central differences require more manipulation to obtain, but one finds

$$\begin{aligned} \theta &= \mu[\delta - \delta^3/3! + (2!)^2\delta^5/5! \\ &\quad - (3!)^2\delta^7/7! + \dots], \end{aligned}$$

$$\begin{aligned} \theta^2 &= 2[\delta^2/2! - \delta^4/4! + (2!)^2\delta^6/6! \\ &\quad - (3!)^2\delta^8/8! + \dots]. \end{aligned}$$

To obtain higher powers write $\theta^3 = \theta \cdot \theta^2$, $\theta^4 = (\theta^2)^2$, $\theta^5 = \theta \cdot \theta^4$, \dots . To apply, one truncates the series at some point, and if desired one can replace Δ , ∇ , δ and $\mu\delta$ by their expressions in terms of E .

In case the derivative is required at a point other than a tabulated one, say at $x_0 + uh$, one must apply E^u , expressing E in terms of the appropriate difference operator. However, the error can be expected to be substantially greater. (See Stirling numbers.)

DIFFERENTIATION UNDER THE INTEGRAL SIGN. The derivative, with respect to the parameter, of a definite integral of a function $f(x, m)$ containing a parameter m , when the limits of the integral are constants a and b , is given by

$$\frac{d}{dm} \int_a^b f(x, m) dx = \int_a^b \frac{\partial f}{\partial m} dx$$

and when the limits of the integral are u and v , functions of m , by

$$\begin{aligned} \frac{d}{dm} \int_u^v f(x, m) dx \\ = \int_u^v \frac{\partial f}{\partial m} dx + f(v, m) \frac{dv}{dm} - f(u, m) \frac{du}{dm}. \end{aligned}$$

DIFFLUENCE. The rate at which adjacent flow is diverging along an axis oriented normal to the flow at the point in question; the opposite of confluence. A difffluence formula, especially useful in meteorology, is

$$\frac{\partial v_n}{\partial n} \quad \text{or} \quad V \frac{\partial \psi}{\partial n},$$

where V is the speed of the wind, the n axis is oriented 90 degrees clockwise from the direction of the wind vector, v_n is the wind component in the n direction and ψ is the wind direction measured in degrees clockwise from a reference direction.

DIFFLUENCE REGION. A region in which the spacing between streamlines increases in the direction of flow.

DIFFRACTION. The deviation of the direction of propagation of a wave, determined by its undulatory character, and occurring when the wave passes the edge of an obstacle, or through a restricted aperture. Diffraction phenomena are characteristic of all wave systems. They are found in water waves, matter waves (e.g., wave phenomena exhibited by electrons, neutrons, etc.), sound waves and electromagnetic waves of all frequencies. They produce patterns which are geometrically similar whenever the relation of the wavelength to the geometry of the obstacle or aperture is the same. (See **wave, diffracted; Fresnel diffraction; Fraunhofer diffraction; Airy disc; rectangular aperture; diffraction grating; slit.**)

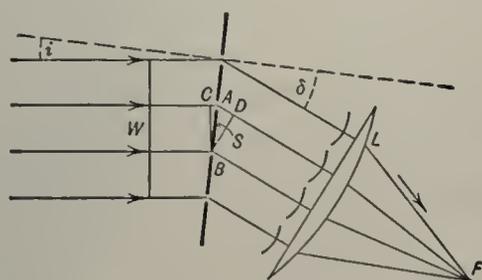

DIFFRACTION, ANGLE OF. See **angle of diffraction.**

DIFFRACTION EVOLUTE. When an object casts a shadow on a plane due to the illumination from a point source, the predominant diffraction figure formed within the shadow is the evolute of the boundary of the shadow and so called a diffraction evolute. When the shadow is circular, the diffraction evolute is an **Arago spot.**

DIFFRACTION, FRAUNHOFER. See **Fraunhofer diffraction.**

DIFFRACTION, FRESNEL. See **Fresnel diffraction.**

DIFFRACTION GRATING, ACTION OF IDEAL PLANE WAVE. A plane, monochromatic light wave W , incident at angle i (see figure), reaches the slits at different times. A

Diffraction by a plane grating.

lens L receives the waves emerging from any two adjacent slits, A and B (among many others), after they have traveled paths differing by $CA + AD$; that is, by $S \sin i + S \sin \delta$, in which $S = AB$. If the lens is so placed that this path difference is a whole number of

wavelengths, $n\lambda$, the successive wave-trains will reach it in the same phase, so that when they are brought to the focus F , they will be in synchronism and will produce a bright image of the distant source. Therefore any angle δ for which this result is possible is subject to the condition

$$S \sin i + S \sin \delta = n\lambda,$$

or

$$\sin \delta = \frac{n\lambda}{S} - \sin i.$$

Bright images will be produced for those angles δ which correspond to $n = 1, 2, 3, 4, \dots$; the numbers denote the "orders" of the images. It is easily shown that for any order the total deviation ($i + \delta$) is least when $\delta = i$ and therefore when

$$\sin \delta = \frac{n\lambda}{2S}.$$

If the incident light is composed of various wavelengths, the corresponding images of any order will appear at different points, since δ varies with λ ; and the result is a **spectrum.**

DIFFRACTION OF NEUTRONS, ANGULAR. When a well collimated beam of slow neutrons (whose de Broglie wavelength λ is of the order of angstroms) falls at a glancing angle upon a crystal, it is preferentially scattered, or reflected, when the angle between the beam and the crystal plane, θ , obeys the Bragg relation

$$n\lambda = 2d \sin \theta$$

where d is the spacing of the crystal planes and n is an integer. Thus slow neutrons behave much as do x-rays in this respect, and have consequently been much used for the investigation of crystal structure. Whereas x-rays are scattered most strongly by atoms of high atomic number Z , however, neutrons are scattered most strongly by protons, i.e., hydrogen atoms. Thus, neutron and x-ray diffraction techniques are largely complementary. In addition neutron diffraction may be used to study the structure of magnetic crystals owing to the scattering which can take place due to the neutron's magnetic moment.

DIFFRACTION PATTERNS. Interference patterns produced by the diffraction of light or x-rays by crystals, slits, liquids, and so on.

DIFFRACTION SPECTRUM. See spectrum, diffraction.

DIFFRACTION THEORY OF ABERRATIONS. See Nijboer-Zernike aberration functions.

DIFFUSER. A duct in which the velocity of a fluid is gradually reduced, with a corresponding increase of pressure. For an effectively incompressible fluid the *efficiency of a diffuser* is defined as the ratio of the actual pressure rise to the pressure rise calculated for the given shape of diffuser with an inviscid fluid. The simplest form of diffuser for subsonic flow consists of a straight tapered duct of circular section. For this case, if the subscripts 1 and 2 refer to the inlet and outlet, respectively, the efficiency for an incompressible fluid is

$$\frac{p_2 - p_1}{\frac{1}{2}\rho V_1^2 \left[1 - \left(\frac{d_1}{d_2} \right)^4 \right]}$$

where V_1 is the velocity at inlet (assumed uniform), d is diameter and p is pressure. Efficiencies up to about 90% can be obtained, with cone angles of about 6 to 8 degrees. For large cone angles separation occurs and the efficiency is much reduced.

For a compressible fluid the efficiency of a diffuser is usually defined as

$$\left\{ \begin{array}{l} \text{Work required per unit mass of fluid for} \\ \text{isentropic compression from inlet pressure} \\ v_1 \text{ to actual outlet pressure } p_2 \end{array} \right\}$$

Kinetic energy of fluid per unit mass, at entry

For a perfect gas this efficiency is equal to

$$\frac{(p_2/p_1)^{\frac{\gamma-1}{\gamma}} - 1}{\left(\frac{\gamma-1}{2} \right) M_1^2}$$

where γ is the ratio of specific heats and M_1 is the inlet Mach number.

When the flow is supersonic at the inlet to the diffuser, as in a diffuser for a supersonic wind tunnel or an air intake for an engine in supersonic flight, part of the compression takes place through one or more shock waves. The efficiency can then be improved by designing the diffuser so that the compression is shared between a number of relatively weak shock waves instead of occurring in one strong one.

DIFFUSE REFLECTANCE. The ratio of the luminous flux diffusely reflected in all directions (other than that of direct reflection) to the total incident flux.

DIFFUSE REFLECTION. A matte surface is continuous but not smooth, i.e., belongs to class C_0 but not class C_1 . When a matte surface is an interface between two media, the resulting reflection of light is diffuse. **Interfaces** belonging to class C_1 produce **regular** or **specular reflections** or refractions.

DIFFUSE SERIES. Series of lines in the spectra of the simpler atoms, the alkalis, alkaline earths, helium, etc., corresponding to transitions from an upper D state to a lower P state.

DIFFUSE TRANSMITTANCE. The ratio of the luminous flux diffusely transmitted in all directions (other than that of direct transmission) to the total incident flux.

DIFFUSION. (1) The process by which molecules intermingle as a result of their random thermal motion. In gases and in liquids in the neighborhood of the **critical point**, the molecular motion resembles a **random walk**, and the diffusion coefficient is of order $\frac{1}{3}\bar{c}\lambda$, where \bar{c} is the mean thermal velocity of a molecule and λ is the **mean free path** of a free molecule. If the liquid is more highly condensed, diffusion depends on thermally induced movements from one stable position in the local lattice to another one, as in diffusion of solids. Diffusion in liquids is extremely slow, but it may be accelerated by inducing a turbulent flow which mingles the separate components intimately and allows molecular diffusion to take place down greatly increased local intensity gradients.

(2) The passage of particles through matter in such circumstances that the probability of scattering is large compared with that of leakage or absorption. It is often limited to phenomena described by a member of the class of differential equations known as diffusion equations.

DIFFUSION AREA, NEUTRON. This area is the square of the **diffusion length** and is equal to one-sixth of the mean square distance traveled by a diffusing neutron, from source to capture.

DIFFUSION BY TURBULENCE. The transport by turbulent motion of a property of the fluid (e.g., momentum, heat, pollution). The process might be described precisely if sufficient detail were permitted, but in the complicated motions conveniently described as turbulence only the mean properties are of importance and the mixing processes are then regarded as equivalent to molecular diffusion, though with a different coefficient.

The distance X traveled by a particle (e.g., of pollution) carried by the motion in time T is given by

$$\overline{X^2} = 2\overline{u'^2} \int_0^T \int_0^t R_\xi d\xi dt$$

where R_ξ is Taylor's autocorrelation coefficient.

DIFFUSION COEFFICIENT. See diffusion, Fick law; transport coefficient.

DIFFUSION COEFFICIENT-MOBILITY RELATION. See Einstein relationship between mobility and diffusion coefficient.

DIFFUSION COEFFICIENT OF ELECTRONS. The variation of concentration n_e of mobile electrons in a semiconductor (see density of mobile charges in semiconductors) obeys the generalized diffusion equation

$$\frac{\partial n_e}{\partial t} = \nabla \cdot (D_e \nabla n_e) + \nabla \cdot (n_e \mu_e \mathbf{E}) - s$$

where D_e is the diffusion coefficient, $\mu_e = eD_e/kT$ where e is the electronic charge, k is Boltzmann's constant, T is the absolute temperature, \mathbf{E} is the electric field strength, and s is the net rate of disappearance of electrons from the conduction band due to trapping, recombination, etc.

An analogous equation holds for the diffusion of holes where the sign of \mathbf{E} is changed.

DIFFUSION COEFFICIENT OF GASES. See diffusion, kinetic theory of.

DIFFUSION COEFFICIENT OF NEUTRONS. When neutron transport through matter is described by diffusion equations governed by Fick's law, the diffusion constant, D , is given as:

$$D = \frac{1}{3\Sigma_s(1 - \overline{\cos \theta})}$$

where Σ_s is the macroscopic scattering cross-section and $\overline{\cos \theta}$ is the average value of neutron scattering angle, θ , in the scattering process.

$\overline{\cos \theta}$ is often put equal to $\frac{3}{2M}$ for scattering by

a nucleus of mass M . For diffusion in a mixture the average diffusion coefficient \bar{D} is given by

$$\frac{1}{\bar{D}} = \sum_i \frac{1}{D_i}$$

DIFFUSION CONSTANT IN A HOMOGENEOUS SEMICONDUCTOR. The quotient of diffusion current density by the charge carrier concentration gradient. It is equal to the product of the drift mobility and the average thermal energy per unit charge of carriers.

DIFFUSION COOLING. In the transport theory of neutrons (see neutron transport theory), this effect refers to the change in the spectrum of thermal neutrons in a moderator caused by the preferential leakage of the faster neutrons.

DIFFUSION EQUATION. See diffusion, Fick law; neutron diffusion theory.

DIFFUSION FACTOR. The diffusion factor (of a secondary source) is the ratio of the arithmetic mean of the values of luminance measured at 20° and 70° to the luminance measured at 5° from the normal, when the secondary source considered is illuminated normally. (1) This quantity is intended to give an indication of the spatial distribution of the diffused flux. The diffusion factor is unity for every uniform diffuser, whatever the value of the diffuse reflection factor. (2) This conception applies both to reflection and to transmission. (3) The C. I. E. at its 10th session (1939) agreed that this form of definition can only be applied to materials for which the indicatrix of diffusion does not differ appreciably from that of ordinary depolished and opal glasses.

DIFFUSION, FICK LAW OF. An empirical relation which states that the diffusion flux, i.e., the quantity of matter or number of particles crossing area A in the direction of the normal n to a surface in a mass transfer process is proportional to the gradient of the concentration c . Hence

$$\mathbf{Q} = -DA \text{ grad } c \quad (1)$$

$$= -DA \frac{dc}{dn}, \quad (2)$$

Formula (2) for flow in one dimension. Making use of the principle of conservation of mass, this equation may be written

$$\nabla^2 c = -\frac{1}{D} \frac{\partial c}{\partial t}. \quad (3)$$

The factor D (in ft²/hr or m²/hr) is known as the *diffusion coefficient*. The Fick law for diffusion is similar to the **Fourier law** for conduction.

DIFFUSION, FORCED. If, in addition to a concentration gradient, there is a steady average force \mathbf{F} acting on the molecules, the simple Fick law must be modified to read

$$\mathbf{J} = -D(\text{grad } n - \frac{n\mathbf{F}}{kT}),$$

where n is the concentration in molecules per unit volume (see **diffusion, Fick law**). The force \mathbf{F} may, for example, be the force of gravity mg as in sedimentation, or the electric force $ze\mathbf{E}$ on an ion of valence z in an electric field of intensity \mathbf{E} .

DIFFUSION INDICATRIX. See **indicatrix of diffusion**.

DIFFUSION KERNEL. See **kernel, diffusion**.

DIFFUSION, KINETIC THEORY OF. In a gas in which there exists a concentration gradient, more particles will move towards the regions of lower concentration than away from them. The diffusion coefficient D is defined by the equation

$$w = -D \frac{dn}{dx},$$

where dn/dx is the concentration gradient and w the net flux of particles in the x -direction. From a consideration of the number of particles crossing a unit area perpendicular to the x -direction either in the positive or in the negative x -direction one finds

$$D = c\lambda v,$$

where c is a numerical constant of order unity, λ the **mean free path**, and v the mean velocity of the particles.

DIFFUSION LENGTH, GENERAL. The mean distance traveled by a diffusing particle from the point of its formation to the point at which it is absorbed. In a homogeneous **semi-conductor**, the particle is a minority carrier.

DIFFUSION LENGTH, NEUTRONS. The quantity $L = \sqrt{D/\Sigma_a}$ where D is the diffusion coefficient and Σ_a the macroscopic absorption cross section characterizing the medium through which neutrons diffuse. The diffusion equation, describing steady-state transport in a homogeneous source-free medium assumes the form,

$$\left(\nabla^2 - \frac{1}{L^2}\right)\Phi = 0.$$

DIFFUSION OF LIGHT. The alteration of the spatial distribution of a beam of light which, after reflection at a surface or passage through a medium, travels on in numerous directions. (See **perfect diffusion; indicatrix of diffusion**.)

DIFFUSION OF SOLIDS. Solids in close contact may diffuse into each other, the rates of diffusion being exponentially related to the absolute temperature and to the time.

A solid may diffuse into itself, the coefficient of self-diffusion depending on temperature according as

$$D = D_0 \exp(-E_A/RT)$$

where E_A is an **activation energy**, and R is the gas constant.

DIFFUSION STABILITY. (See **thermodynamic stability conditions, stability of phases**.) In systems containing more than one component, the initial uniform phase is stable in respect to a perturbation consisting of the appearance of a heterogeneity in composition. Stability conditions with respect to perturbations of this kind are called **diffusion stability conditions**.

In a binary system at constant p and T the diffusion stability condition is

$$\frac{\partial^2 g}{\partial x_A^2} > 0 \quad (1)$$

where

$$g = \frac{G}{n} \quad (2)$$

is the Gibbs free energy per mole (see **thermodynamics, characteristic functions** of) and x_A , the mole fraction of component A .

DIFFUSION THEORY, BOUNDARY. See boundary conditions, diffusion theory.

DIFFUSION THEORY, MULTIGROUP NEUTRON. See neutron diffusion theory, multigroup.

DIFFUSION THEORY, NEUTRON. See neutron diffusion theory.

DIFFUSION TIME, NEUTRON. In nuclear reactor theory, the average time spent by a thermal neutron from its appearance as thermal, to its capture. It is approximately equal to $(\Sigma_a(vp)vp)^{-1}$ where vp is the most probable neutron speed in the distribution of thermal neutrons and Σ_a is the macroscopic absorption cross-section characteristic of the moderator.

DIFFUSION VELOCITY. The flow of component γ (see Equation (3) of **conservation of mass in continuous systems**) can be decomposed into a flow with the average mass velocity ω (see Equation (2) of **conservation of mass in continuous systems**) and a diffusion flow relative to ω

$$\rho_\gamma \omega_\gamma = \rho_\gamma \omega + \rho_\gamma (\omega_\gamma - \omega) = \rho_\gamma \omega + \rho_\gamma \Delta_\gamma \quad (1)$$

where Δ_γ denotes the diffusion velocity with respect to ω . We may note that

$$\sum_\rho \rho_\gamma \Delta_\gamma = 0. \quad (2)$$

(See **flux vectors**.)

DIFFUSIVITY. See **Fourier law**.

DIGITAL COMPUTER. As contrasted with **analog computer**, a computing aid that represents numbers digitally, in decimal, binary, or (conceivably) other base. The simplest artificial example is the abacus, which represents numbers digitally in such a way as to facilitate carrying out additive operations, hence multiplication and division as sequences of these. Desk computers perform these operations automatically, and sometimes also square-rooting or other special sequences. The very high speed, general purpose computers are **stored-program computers** and are digital.

DIGITAL COMPUTER, PARALLEL. A digital computer in which the digits are

handled in parallel. Mixed serial and parallel machines are frequently called serial or parallel according to the way arithmetic processes are performed. (See also **digital, computer, serial**.)

DIGITAL COMPUTER, SERIAL. A digital computer in which the digits are handled serially. Mixed serial and parallel machines are frequently called serial or parallel according to the way arithmetic processes are performed. (See also **digital, computer, parallel**.)

DIGITS (SIGNIFICANT). The significant digits of a number like 2301 or 0.02301, etc., are those digits which determine the ratio of the error (5 in the next decimal place) to the number. Thus, the accuracy, in this sense, of the two numbers given above is the same in each case, namely 5/23010, and each of them is said to have 4 significant digits. The significant digits can be defined as the digits beginning with the first non-zero digit on the left and ending with the last digit on the right. Thus 0.023010 has 5 significant digits. The number of significant digits in a number like 230 is usually taken to be 3, but may actually be 2, depending on whether the meaning is that $229.5 < 230 < 230.5$ or $225 < 230 < 235$. There is need, therefore, of two different symbols for zero, but a second such symbol, \emptyset , is very seldom used.

DIGRAPH. A digraph D is a finite set of vertices $\beta_1, \beta_2, \dots, \beta_v$, together with certain directed lines $\beta_1\beta_2$ (from vertex β_1 to β_2). The possibility that both $\beta_1\beta_2$ and $\beta_2\beta_1$ are lines of the digraph is not excluded. Thus an **oriented graph** is a digraph but not conversely.

The adjacency matrix (see **matrix, adjacency**) $A = (a_{ij})$ of a digraph D is defined as follows: $a_{ij} = +1$ if line $\beta_i\beta_j$ is in D and $a_{ij} = 0$ otherwise. It is important to note that A is not necessarily symmetric ($a_{ij} = a_{ji}$) as is the case for the adjacency matrix of a **non-oriented graph**. A is square and of order v , the number of vertices.

A **tree** T of D with sink β (a vertex) is

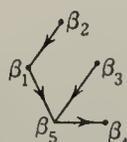

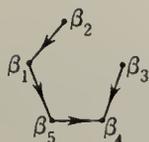

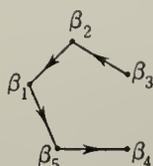

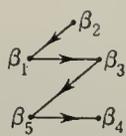

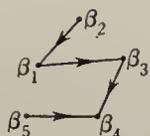

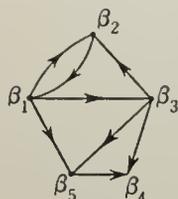

- a subgraph of D which contains all the vertices of D ;
- in T there is a directed path leading to β from every other vertex in D ;
- every vertex other than β is the initial vertex (see **vertex, initial**) of exactly one directed line in T ;

(d) there is no directed line in T for which β is the initial vertex.

An example of a digraph and its five trees is given in the accompanying figure.

$$M = \begin{vmatrix} 3 & -1 & -1 & 0 & -1 \\ -1 & 1 & 0 & 0 & 0 \\ 0 & -1 & 3 & -1 & -1 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 1 \end{vmatrix}.$$

The degree matrix B for D is defined to be that diagonal matrix of order v which is such that the difference $M = B - A$ has every row sum to zero. The matrix tree theorem for digraphs states that the co-factors of the elements in the i^{th} row of M are all equal and each of them gives the number of trees of D with sink β_i . The matrix M associated with the digraph D of the illustrative example above also appears in the figure.

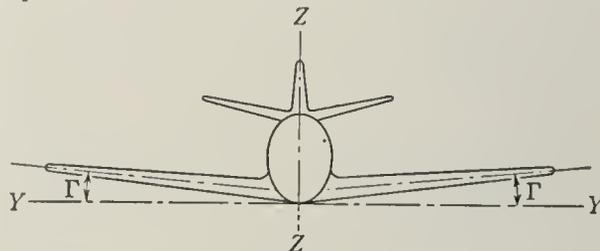

DIHEDRAL ANGLE. The angle between two planes. The dihedral angle is zero if the planes are parallel. If the direction cosines of perpendiculars to two planes are λ, μ, ν and λ', μ', ν' the dihedral angle between the planes is given by

$$\cos \theta = \lambda\lambda' + \mu\mu' + \nu\nu'.$$

DIHEDRAL ANGLE OF WING. The figure shows a front view of an aircraft. ZZ is the plane of symmetry and YY is a perpendicular plane. The dihedral angle of the wing

is the angle Γ in the figure. In general, this may vary along the span of the wing. The dihedral angle has an important effect on the derivative L_v , the rolling moment due to side-slip.

Front view of aircraft, showing dihedral angle of wing.

DIHEDRAL GROUP. The group generated by the relations $C^n = E, S^2 = E, SC = C^{-1}S$, designated by D_n and of order $2n$. Consider a regular polygon in the XY -plane with coordinates of the n corners $x_k = r \cos 2\pi k/n, y_k = r \sin 2\pi k/n, k = 0, 1, \dots, (n - 1)$. The proper rotations of this object through $2\pi/n$, indicated by $C(\phi)$, and the improper rotations, $S(\phi)$, which transform the polygon into itself constitute D_n .

DILATATION. (1) The increase of volume per unit volume of a continuous material. (See also **cubical dilatation**.) (2) Dilatation of time, see **relativity**.

DILATATION RATE. The rate of extension of fluid elements. The cubical dilatation at a point is equal to the divergence of velocity.

DIMENSION. For the purposes of applied mathematics, the dimension of a set of elements is most conveniently defined as the number of parameters necessary to give an **analytic** description of the set. Thus, a space is said to have n dimensions when n coordinates are necessary to fix the position of a point in the space.

DIMENSIONAL ANALYSIS. Since the quantities represented by the two sides of an equation must have the same dimensions, it is often possible to arrive at the form of an equation connecting physical quantities by a consideration only of the dimensions of the quantities involved, without a detailed theory and without consideration of magnitudes. The equations obtained in this way may be in error by a multiplying constant, which can often be determined empirically. In order that two physical quantities may be equal, or that one may be added to or subtracted from the other,

it is obvious that they must have the same makeup and be expressible by the same combination of fundamental units. It follows that in an equation expressing relationship between physical magnitudes, both members and all terms of each member must have the same dimension formula. For example, the total area of a right circular cone of altitude h and having a base of radius r is $a = \pi r^2 + \pi r \sqrt{r^2 + h^2}$, each term of which has the dimension formula L^2 (since π is abstract). Again, the phase angle ϕ of an **alternating current** of frequency n (per second) in a circuit of resistance R (ohms), inductance L (henrys), and capacitance C (farads) is given by

$$\tan \phi = \frac{4\pi^2 n^2 LC - 1}{2\pi n RC}$$

Since $\tan \phi$ is an abstract quantity, the fraction on the right must also be abstract. Since the 1 in the numerator is abstract, the other term $4\pi^2 n^2 LC$ and the whole numerator must be also; hence the denominator is abstract. That is, n , R , and C should have such dimensions that the component fundamental magnitudes cancel when the product nRC is formed. This is true; for the dimension formula of n is $1/T$, and (in electromagnetic measure) that of R is $\mu L/T$, and of C , $T^2/\mu L$; in which μ represents magnetic permeability.

DIMENSIONLESS GROUPS, OR NUMBERS. Expressions of the type

$$G = A^\alpha B^\beta C^\gamma \dots$$

in which A , B , C , etc., denote some physical quantities, and the exponents α , β , γ , etc., are pure numbers, which have the property that their physical dimensions in terms of some chosen system of fundamental dimensions reduces to a pure number. (For examples of dimensionless groups, see **Reynolds number**, **Nusselt number**, **Prandtl number**, **Mach number**, **Froude number** and **Grashof number**.)

DIMENSIONLESS NUMBER. See **dimensionless groups**.

DIOPHANTINE EQUATIONS. A set of **algebraic equations**, usually indeterminate (i.e., with fewer equations than unknowns) and with integral coefficients, for which integral solutions are desired.

DIOPTER. The metric unit of refractive power. The power of an optical system in

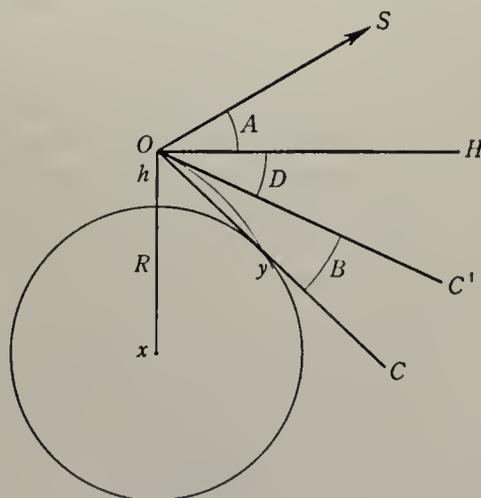

diopeters is numerically equal to the reciprocal of the **focal length** in meters. In ophthalmic optics the deviation of a prism is measured in terms of a similarly named but different unit, the *prism diopter*.

DIOPTICS. That branch of optics dealing with the refraction of light, as opposed to **catoptics** (dealing with reflection).

DIP OF THE HORIZON. The fundamental observation in nautical astronomy is the determination of the altitude of a celestial object. At sea the mariner's sextant is used to measure the angle from the sensible horizon OC' to the direction of the object OS . The observer is a height h above the surface of the assumed spherical earth. OC is the direction of the line from the observer tangent to the earth at y . The light from y to O passes through the atmosphere of the earth in the strata of varying index of refraction. This light follows a curved path and enters the sextant as though coming from C' , the direction of the sensible horizon.

OH is the direction of the astronomic horizon and A is the astronomic altitude of S , uncorrected for parallax or for semidiameter if the altitude of a limb of an object of finite size is observed, e.g., moon, sun, etc.

The direction from the sensible horizon to the astronomic horizon is known as the dip of the horizon, and it is evident that $A = SOC' - D$ in which A is the astronomic altitude uncorrected for parallax or semidiameter.

There is no accurate method known for determining the value of the dip of the horizon from theoretical methods. Long series of observations have resulted in an empirical expression for dip as $D = 0.97h^{1/2}$, with h the height

of the eye above sea level in minutes of arc. There is still uncertainty in the value of the dip as determined from this expression. The Carnegie Institution of Washington found that for 5,000 determinations of the dip at sea no value differed from that computed from the formula by more than 2'5 except one difference of 10'6. Difference from the computed values have been reported as great as 30' and in the polar regions differences as great as several degrees have been reported.

DIPOLE-DIPOLE INTERACTION ENERGY. The mutual energy of interaction of two permanent dipoles of moments P_1 and P_2 , separated by a displacement \mathbf{r} , is (in rationalized units):

$$\frac{1}{4\pi\epsilon_0 r^3} \left[\mathbf{P}_1 \cdot \mathbf{P}_2 - \frac{3(\mathbf{P}_1 \cdot \mathbf{r})(\mathbf{P}_2 \cdot \mathbf{r})}{r^2} \right].$$

DIPOLE, ELECTRIC. Two electrically-charged particles of equal magnitude and opposite sign, separated by a very small distance. The electric potential due to static electric dipole is (in rationalized mksa units):

$$V = p \cos \theta / 4\pi\epsilon_0 r^2$$

where $p = qd$ is the magnitude of the dipole moment.

The electric field due to a static dipole is given by $\mathbf{E} = -\nabla V$ (see **grad**). The torque on a dipole in a field \mathbf{E} is given by $\mathbf{L} = \mathbf{p} \times \mathbf{E}$, and the force on a dipole in a non-uniform inhomogeneous field is given by $\mathbf{F} = \nabla(\mathbf{p} \cdot \mathbf{E})$ where $(-\mathbf{p} \cdot \mathbf{E})$ is the energy of the dipole due to its orientation in the field \mathbf{E} .

Asymmetrical molecules behave as dipoles, since the centers of gravity of the positive and negative charges do not coincide. They tend to orient themselves in external electrical fields or by mutual interactions. The molecular dipole moments are usually expressed in **Debye units** D , where $D = 10^{-18}$ esu.

DIPOLE FIELD (STATIC). At the position r, θ, ϕ , in a spherical polar coordinate system having its polar axis along the direction of the dipole moment, the field due to a dipole has the form, in rationalized units:

$$E_r = \frac{p \cos \theta}{4\pi\epsilon_0 r^3}; \quad E_\theta = \frac{p \sin \theta}{4\pi\epsilon_0 r^3}; \quad E_\phi = 0$$

where p is the magnitude of the dipole moment ($p = qd$ for an electric dipole). For a mag-

netic dipole, $p = iA$ and H replaces E . These expressions are valid only when r , the distance from the dipole to the point at which the field is measured, is very much larger than any dimension of the dipole. If this condition is not satisfied, the effects of **multipole moments** must be included in the field.

DIPOLE, MAGNETIC. A circulating current loop, of dimensions small compared to the distance at which it is being observed, acts like a dipole of moment of magnitude $m = iA$, where i is the current and A is the area of the loop. The *magnetic dipole moment* can be considered as a vector whose direction is normal to the plane of the loop and whose sense is taken as the direction of progression of a right-handed screw rotating with the current.

The *magnetic scalar potential* $\phi [= \mathbf{m} \cdot \nabla \left(\frac{1}{r} \right)]$,

where \mathbf{m} is the magnetic moment] and the *magnetic flux density* \mathbf{B} produced by a static magnetic dipole are given by expressions that are identical, except for obvious changes of symbols, to those for the potential V and electric field \mathbf{E} produced by an electric dipole. (See **dipole, electric**.)

DIPOLE MOMENT, ELECTRIC. For an electric dipole consisting of two charges, $+q$ and $-q$, the dipole moment is the vector $\mathbf{p} = q\mathbf{d}$, where \mathbf{d} is the displacement of the positive charge with respect to the negative charge.

DIPOLE MOMENT, INDUCED. A dipole moment induced in a system (e.g., in an atom or molecule) because it is brought into an electric or magnetic field. (See **polarizability**.)

DIPOLE MOMENT, MAGNETIC. See **dipole, magnetic; dipole field (static)**.

DIPOLE MOMENT, MOLECULAR. It is found from measurements of **dielectric constant** (i.e., by its temperature dependence, as in the Debye equation for total polarization) that certain molecules have permanent dipole moments. These moments are associated with the distribution of charge within the molecule, and provide valuable information as to the molecular structure.

DIPOLE ORIENTATION. The effect by which the free rotation of the molecules in a solid may be hindered, so that their **dipole moments** may only take on certain discrete

orientations. This may have a marked effect on the dielectric constant. (See steric hindrance.)

DIPOLE, OSCILLATING. A dipole whose dipole moment oscillates harmonically with time, $\mathbf{p} = p_0 e^{j\omega t}$. Oscillating electric and magnetic dipoles radiate electromagnetic waves. (See dipole radiation entries.)

DIPOLE, PERMANENT. A dipole whose dipole moment does not vanish in the absence of an externally applied field.

DIPOLE RADIATION, ELECTRIC. The electromagnetic radiation sent out by an oscillating electric dipole, $\mathbf{p} = \mathbf{p}_0 e^{-j\omega t}$. The electric and magnetic fields at a distance r from the dipole are (in spherical polar coordinates and in rationalized mksa units):

$$E_\theta = \frac{-k^2 p_0 \sin \theta e^{j(k-\omega t)}}{4\pi \epsilon_0 r},$$

$$H_\phi = \frac{\omega k p_0 \sin \theta e^{j(k-\omega t)}}{4\pi r},$$

$$H_r = 0,$$

where $k = \omega/c$. The term is often applied to radiation from quantized atomic or molecular systems whose transitions produce radiation having the same dependence on θ as does the radiation from a classical electric dipole.

DIPOLE RADIATION, MAGNETIC. The electromagnetic radiation sent out by an oscillating magnetic dipole, $\mathbf{m} = \mathbf{m}_0 e^{-j\omega t}$ where $m_0 = i_0 A$. The structure of the field is identical with that of the electric dipole (see dipole radiation, electric) except that H replaces E . Thus, the field is given by

$$E_\phi = \frac{k^2}{4\pi} \sqrt{\frac{\mu}{\epsilon}} \frac{m_0 \sin \theta e^{j(k-\omega t)}}{r},$$

$$H_\theta = \frac{k^2 m_0 \sin \theta e^{j(k-\omega t)}}{4\pi r},$$

$$H_r = 0.$$

DIPOLE TRANSITION, ELECTRIC AND MAGNETIC. Transitions from one energy state to another, accompanied by the absorption or emission of dipole radiation. Depending on the nature of the initial and final states, the radiation may be electric dipole radiation or magnetic dipole radiation.

DIRAC DELTA FUNCTION. See distribution theory.

DIRAC EQUATION. The relativistic wave equation discovered by Dirac in 1928 while trying to overcome the difficulties of negative probabilities associated with the one-particle interpretation of the Klein-Gordon equation if one does not adopt the manifold of positive energy solutions as the set of realizable states. Dirac was led to the equation bearing his name by requiring that it be of first order in the time like the Schrödinger equation. Relativistic covariance requires that there be complete symmetry in the treatment of the space and time components so that the equation must likewise be of first order in the space derivatives. The superposition principle of quantum mechanics requires that it be linear. Finally the requirement that in the correspondence limit classical relativity be valid implies that the wave function ψ also satisfy the equation

$$(\square + m^2 c^2 / \hbar^2) \psi(x) = 0 \quad (a)$$

since this is the statement that ψ describes a free particle of mass m for which the energy momentum equation $p^2 = m^2 c^2$ is to hold. The most general equation which satisfies these conditions is then of the form

$$\begin{aligned} \frac{1}{c} i \frac{\partial \psi}{\partial t} &= i \boldsymbol{\alpha} \cdot \nabla \psi + \frac{mc}{\hbar} \beta \psi \\ &= H \psi \end{aligned} \quad (b)$$

where $\boldsymbol{\alpha} = (\alpha_1, \alpha_2, \alpha_3)$, β are square matrices and ψ an N -component quantity. The right-hand side of (b) can be taken as the Hamiltonian, H , which must be hermitian. The matrices α and β must therefore be hermitian. The requirement that (a) be satisfied requires that these matrices satisfy the following commutation rules:

$$\begin{aligned} \alpha^k \alpha^l + \alpha^l \alpha^k &= 2\delta^{kl} & k, l = 1, 2, 3 \\ \alpha^k \beta + \beta \alpha^k &= 0 \\ \beta^2 &= 1. \end{aligned} \quad (c)$$

These in turn imply that there exist but one irreducible representation of these matrices. This representation is 4-dimensional. The wave function ψ thus has 4 components. The equation can be shown to be form invariant under Lorentz transformations

$$x \rightarrow x' = \Lambda x + a, \quad (d)$$

if the transformed wave function ψ' , is related to ψ by

$$\psi'(x') = S(\Lambda)\psi(\Lambda^{-1}(x' - a)) \quad (e)$$

where $S(\Lambda)$ is a 4×4 matrix operating on the components of ψ and which satisfies the equation

$$S^{-1}\gamma^\lambda S = \sum_{\mu=0}^{\infty} \Lambda_\mu^\lambda \gamma^\mu. \quad (f)$$

The 4×4 matrices γ^μ , $\mu = 0, 1, 2, 3$, are related to the α and β matrices by $\gamma^i = \beta\alpha^i$, $i = 1, 2, 3$ and $\gamma^0 = \beta$. They satisfy the following commutation rules

$$\gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu = 2g^{\mu\nu} \quad (g)$$

where $g^{\mu\nu}$ is the metric tensor.

A particle described by the Dirac equation has in addition to its orbital angular momentum $\mathbf{r} \times \mathbf{p}$, an intrinsic angular momentum, or spin, of magnitude $\hbar/2$. The spin is described by an operator $\frac{\hbar}{2}\Sigma$ (a 4×4 matrix) whose component in any direction has eigenvalues $\pm\hbar/2$. A Dirac particle is therefore a spin $\frac{1}{2}$ particle. The total angular momentum of a Dirac particle is the vector sum of orbital and spin angular momentum.

The Dirac equation admits of both positive and negative energy solutions, i.e., solutions of the form $\psi \sim \exp(-ip_\mu x^\mu)u(\mathbf{p})$ with $p_0 = +c\sqrt{\mathbf{p}^2 + mc^2}$ positive energy solutions and $p_0 = -c\sqrt{\mathbf{p}^2 + mc^2}$ for negative energy solutions. For each three dimensional momenta \mathbf{p} there are two linearly independent solutions of positive energy and two linearly independent solutions of negative energy. These linearly independent solutions can be chosen to be eigenfunctions of the helicity operator $S(p) = \Sigma \cdot \mathbf{p}/|\mathbf{p}|$, whose eigenvalues are $+1$ and -1 depending on whether the spin of the particle is parallel or anti-parallel to the direction of motion. In the presence of an external electromagnetic field the Dirac equation for an electrically charged particle of charge e is

$$\gamma^\mu \left(i\hbar\partial_\mu - \frac{e}{c}A_\mu(x) \right) \psi(x) = mc\psi(x). \quad (h)$$

This equation predicts that a charged spin $\frac{1}{2}$ particle has a magnetic moment, μ , of one Bohr magnetron: $\mu = \mu_0 = \frac{e\hbar}{2mc}$. The non-relativistic **Pauli theory** had to ascribe arbitrarily a magnetic moment μ to the spin, whose value it

took from the experimental results. Dirac's equation on the other hand contains implicitly an interaction of the spin with a magnetic field. The resulting magnetic moment $\mu = \mu_0 = e\hbar/2mc$ is in almost exact agreement with experiment in the case of the electron. (See **anomalous magnetic moment of a spin $\frac{1}{2}$ particle.**) Equation (h) may be applied to the hydrogen atom by choosing $A_i = 0$, $i = 1, 2, 3$, $A_0 = Ze^2/r$, i.e., by considering the nucleus as the source of the Coulomb field in which the electron moves. For this situation the equation can be solved exactly and the energy levels, $E_{n,j}$, for the positive energy states, are described by the principal quantum number n and the total angular momentum quantum number j with

$$E_{n,j} = mc^2 \left\{ 1 + \frac{\alpha^2 Z^2}{(n' + \sqrt{(j + \frac{1}{2})^2 - \alpha^2 Z^2})^2} \right\}^{\frac{1}{2}} \quad (i)$$

$$n' = 0, 1, 2, \dots, \quad j = \frac{1}{2}, \frac{3}{2}, \dots$$

or approximately

$$E_{n,j} \approx mc^2 - \frac{\alpha^2 mc^2 Z^2}{2n^2} \left[1 + \frac{\alpha^2 Z^2}{n} \left(\frac{1}{j + \frac{1}{2}} - \frac{3}{4n} \right) + \dots \right] \quad (j)$$

$$n = n' + j + \frac{1}{2} = 1, 2, \dots$$

The observed fine structure of the levels of hydrogen and hydrogen-like atoms, particularly He^+ , is in good agreement with the Dirac equation. This agreement includes the degeneracy of levels with the same j except for one case, namely the $S_{\frac{1}{2}}$ and $P_{\frac{1}{2}}$ level. In this case Lamb found the $2S_{\frac{1}{2}}$ state of hydrogen to be about 1057.77 megacycles higher than the $2P_{\frac{1}{2}}$ state, a separation which has been explained by radiative corrections to the simple Dirac equation. (See **level displacements of hydrogen-like atoms.**)

Although by adopting the manifold of positive energy solutions as the set of realizable states for a spin $\frac{1}{2}$ particle, good agreement is obtained with many experimental facts relating to the behavior of such particles, nonetheless there remains within the framework of a one-particle interpretation of the Dirac equation, several unacceptable features connected with the negative energy solutions.

These states are not realized in nature. The Dirac equation, however, predicts the possibility of radiative transitions with the emission of light from positive to negative energy states. No regular (positive energy) state could thus be stable since there are an infinite number of negative energy states to which such a positive energy particle could make a transition with the emission of a quantum of light. To overcome these difficulties, Dirac put forth the hypothesis that the vacuum corresponds to the state in which all negative energy states are occupied (by just one particle, in view of Pauli's exclusion principle) but that this infinite "sea" of particles does not produce any electromagnetic effects. Only a deviation from this normal condition, e.g., the presence of a positive energy particle or the absence of a negative energy particle (a "hole" in the sea of particles) leads to observable effects. Such a hole, corresponding to a negative energy $-E$, behaves like a positively charged particle of positive energy $+E$. The Dirac hypothesis is known as the **hole theory**. While Dirac first meant to identify the holes as protons, it was shown by Oppenheimer and Weyl that relativistic invariance requires that hole and particle have the same mass. This prediction of the theory was confirmed by Anderson's discovery of positrons, particles of mass m_e , the electronic mass, but having a charge equal and opposite to that of electrons.

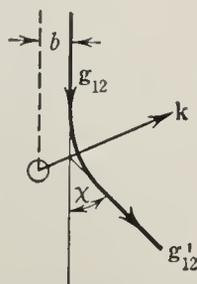

Thus although Dirac's equation was designed to describe one particle, the above makes it clear that this interpretation cannot be maintained. Since particles may be created and annihilated by transitions from and to negative energy states, the number of particles is not a constant and a field theoretical description is called for. Accordingly, the arguments advanced for the particular form of Dirac's equation are no longer valid although it is undoubtedly the correct equation for "simple" spin $\frac{1}{2}$ systems such as the electron and μ meson (where by simple spin $\frac{1}{2}$ systems we understand particles which undergo only weak or electromagnetic interactions).

DIRAC FORMULA FOR HYDROGEN FINE STRUCTURE. See **hydrogen fine structure**.

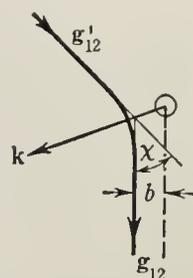

DIRAC \hbar . See **h-bar**.

DIRAC OPERATORS. See **Dirac equation**.

DIRECT AND INVERSE COLLISION. For any molecular collision characterized by an initial relative velocity g_{12} and a final relative velocity g'_{12} , there exists an analogous *inverse collision* or *encounter* with initial relative velocity g'_{12} and final relative velocity g_{12} . By definition, the last of these processes is called

Direct Collision

Inverse Collision

Direct and inverse collision. The unit vectors along the apse line and the angle of deflection are of opposite sign and equal magnitude for the direct and inverse processes.

the *direct collision* or *encounter*. (See figure.) Equilibrium is established when the frequencies of direct and inverse collision are equal.

DIRECT CURRENT. Unidirectional current as produced from batteries, from dynamo machinery equipped with **commutators**, or by means of **rectifiers**.

DIRECT-CURRENT CIRCUITS. See **electric circuits**; **Ohm's law**; **Kirchhoff laws**.

DIRECTED GRAPH. See **digraph**.

DIRECTED PATH. See **path, directed**.

DIRECTED VALENCY. One of the characteristics of the covalent bonds is that they are usually directional in character and rapidly saturated. (See **bond types**.)

In the case of H_2O , for example, the O atom reacts with two H atoms only, and forms two bonds at an angle of 105° to one another.

Directional valency results from the non-spherical symmetry of the p , d and f electron orbitals and of their hybrid **wave functions** with s orbitals. The bonds tend to form with a maximum interaction, i.e., a maximum overlap of the wave functions. (See **hybridization of electron orbitals**.)

DIRECT INTERACTION. The process whereby a nuclear reaction can sometimes take place without the formation of a compound

nucleus. The most notable type of reaction is the (d,p) reaction, for example

in which the relatively loosely-bound deuteron (d) loses its neutron to the O^{16} target nucleus to form O^{17} , the proton continuing on its way deflected only by a small angle. The delicate balance of angular momentum and linear momentum in such a reaction gives rise to a highly characteristic angular distribution of the protons relative to the bombarding deuteron beam, and this may be used to measure spin and parity of the states of the residual nucleus so formed.

DIRECTION. The position of one point in space relative to another without reference to the distance between them. Direction may be either three-dimensional or two-dimensional. Direction is not an angle but is often indicated in terms of its angular difference from a reference direction. The *direction angles* of a line are the 3 angles it makes with the positive directions of the coordinate axes. Its *direction cosines* are the cosines of these angles. Any set of 3 numbers proportional to its direction cosines are called *direction numbers* for the line. A direction at a point on a surface in which the curvature of a normal section is a maximum or a minimum is called a *principal direction*.

DIRECTIONAL. The directional derivative of function f of any number of variables is its rate of change with respect to arc-length along a curve in the given direction. Thus, if the curve is given parametrically by $x = x(t)$, $y = y(t)$, $z = z(t)$, the directional derivative of $f(x,y,z)$ is given by,

$$\frac{df}{dt} = \frac{\partial f}{\partial x} \frac{dx}{dt} + \frac{\partial f}{\partial y} \frac{dy}{dt} + \frac{\partial f}{\partial z} \frac{dz}{dt}.$$

DIRECTIONAL CHARACTERISTIC OF A CIRCULAR-RING SOUND SOURCE. The directional characteristic of a circular-ring sound source of uniform strength and the same phase at all points on the ring is

$$R_\alpha = J_0 \left[\left(\frac{2\pi R}{\lambda} \right) \sin \alpha \right] \quad (1)$$

where R_α is the ratio of the sound pressure for an angle α to the sound pressure for an angle $\alpha = 0$, J_0 is the Bessel function of zero order,

R is the radius of the circle, in centimeters, and α is the angle between the axis of the circle and the line joining the point of observation and the center of the circle.

DIRECTIONAL CHARACTERISTIC OF A CURVED-LINE SOUND SOURCE (ARC OF A CIRCLE). A curved-line sound source may be made up of a large number of point sound sources vibrating in phase on the arc of a circle separated by very small distances. The directional characteristics of such a line in the plane of the arc are,

$$R_\alpha = \frac{1}{2m+1} \left| \sum_{k=-m}^{k=m} \cos \left[\frac{2\pi R}{\lambda} \cos(\alpha + k\theta) \right] + j \sum_{k=-m}^{k=m} \sin \left[\frac{2\pi R}{\lambda} \cos(\alpha + k\theta) \right] \right| \quad (1)$$

where R_α is the ratio of the pressure for an angle α to the pressure for an angle $\alpha = 0$, α is the angle between the radius drawn through the central point and the line joining the source and the distant observation point, λ is the wavelength, in centimeters, R is the radius of the arc, in centimeters, $2m+1$ is the number of points, θ is the angle subtended by any two points at the center of the arc, and k is variable.

Another method is to break up the arc into a large number of equal chords. The strength is assumed to be uniform over each chord. Also the phase of all the chords is the same. In this case the result takes the form,

$$R_\alpha = \frac{1}{2m+1} \left| \sum_{k=-m}^{k=m} \cos \left\{ \frac{2\pi R}{\lambda} \cos(\alpha + k\theta) \right\} \times \frac{\sin \left[\frac{\pi d}{\lambda} \sin(\alpha + k\theta) \right]}{\frac{\pi d}{\lambda} \sin(\alpha + k\theta)} + j \sum_{k=-m}^{k=m} \sin \left\{ \frac{2\pi R}{\lambda} \cos(\alpha + k\theta) \right\} \times \frac{\sin \left[\frac{\pi d}{\lambda} \sin(\alpha + k\theta) \right]}{\frac{\pi d}{\lambda} \sin(\alpha + k\theta)} \right| \quad (2)$$

where R_α is the ratio of the pressure for an angle α to the pressure for an angle $\alpha = 0$, λ is

the wavelength, in centimeters, R is the radius of the arc, in centimeters, $2m + 1$ is the number of chords, θ is the angle subtended by any of the chords at the center of circumscribing circle, and d is the length of one of the chords, in centimeters.

DIRECTIONAL CHARACTERISTIC OF A NONUNIFORM STRAIGHT LINE SOUND SOURCE. The directional characteristic of a line sound source, all parts vibrating in phase, in which the strength varies as a function of the distance x along a line is given by

$$R_\alpha = \frac{\int_{-\frac{d}{2}}^{+\frac{d}{2}} f(x) \epsilon^{-j(2\pi x/\lambda) \sin \alpha} dx}{\int_{-\frac{d}{2}}^{+\frac{d}{2}} f(x) dx} \quad (1)$$

where R_α is the ratio of the sound pressure for the angle α to the sound pressure for the angle $\alpha = 0$. The direction $\alpha = 0$ is normal to the line, x is the distance from the center of the line, in centimeters, d is the total length of the line, in centimeters and $f(x)$ is the strength distribution function.

DIRECTIONAL CHARACTERISTICS OF A PLANE CIRCULAR-PISTON SOUND SOURCE. The directional characteristics of a circular-piston sound source mounted in an infinite baffle with all parts of the surface of the piston vibrating with the same strength and phase are

$$R_\alpha = \frac{2J_1\left(\frac{2\pi R}{\lambda} \sin \alpha\right)}{\frac{2\pi R}{\lambda} \sin \alpha} \quad (1)$$

where R_α is the ratio of the sound pressure for an angle α to the sound pressure for an angle $\alpha = 0$, J_1 is the Bessel function of the first order, R is the radius of the circular piston, in centimeters, α is the angle between the axis of the circle and the line joining the point of observation and the center of the circle, and λ is the wavelength, in centimeters.

DIRECTIONAL CHARACTERISTIC OF A PLANE RECTANGULAR-SURFACE SOUND SOURCE. The directional characteristic of a rectangular-surface source with all

parts of the surface vibrating with the same strength and phase are

$$R_{\alpha\beta} = \frac{\sin\left(\frac{\pi l_a}{\lambda} \sin \alpha\right)}{\frac{\pi l_a}{\lambda} \sin \alpha} \cdot \frac{\sin\left(\frac{\pi l_b}{\lambda} \sin \beta\right)}{\frac{\pi l_b}{\lambda} \sin \beta} \quad (1)$$

where $R_{\alpha\beta}$ = ratio of sound pressure for the angles α, β to the sound pressure for the angle $\alpha, \beta = 0$, l_a is the length of the rectangle, l_b is the width of the rectangle, α is the angle between the normal to the surface source and the projection of the line joining the middle of the surface and the observation point on the plane normal to the surface and parallel to l_a , and β is the angle between the normal to the surface source and the projection of the line joining the middle of the surface and the observation point on the plane normal to the surface and parallel to l_b .

The directional characteristic of a plane rectangular-surface source with uniform strength and phase is the same as the product of the characteristic of two line sources at right angles to each other and on each of which the strength and phase are uniform.

DIRECTIONAL CHARACTERISTIC OF A SERIES OF POINT SOUND SOURCES. The directional characteristic of a sound source made up of any number of equal point sound sources, vibrating in phase, located on a straight line and separated by equal distances is given by

$$R_\alpha = \frac{\sin\left(\frac{n\pi d}{\lambda} \sin \alpha\right)}{n \sin\left(\frac{\pi d}{\lambda} \sin \alpha\right)} \quad (1)$$

where R_α is the ratio of the sound pressure for an angle α to the sound pressure for an angle $\alpha = 0$. The direction $\alpha = 0$ is normal to the line, n is the number of sources, d are distances between the sources, in centimeters, and λ is wavelength, in centimeters.

DIRECTIONAL CHARACTERISTIC OF A STRAIGHT-LINE SOUND SOURCE. A straight-line sound source may be made up of a large number of points of equal strength and phase on a line separated by equal and very small distances. If the number of sources n approach infinity and d , the distance between the sources, approaches zero in such a way that

$$nd = l \quad (1)$$

the limiting case is the line source. If this is carried out, Equation 1 of **directional characteristic of a series of point sound sources** becomes

$$R_\alpha = \frac{\sin\left(\frac{\pi l}{\lambda} \sin \alpha\right)}{\frac{\pi l}{\lambda} \sin \alpha} \quad (2)$$

where R_α is the ratio of the sound pressure for the angle α to the sound pressure for the angle $\alpha = 0$. The direction $\alpha = 0$ is normal to the line, l is the length of the line, in centimeters and λ is wavelength, in centimeters.

DIRECTIONAL CHARACTERISTIC OF A TAPERED STRAIGHT-LINE SOUND SOURCE. The directional characteristic of a line sound source, all parts vibrating in phase, in which the strength varies linearly from its value at the center to zero at either end, is given by

$$R_\alpha = \frac{\sin^2\left(\frac{\pi l}{2\lambda} \sin \alpha\right)}{\left(\frac{\pi l}{2\lambda} \sin \alpha\right)^2} \quad (1)$$

where R_α is the ratio of the sound pressure for an angle α to the sound pressure for an angle $\alpha = 0$. The direction $\alpha = 0$ is normal to the line, l is the total length of the line in centimeters, and λ is the wavelength, in centimeters.

DIRECTIONAL CHARACTERISTICS OF END FIRED LINE SOUND SOURCE. An end fired line sound source is one in which there is progressive phase delay between the elements of the line. In the case in which the time delay of excitation between the elements corresponds to the time of wave propagation in space for this distance the maximum directivity occurs in direction corresponding to the line joining the elements. The directional characteristics of an end fired line of this type and of uniform strength is given by

$$R_\alpha = \frac{\sin \frac{\pi}{\lambda} (l - l \cos \alpha)}{\frac{\pi}{\lambda} (l - l \cos \alpha)} \quad (1)$$

where R_α is the ratio of the pressure for an angle α to the pressure for the angle $\alpha = 0$. The direction $\alpha = 0$ is along the line, l is the length of the line, and λ is the wavelength.

DIRECTION COSINE. See **direction**.

DIRECTION COSINES, OPTICAL. See **optical direction cosines**.

DIRECTION OF PROPAGATION. At any point in a homogeneous, isotropic medium, the direction of time-average energy-flow. In a uniform **waveguide**, the direction of propagation is often taken along the axis. In the case of a uniform lossless waveguide, the direction of propagation at every point is parallel to the axis, and in the direction of time-average energy-flow.

DIRECTIONS, CONJUGATE. See **conjugate directions**.

DIRECTION, SELF-CONJUGATE. See **conjugate directions**.

DIRECTIONS, PRINCIPAL. See **principal directions**.

DIRECTIONS, PRINCIPAL, OF SYMMETRIC SECOND-ORDER TENSOR. See **principal directions of symmetric second-order tensor**.

DIRECT METHODS. Methods usually contrasted with **iterative methods** or methods of successive approximation for **matrix inversion** and the solution of equations. The exact inverse or solution is expressed as the result of a finite sequence of operations on scalars.

DIRECT METHODS IN GEOMETRIC OPTICS. The application of the **Hamiltonian theory**. For theoretical purposes it is pre-eminent but for practical design its use is limited.

DIRECTOR SURFACE. A reference surface which is cut by all the curves of a **congruence of curves**.

DIRECT PRODUCT (OF SUBGROUPS). A **group** G is said to be the direct product of two of its normal subgroups A and B having only the identity in common if every element in G can be represented as the product of an element of A with an element of B , and simi-

larly for the case of more than two subgroups. The G is said to be completely reducible if it is the direct product of simple groups.

DIRECT REFLECTANCE. The ratio of the luminous flux reflected in accordance with the laws of regular **reflection** to the total incident flux.

DIRECTRIX (OF A RULED SURFACE). A reference curve on the **ruled surface** cutting every generator. (See also **conic**.)

DIRECT STRESS. See **stress, direct**.

DIRECT SUM. Let \mathfrak{H}_i ($i = 1, 2, \dots, n$) be a sequence of **Hilbert spaces**. The set of sequences $\{f_1, f_2, \dots\}$ with $f_i \in \mathfrak{H}_i$ can be made into a vector space with the definition

$$\alpha\{f_1, f_2, \dots, f_n\} + \beta\{g_1, g_2, \dots, g_n\} \\ = \{\alpha f_1 + \beta g_1, \alpha f_2 + \beta g_2, \dots\}.$$

The set of all such sequences with $\sum_{i=1}^n (f_i, f_i) < \infty$ where (f_i, f_i) denote the scalar product in \mathfrak{H}_i is then a Hilbert space with the scalar product

$$(\{f_1, f_2, \dots, f_n\}, \{g_1, g_2, \dots, g_n\}) = \sum_{i=1}^n (f_i, g_i).$$

We denote this Hilbert space by $\mathfrak{H}_1 \oplus \mathfrak{H}_2 \oplus \dots \oplus \mathfrak{H}_n$. If $T_g^{(i)}$ is a **representation** of the group G in \mathfrak{H}_i then the direct sum representation

$$T_g = T_g^{(1)} \oplus T_g^{(2)} \oplus \dots \oplus T_g^{(n)}$$

in $\mathfrak{H}^{(1)} \oplus \mathfrak{H}^{(2)} \oplus \dots$ is defined by the equation

$$T_g\{f_1, f_2, \dots\} = \{T_g^{(1)}f_1, T_g^{(2)}f_2, \dots\}.$$

DIRECT TRANSMITTANCE. The ratio of the luminous flux transmitted in accordance with the laws of direct **transmission** to the total incident flux.

DIRICHLET INTEGRAL. The integral

$$\frac{1}{\pi} \int_{-\pi}^{\pi} f(t) \frac{\sin(n + \frac{1}{2})(t-x)}{2 \sin \frac{1}{2}(t-x)} dt$$

expressing the n th partial sum of a **Fourier series**.

DIRICHLET PRINCIPLE. The principle that the solution of the equation $u_{xx} + u_{yy} = 0$, satisfying given boundary conditions, will be given by the function, among all functions

satisfying the boundary conditions, which minimizes the integral

$$\iint (u_x^2 + u_y^2) dx dy.$$

The principle, which requires certain reservations, was named after Dirichlet by Riemann but ought to have been named after Gauss and Lord Kelvin. It is important as a link between **partial differential equations** and the calculus of **variations**. The name is sometimes also given to the corresponding principle for more general elliptic differential equations.

DIRICHLET PROBLEM. See **boundary value problem**.

DIRICHLET SERIES. A series of the form,

$$a_1 + \frac{a_2}{2^x} + \frac{a_3}{3^x} + \dots + \frac{a_n}{n^x} + \dots$$

DISADVANTAGE FACTOR. In **neutron transport theory**, in a situation in which one body is embedded in another (usually a fuel plate or foil in moderator) the disadvantage factor is the ratio of the average neutron **flux** in the first body to that in the second.

DISCONTINUITY. A point at which a function is not continuous. If the point $x = a$ is such that $f(x)$ approaches distinct finite limits as x approaches a from the left or from the right, then a is said to be a **jump discontinuity** of $f(x)$, or $f(x)$ is said to have a jump discontinuity at a . If $f(x)$ can be made continuous at a by giving a suitable definition to $f(a)$, then $f(x)$ is said to have a **removable discontinuity** at a .

DISCONTINUOUS SPECTRUM. See **spectrum, discontinuous**.

DISCONTINUOUS SYSTEM. A term used in thermodynamics for systems which consist of a finite number of homogeneous regions. The intensive **state variables** have the same value throughout each homogeneous region, but they have different values in different regions. As a result they are discontinuous at the boundary. (See also **continuous systems**.)

DISCRETENESS. (1) A term referring to the distribution of allowed values of a physical quantity over a given interval. The distribution is discrete if only a denumerable set of

values is permitted. This is the case, for example, with the allowed frequencies of vibration of a finite stretched string, and quantized quantities such as the energy states of a bound system or the quantized values of angular momentum. (2) The atomicity of mass and charge.

DISCRETE ORDINATES METHOD. In neutron transport theory, a method synonymous with the Wick-Chandrasekhar method.

DISCRETE SPECTRUM. See **spectrum, discrete**.

DISCRETE VARIATE. A variate which occurs only in terms of integral values of a certain unit. Examples are the number of votes cast in an election, or the number of beta particles emitted by a radioactive substance.

DISCRIMINANT. The discriminant of an algebraic equation $x^n + a_1x^{n-1} + \dots + a_n = 0$ is the product of the squares of all the differences of the roots taken in pairs. It is rational in the coefficients.

DISCRIMINANT FUNCTION. Suppose we have two normal multivariate populations with equal variances and covariances but different means, and an observation which is known to come from one or other of the populations. Overlap in the distributions of the individual variates may make it difficult to allot the observation to its correct population with certainty, but we can construct a function of the variates, the discriminant function, which will allocate a member to one class or the other with a known probability of correctness. The function is usually chosen so as to maximize this probability, and is then linear in the variates for normal variation with equal dispersions. In other cases, more complicated discriminants are required. The procedure extends the allocation to more than two populations.

DISINTEGRATION. (1) Loss of form or powdering. (2) The passage of a metal into colloidal solution when it is made an electrode under certain conditions. (3) Transformations of radioactive elements are termed disintegrations when they result from radioactivity.

DISINTEGRATION CONSTANT. The probability per unit time, λ , that a given unstable

particle of system, such as a radioactive atom, will undergo spontaneous transformation. It is defined by the equation $dN/dt = -\lambda N$, where N is the number of untransformed particles or systems existing at time t . It is the reciprocal of the **mean life** of the given system before undergoing transformation.

DISINTEGRATION CONSTANT, PARTIAL. One of **disintegration constants** of a particle or system that undergoes more than one mode of disintegration. (See **branching**.)

DISINTEGRATION ENERGY, GROUND STATE. The disintegration energy of a nuclear disintegration when all the reactant and product nuclei end in their ground states. (See **disintegration energy, nuclear**.)

DISINTEGRATION ENERGY, NUCLEAR. The energy evolved, or the negative of the energy absorbed, in a nuclear disintegration; symbol Q . It is equal to the energy equivalence of the sum of the masses of the reactants minus the sum of the masses of the products. (For each reactant or product which is a nucleus, the appropriate mass is that of the corresponding neutral atom.) If the disintegration energy is positive, the disintegration is exothermic; if it is negative, the disintegration is endothermic. Radioactive disintegrations have positive Q -values; nuclear reactions may have positive values of either sign. Sometimes the term nuclear disintegration energy is applied to the ground-state disintegration energy. (See **disintegration energy, ground-state**.)

DISJOINT SUBGRAPHS. See **subgraphs, disjoint**.

DISLOCATION. A discontinuity in the displacement field of the type produced in a solid body by making a cut in it which does not bisect the body, displacing the cut surfaces relative to each other and joining them. Alternatively, two portions of the surface of the body may be brought together and joined.

An important type of dislocation is that occurring in a lattice. It is a region of departure from the normal lattice arrangement localized in the neighborhood of a line or curve, called the *dislocation line*. The atomic arrangement remote from the dislocation line is identical with that for a perfect crystal lat-

tice, except for a small elastic distortion. One can associate a vector \mathbf{t} with the line joining an atom to one of its nearest neighbors, $\mathbf{t}^{(0)}$ being the corresponding vector in the undistorted lattice. If we now consider a closed path enclosing a dislocation line, we have

$$\begin{aligned}\Sigma \mathbf{t} &= 0 \text{ by definition} \\ \Sigma \mathbf{t}^{(0)} &= \mathbf{t}' \neq 0\end{aligned}$$

where \mathbf{t}' is the same for all paths encircling the dislocation line in the same sense, and is called the **slip vector**, or **Burger's vector**, of the dislocation.

DISLOCATION LINE. See **dislocation**.

DISPERSION. (1) In a medium in which the velocity of progressive waves of small amplitude varies with the wavelength, a disturbance of arbitrary form, which (according to **Fourier theorem**) may be regarded as composed of superposed trains of waves of all wavelengths, changes shape as it progresses because the different component wave trains travel at different speeds. The disturbance is then said to be dispersed. The time required for a pulse (or concentrated disturbance) which is subsequently dispersed to pass a point is the difference between the times of arrival of the fastest and slowest moving component waves traveling with their **group velocities**. Since the group velocity differs from the phase velocity in a dispersive medium, a dispersed pulse has waves moving through it with their appropriate wave velocity. Each wave changes its length as it moves through the disturbance, at each point having a length determined by the time of arrival of these waves traveling with the group velocity from the original pulse.

All gravity waves in fluids are dispersive.

As defined above, dispersion is the separation of a complex wave into components. The term is also applied to the property of an optical device or medium giving rise to the phenomenon, or the numerical value of this property.

(2) In statistics, dispersion is a general term denoting the spread of a series of values, usually about some central point such as the mean or median. The chief measure of dispersion in use is the **standard deviation** but the **mean deviation** and the **mean difference** are also employed.

In a multivariate situation, dispersion is a useful word to cover measures of **variance** and **covariance**. Thus, the dispersion matrix of a set of variates is the matrix (α_{ij}) where α_{ij} is the covariance of the i^{th} and j^{th} variates. This is also known as the *covariance matrix* or the *variance-covariance matrix*.

DISPERSION, ANOMALOUS. See **anomalous dispersion**.

DISPERSION FORCES. The dispersion forces make an essential contribution to the attractive part of the **intermolecular forces**. At any instant the electrons in molecule A are in some configuration which results in an instantaneous **dipole moment**. This instantaneous dipole moment induces a dipole moment in molecule B and *vice versa*. The net result is an *attraction* between the molecules A and B . Quantum mechanics gives the following first approximation for this attraction

$$\phi(r) = -\frac{3}{4} \left(\frac{h\nu_A h\nu_B}{h\nu_A + h\nu_B} \right) \frac{\alpha_A \alpha_B}{r^6} \quad (1)$$

in which $h\nu_A$, $h\nu_B$ are characteristic energies of the order of the **ionization potentials** of molecules A and B and α_A , α_B are the **polarizabilities**.

Formula (1) was first derived by F. London, and so these forces are also called the *London forces*. In the derivation, concepts somewhat similar to those of the optical dispersion theory appear. (See entries following.) Therefore these forces are commonly called dispersion forces.

DISPERSION FORMULA. An empirical expression for the refractive index of a substance as a function of wavelength is a dispersion formula. (See **Hartmann dispersion formula**; **Helmholtz-Ketteler formula**; **Herzberger Dispersion formula**; **Eykman formula**; **Cauchy formula for refractive index**.)

DISPERSION OF LIGHT, CLASSICAL THEORY OF (FOR GASES). In this theory atoms are considered as including electrons, not rigidly fixed, which can oscillate about equilibrium positions when acted up by oscillatory forces (see **atom, Thomson**). The classical laws of motion and of electromagnetism are used. An electron set into oscillatory motion by an incident electromagnetic wave will in turn emit electromagnetic radia-

tions (see **dipole, oscillating**). It will thus act like a forced damped harmonic oscillator and the radiation it emits will be out of phase with the incident radiation (see **oscillator, forced**). If there are N_k electrons per unit volume with natural frequency ω_k and damping constant g_k , the refractive index of the gas will be given (in mksa units) by

$$n = 1 + \frac{1}{2} \sum_k \frac{(N_k e^2 / m \epsilon_0)(\omega_k^2 - \omega^2)}{(\omega_k^2 - \omega^2)^2 + \omega^2 g_k^2},$$

where the summation is carried over the different types of dispersion electrons. This equation accounts for the phenomena of anomalous dispersion at frequencies close to $\omega_k/2\pi$.

DISPERSION OF ROTATION. The **angle of rotation** of the plane of vibration in optically active substances is $\rho = K/\lambda^2 + a$ where K is constant and a depends on natural free periods of vibration in the crystal. This relation is called the dispersion of the rotation.

DISPERSION, PARTIAL. In the correction of the secondary spectrum of chromatic aberration in an optical system the partial dispersion of a medium $P_\lambda = (n_\lambda - n_F)/(n_F - n_C)$ occurs as a discrete substitute for $d^2n/d\lambda^2$. The indices of refraction n_F, n_C are for light of the wavelength of the blue F and red C hydrogen lines, respectively. (See **Abbe number**.)

DISPERSION, QUANTUM THEORY OF. See **quantum theory of dispersion**.

DISPERSION, RECIPROCAL LINEAR. The derivative $d\lambda/dx$, where λ is **wavelength** and x is the distance along the **spectrum**. The reciprocal linear dispersion is usually expressed in Ångströms per millimeter.

DISPERSION, RECIPROCAL MEAN. See **Abbe number**.

DISPERSION RELATIONS. Dispersion relations are integral formulas connecting the real and imaginary parts of **scattering amplitudes** (S matrix elements). Kronig and Kramers were the first to point out that the coherent forward scattering amplitude of light by matter, $f(\omega)$, has the property that its real and imaginary part are related by

$$\text{Re}[f(\omega) - f(0)] = \frac{2\omega^2}{\pi} P \int_0^\infty \frac{\text{Im} f(\omega')}{\omega'(\omega'^2 - \omega^2)} d\omega'$$

where P denotes the principal value. It was also pointed out by Kramers that these "dis-

persions relations" were a consequence of the principle of **causality**, i.e., that all interactions (signals) propagate with velocities not greater than the velocity of light. The quantity $\text{Im} f(\omega)$ is furthermore related to the total cross section through the **optical theorem**

$$\sigma(\omega) = \frac{4\pi}{k} \text{Im} f(\omega),$$

where k is the wave number corresponding to ω ($\omega = kc$). Thus the real part of the forward scattering amplitude is determined by an integral over the total cross section.

In establishing dispersion relations in field theory, the following assumptions are usually made:

- (a) that local fields can be used to describe the particles, and that these fields have well defined transformation properties under Lorentz transformations;
- (b) that these operators satisfy the principle of microscopic **causality**, i.e., if $A(x), B(y)$ are two observable Heisenberg fields then $[A(x), B(y)] = 0$ if $(x - y)^2 < 0$;
- (c) that the totality of all possible physical states of the field system forms a set of basis vectors which is complete in the quantum mechanical sense, and that these states have an energy-momentum spectrum which is positive time-like. Furthermore, that there exists a unique invariant state of energy-momentum zero, the vacuum state;
- (d) that the field operators satisfy **asymptotic conditions**.

Axioms (b) and (c) allow us to infer that the scattering amplitudes are boundary values of analytic functions in momentum space. The dispersion relations are a reflection of these analytic properties.

In the case of meson-nucleon scattering (see **S-matrix** and **quantized field theory**) the matrix element of the S -matrix can be written in the following form

$$T(k_0, \Delta^2) = i \int d^4x \exp [ik_0 x_0 - i\mathbf{k} \cdot \mathbf{x}] \theta(x_0) \left\langle \frac{\Delta}{2} \left| \left[j\left(\frac{x}{2}\right), j\left(-\frac{x}{2}\right) \right] \right| - \frac{\Delta}{2} \right\rangle$$

where $j = (\square + \mu^2)\phi$ and ϕ is the field operator for the mesons (isotopic spin considerations

have been neglected). The matrix element of the commutator in the above is taken between one-nucleon states, in the particular coordinate frame where the initial and final nucleon have momenta $+\Delta/2$ and $-\Delta/2$ the initial and final value of the meson momenta \mathbf{k} are $\pi \pm \frac{\Delta}{2\mathbf{k}'}$, respectively. The quantity k_0 is the meson energy given by

$$k_0 = \left(\mu^2 + \pi^2 - \frac{\Delta^2}{4} \right)^{1/2}$$

where

$$|\pi| = \left(k_0^2 - \mu^2 - \frac{\Delta^2}{4} \right)^{1/2}.$$

It will be noted that in the expression defining T , the energy variable occurs only in the exponent. The vanishing of the commutator outside the light cone allows one to extend the energy dependence into the complex k_0 plane. This extension is justified if the mass μ is made imaginary and sufficiently large in absolute value. The use of **Dyson representation** for this causal commutator and the spectral properties allow one to derive the following analytic properties of T considered as function of the invariants $W^2 = (p+k)^2$ and $\Delta^2 = \frac{1}{4}(p-p')^2$ where p, p' and k, k' are the initial and final nucleon and meson momenta. M is an analytic function in a certain region of the Δ^2 plane, the boundary of which can be expressed as of function of W^2 and μ^2 , and for $\mu^2 < -\frac{\Delta^2}{4}$ is an analytic function in the upper half of the complex W^2 plane. Hence for this case

$$T(W^2, \Delta^2, \mu^2) = \frac{1}{\pi} \int dW'^2 \frac{\text{Im } T(W'^2, \Delta^2, \mu^2)}{W'^2 - W^2}.$$

Symmetry properties and spectral properties of $\text{Im } T$ allow us to rewrite the right-hand side only over the range W'^2 from $(\mu + M)^2$. It is further necessary to show that this relation holds for μ^2 extrapolated to its physical value; this can be done.

The problem of proving the analytic properties relevant for the dispersion relations is a special case of the general task of finding what analytic properties of **Green's functions** follow from (a) Lorentz invariance, (b) causality, and (c) spectral conditions. For the two-particle scattering amplitude, one is dealing with the vacuum expectation value of the retarded or time ordered product of four operators and thus with a function of the 6 scalar

products which can be formed from the 3 independent vectors $p + p', p + k', p' + k$. Local commutativity and spectral conditions assert that these functions are analytic in a certain domain D in the space of 6 complex variables. The problem is then to characterize this domain and to compute its envelope of holomorphy $E(D)$ and to derive a representation of the most general function in the class of interest which is analytic in $E(D)$ and has singularities everywhere on the boundary.

DISPERSION, ROTATORY. See **rotatory dispersion**.

DISPERSIVE POWER. (1) The ratio of the difference in **deviation** of light of two different wavelengths relative to the deviation for light whose wavelength is an average of the two. Thus, if D_A, D_B are the **deviations** for wavelength $\lambda = A$ and $\lambda = B$ and if D_C is that for light of some intermediate wavelength $\lambda = C = \frac{1}{2}(A + B)$, then the dispersive power is given by

$$d = \frac{D_A - D_B}{D_C}.$$

(2) A quantity which is approximately equal to the reciprocal of the dispersive power, also referred to as the Abbe number or as ν -value, is defined by lens designers and manufacturers of optical glass as

$$\nu = \frac{n_D - 1}{n_F - n_C}$$

where n_D, n_F and n_C are the refractive indices of the glass for the **D, F, and C Fraunhofer lines**.

DISPERSIVITY, MOLAR. The difference in molar **refraction** at two wavelengths.

DISPERSIVITY, SPECIFIC. The difference in specific **refraction** at two wavelengths.

DISPLACEMENT. (1) The vector quantity denoting change in position of a point is called displacement. The term *linear displacement* is employed occasionally to distinguish displacement from *angular displacement*. Angular displacement, the change in angular position, is not a vector quantity.

(2) In a piston and cylinder mechanism, displacement means the volume swept out by the piston face. Given the bore and stroke as D

and L , the number of cylinders n , the displacement is:

$$\frac{\pi D^2 L n}{4}$$

(3) The term displacement is also applied to ships. The portion of a ship which is immersed in water is buoyed up by a force equal to the weight of water displaced by the body. Hence the displacement of a ship in tons of water is equal to the weight of the ship and of its contents. Various legal and conventional definitions of the displacement of a ship are related, but not equal, to the buoyancy.

(4) For electric displacement, see **electric induction** and **current, displacement**.

DISPLACEMENT, COMPLEX. In solving for the transient and steady state behavior of a vibrating system undergoing **forced oscillations**, it is often mathematically useful to construct a complex displacement $x_c = x + ix'$, where x is the real, and x' the imaginary part.

DISPLACEMENT COMPONENTS. Change of the coordinates, in some reference system, of a particle of a body arising from a **deformation** of the body.

DISPLACEMENT CURRENT. See **current, displacement**.

DISPLACEMENT, ELECTRIC. See **electric induction** and **current, displacement**.

DISPLACEMENT FIELD (IN A BODY). The vector field defined by the **displacement** vector throughout the body.

DISPLACEMENT, GENERALIZED. Angular displacement, rotation, curvature, change in volume, change in length, etc., may be considered as generalized displacements. Each has a corresponding generalized force (moment, pressure, force, etc.) which multiplied by the generalized displacement, gives a virtual or real work quantity.

DISPLACEMENT LAW, SOMMERFELD-KOSSEL. See **Sommerfeld-Kossel displacement law**.

DISPLACEMENT OPERATOR. See **difference operators**.

DISPLACEMENTS, COMPATIBLE. Displacements compatible with the **constraints** is a phraseology employed in some statements of

the theorem of **virtual work**. Its meaning is that the displacements chosen for the system do not violate the actual conditions of support or constraint of the system.

DISPLACEMENT THICKNESS OF BOUNDARY LAYER. The displacement thickness δ^* for a boundary layer is defined by

$$\delta^* = \int_0^\delta \left(1 - \frac{u}{U}\right) dy,$$

where u is the velocity at a distance y from the wall and U is the velocity outside the boundary layer, i.e., for $y > \delta$.

The streamlines in the potential flow outside the boundary layer are displaced away from the wall by an amount δ^* , due to the reduced velocity in the boundary layer.

DISPLACEMENT, VIRTUAL. Any displacement of a system may be termed a virtual displacement. Often the term is restricted to infinitesimal displacements compatible with the constraints.

DISSIPATION. (1) The interaction between matter and energy incident upon it, such that the portion of the energy used up in the interaction is no longer available for conversion into useful work. (2) A persistent loss of mechanical energy because of the presence of frictional or frictionlike forces or resistances. (3) In free oscillatory motion, a persistent loss of mechanical energy due to presence of friction-like resistance to motion which eventually exhausts the total energy of the system and causes it to come to rest. Such motion is said to be damped. (See **oscillations, damped**.)

DISSIPATION FACTOR. The reciprocal of **Q**, the **storage factor**.

DISSIPATION FUNCTION. A mathematical expression related to the loss of the mechanical energy in a system. For example, if a system consists of a number of particles, and the equations of motion for a typical particle are

$$m\ddot{x} = -R_1\dot{x} + X$$

$$m\ddot{y} = -R_2\dot{y} + Y$$

$$m\ddot{z} = -R_3\dot{z} + Z$$

(X , Y , and Z are the components of the total force, external and molecular, on the particle,

except the force of resistance; R_1, R_2, R_3 are the friction constants for the typical particle), then the function $F = \frac{1}{2}\Sigma R_1\dot{x}^2 + R_2\dot{y}^2 + R_3\dot{z}^2$ is the dissipation function of the system. If q_1, q_2, \dots, q_n are the generalized coordinates of the system and if Q_r denotes the expression

$$Q_r = \sum_1^N \left[X \frac{\partial x}{\partial q_r} + Y \frac{\partial y}{\partial q_r} + Z \frac{\partial z}{\partial q_r} \right],$$

and if T is the kinetic energy of the system, the equation of motion can be written in the form

$$\frac{d}{dt} \left(\frac{\partial T}{\partial \dot{q}_r} \right) - \frac{\partial T}{\partial q_r} + \frac{\partial F}{\partial \dot{q}_r} = Q_r \quad (r = 1, 2, \dots, n).$$

Dots mean derivatives with respect to time. (See also **time variation of entropy production**; **Rayleigh dissipation function**.)

DISSIPATIVE FORCE. Non-conservative forces are dissipative. The work they do is path-dependent. Part or all of this work is converted to non-available energy and does not appear as kinetic or potential energy.

DISSIPATIVE FUNCTION. See **dissipation function**.

DISSOCIATION ENERGY OF A MOLECULE. The energy necessary for the complete separation from each other of the two atoms forming a diatomic molecule, or for the removal of an atom or a group of atoms from a polyatomic molecule. More exactly, the dissociation energy is the difference between the energy of the molecule and its dissociation products in their respective ground states. If therefore the actual dissociation process leads to atoms (or radicals) in excited states the dissociation energy is the energy needed for their separation minus the excitation energy. (See also **potential functions**; **atomic heats of formation**; **bond energies**.)

DISSOCIATION LAWS. See **Saha equilibrium formula**.

DISSOCIATION OF DIATOMIC GAS. See **Saha equilibrium formula**.

DISSYMMETRY FACTOR OR ANISOTROPY FACTOR. A quantity used to express conveniently the magnitude of **circular dichromism**. It is defined by the following formula:

$$g = \frac{(\kappa_l - \kappa_r)}{\kappa}$$

where g is the dissymmetry factor, κ_l and κ_r are the absorption indices for the left- and right-circularly polarized light, and κ is the absorption index for ordinary light of the same wavelength.

DISTANCE, GEODESIC. Geodesic distance. (See **geodesic parallels**.)

DISTORTION. In general, a change of form, shape, or wave form. The last usage applies to acoustics and electromagnetics. In optics, the following specific usages apply: (1) Qualitatively, the **image error** due to the departure of optical imagery from a similarity transformation. (2) Quantitatively, one of the five **Seidel aberrations**.

DISTORTIONAL STRAIN ENERGY. See **Mises yield condition**.

DISTORTIONAL WAVE. See **wave(s), shear**.

DISTORTION, AMPLITUDE. A type of distortion that occurs in an amplifier or other device when the amplitude of the output is not exactly a linear function of the input amplitude. (See also **distortion, amplitude-frequency**; and **distortion, harmonic**.)

DISTORTION, AMPLITUDE-FREQUENCY. Distortion due to an undesired amplitude-frequency characteristic. The usual desired characteristic is flat over the frequency range of interest. Amplitude-frequency distortion is sometimes called *amplitude distortion* or *frequency distortion*.

DISTORTION ENERGY. The energy stored elastically may be considered to be the sum of a volumetric and a shear strain or distortional energy. The volumetric energy is that associated with the mean stress, the distortion energy with the stress deviation. For an isotropic material the distortion energy per unit volume is

$$\frac{1}{12G} [(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2]$$

where $\sigma_1, \sigma_2, \sigma_3$ are principal stresses and G is the shear modulus or modulus of rigidity.

DISTORTION, ENVELOPE DELAY. That form of distortion which occurs when the rate of change of phase shift with frequency of a circuit or system is not constant over the fre-

quency range required for transmission. Envelope delay distortion is usually expressed as one-half the difference in microseconds between the maximum and minimum envelope delays existing between the two extremes of frequency defining the channel used.

DISTORTION, GEOMETRICAL. See **geometrical distortion**.

DISTORTION, HARMONIC. Nonlinear distortion characterized by the appearance in the output of harmonics other than the fundamental component when the input wave is sinusoidal. Harmonic distortion is sometimes called amplitude distortion.

DISTRIBUTED FORCE. See **force, distributed**.

DISTRIBUTION. If a variable can take a set of values $\{x\}$ with relative frequency or probability $f(x)$, it is said to be distributed over these values and to have a distribution.

$f(x)$ is called the *frequency function* and its sum or integral $\int_{-\infty}^x f(x)dx = F(x)$ is called the *distribution function*. Similar definitions apply if x is continuous and mathematically it may be more convenient to define $F(x)$ and to regard $f(x)$ as its derivative when existent.

There are many variants of these names. The frequency function is often called the *probability density function* and the distribution function is called the *cumulative frequency function* or *cumulative probability function* or even the *probability function*.

The terminology extends immediately to more than one variable. (See also **binomial distribution**; **Edgeworth's series**; **Gram-Charlier series**; **normal distribution**; **Pearson distribution**; **Poisson distribution**; **Maxwell distribution**; **Maxwell-Boltzmann distribution**; **distribution-in-momentum**; **distribution theory**.)

DISTRIBUTION, ARC-SINE. See **arc-sine distribution**.

DISTRIBUTION, CAUCHY. See **Cauchy distribution**.

DISTRIBUTION COEFFICIENTS (CHEMICAL). See **Nernst distribution law**.

DISTRIBUTION COEFFICIENTS (OPTICAL). The tristimulus values, on any given colorimetric system, of the monochromatic

components of an equal energy spectrum. The set of distribution coefficients defines the *distribution functions* or *distribution curves*. (See **CIE-distribution coefficients**.)

DISTRIBUTION FACTORS. The **moment distribution factors** which multiply the unbalanced moment at a joint to give the moments to be distributed to the members framing into the joint.

DISTRIBUTION-FREE INFERENCE. A method of inference in statistics which does not depend on the precise form of the parent distribution. For example, if treatments A and B are applied to n pairs of plots, the n differences in yield typified by $x_A - x_B$ can be tested for significance by considering their sign only, a large preponderance of positive signs indicating that A is better than B ; and this does not depend on the **distribution** of the x values.

DISTRIBUTION FUNCTION. See **distribution**.

DISTRIBUTION FUNCTION, FERMI-DIRAC. See **Fermi-Dirac distribution function**.

DISTRIBUTION IN ENERGY. A probability distribution function for various energy values.

DISTRIBUTION IN MOMENTUM. A probability distribution function for various values of momentum.

DISTRIBUTION IN PHASE. A probability distribution function in phase space.

DISTRIBUTION, MOMENT OF. See **moment of a distribution**.

DISTRIBUTION OF MOLECULAR VELOCITIES, LAW OF. At any given temperature different molecules of a gas have different velocities which range from very small to very large values. A large majority of molecules have velocities falling in a narrow range, but a small fraction of molecules have very low or high velocity. As the temperature is raised the maximum in the velocity distribution curve shifts to higher velocities and flattens out. (See **Maxwell distribution law**.)

DISTRIBUTION THEORY. The usual definition of the Dirac δ function given by

$$\delta(x) = 0, x \neq 0 \quad \text{and} \quad \int_{-\infty}^{+\infty} \delta(x)dx = 1,$$

is not a mathematically valid definition since if a function is zero everywhere except at a point, its integral, with the usual Lebesgue definition of the integral, vanishes. The theory of distributions of L. Schwartz generalizes the notion of the ordinary (measurable) function and defines the notion of a "generalized function." Such generalized functions encompass δ functions and their derivatives and justify their use. In the following a complex valued function $\phi(x) = \phi(x_1 \cdots x_n)$ of n real variables $x_1, x_2 \cdots x_n$, where $x_1 \cdots x_n$ range over n dimensional Euclidean space R^n , is said to be a "test function" if it is infinitely differentiable, and vanishes outside some compact set K (i.e., a closed and bounded interval in the case $n = 1$). The complement of the largest open set where $\phi(x)$ is zero is called the *support* of $\phi(x)$. We denote by D the set of these test functions: D is the vector space of all C^∞ functions that have compact support. A sequence $\{\phi_n(x)\}$ of test functions is said to converge to zero if the functions $\phi_n(x)$ and all their derivatives converge uniformly to zero and if all ϕ_n have the same compact support. (Uniform convergence is required for each fixed order of the derivatives, not for all orders collectively.) This notion of convergence defines a (pseudo-) topology in D . A **functional** T on D is an operation that associates with every $\phi \in D$ a complex number. This associated number is denoted by $T(\phi)$. A functional T on the space of test function D is said to be linear if

- (a) $T(\phi_1 + \phi_2) = T(\phi_1) + T(\phi_2)$ for every ϕ_1, ϕ_2 in D .
- (b) $T(\lambda\phi) = \lambda T(\phi)$ for every ϕ in D and every complex number λ .

A functional is said to be continuous if $T(\phi_j)$ converges to zero for any sequence $\{\phi_j\}$ of functions ϕ_j in D that converge to zero as defined above.

A *distribution* as defined by Schwartz is a continuous linear functional on the space of test functions D . The space of all distributions is denoted by D' and is the dual space of D . A distribution T is said to be zero in an open set Ω of R^n if $T(\phi) = 0$ for all test functions ϕ in D whose support is contained in Ω . The support

of a distribution is the complement of the largest open set in which T is zero.

Let E be the vector space of all C^∞ (infinitely differentiable) functions with arbitrary support. Convergence in E is defined as follows: A sequence $\{\phi_j\}$, ϕ_j in E , converges to zero if the ϕ_j converge to zero in every compact subset of R^n and the same is true for the derivatives of any order. (Uniform convergence is again required only for fixed order of the derivatives, not for all order collectively.) If ϕ_0 is a fixed function in E , we can define as neighborhoods of the sets $\{\phi \mid |\phi(x) - \phi_0(x)| < \epsilon\}$ for x in K , where $\epsilon > 0$ and K is a compact set. This definition of neighborhoods defines a topology in that a sequence is convergent in this topology if it is convergent as defined above. The dual space of E , that is, the space of continuous linear functional on E is denoted by E' . Schwartz has shown that E' consists exactly of those distributions in D' that have compact support.

It is sometimes convenient to write a distribution as an integral over a "generalized function" as follows:

$$T_f(\phi) = \int_{-\infty}^{+\infty} f(x)\phi(x)dx$$

where the integral and the "generalized function" $f(x)$ is defined by this equation. The Dirac δ -function as well as the singular functions $\Delta, \Delta_{(1)}$ etc., are such generalized functions.

On the other hand if $f(x)$ is a summable function, then the Lebesgue integral $\int_{-\infty}^{+\infty} f(x)\phi(x)dx$ defines a distribution which is again denoted by $T_f(\phi)$.

The derivative of a generalized function is defined in such a way that it remains valid when the generalized function is also a differentiable function. One defines the derivative of a generalized function $f'(x)$ by

$$\int_{-\infty}^{+\infty} f'(x)\phi(x)dx = - \int_{-\infty}^{+\infty} f(x)\phi'(x)dx.$$

For every test function ϕ the right hand side always exists and hence the left hand side gives a definition of $f'(x)$. The distribution derivative DT_f is defined by

$$DT_f(\phi) = -T_f(d\phi/dx).$$

A function $f(x)$ is said to be "rapidly decreasing" if it tends to zero faster than any polynomial as $|x| \rightarrow \infty$. Let S be the set of these functions. A sequence $\{\phi_n(x)\}$ in S tends to

zero if $\{D^l P(x)\phi_n(x)\}$ tends to zero uniformly for all x as $n \rightarrow \infty$, for each polynomial P and each l .

A "tempered distribution" T is a linear functional on S such that $T(\phi_n) \rightarrow 0$, if $\{\phi_n\} \rightarrow 0$. The set of tempered distributions, S' , is the largest set in which Fourier transforms map the space into itself. The Fourier transform \tilde{T} of any T in S' is defined to be that distribution for which

$$T(\hat{\phi}) = \tilde{T}\bar{\phi}$$

where $\hat{\phi}(x) = \phi(-x)$ and $\bar{\phi}$ is the Fourier transform of ϕ which, if ϕ is S , is also in S . When T corresponds to an absolutely integrable function, this above definition reduces to the usual Fourier transformation.

DISTRIBUTIVE LAW. An operator A is distributive over addition (obeys the distributive law) if $A(a + b) = Aa + Ab$. Thus, in elementary arithmetic, multiplication is distributive over addition.

DIVERGENCE. The scalar product of the vector differential operator, **del** (∇) and a **vector**. In Cartesian coordinates

$$\nabla \cdot \mathbf{v} = \text{div } \mathbf{v} = \frac{\partial V_x}{\partial x} + \frac{\partial V_y}{\partial y} + \frac{\partial V_z}{\partial z}.$$

The divergence of a position vector is constant; $\nabla \cdot \mathbf{R} = 3$; $\mathbf{R} = \mathbf{i}x + \mathbf{j}y + \mathbf{k}z$.

If \mathbf{v} represents at each point in space the direction and magnitude of a vector, then $\text{div } \mathbf{v}$ is the outward flux of the vector per unit volume.

If the divergence of a vector function of position vanishes everywhere in a certain region, the function is said to be a solenoidal vector in that region. It follows that if \mathbf{v} is a solenoidal vector so that $\nabla \cdot \mathbf{v} = 0$, then $\mathbf{v} = \nabla \times \mathbf{w}$, or \mathbf{v} is the **curl** of some vector \mathbf{w} .

DIVERGENCE LOSS (SOUND). That part of the **transmission loss** which is due to the divergence or spreading of the sound rays in accordance with the geometry of the system (e.g., spherical waves emitted by a point source).

DIVERGENCES IN QUANTIZED FIELD THEORY, REMOVAL OF. In any quantized

field theory corresponding to the interaction of fermions with bosons based on a Lagrangian with an interaction term of the form $G\bar{\psi}\Gamma\psi\phi$ where ψ is the fermion field operator and ϕ that of the boson field, the **S-matrix** expansion in powers of G will contain divergences in the higher order terms. In particular, for the case of quantum electrodynamics the rules for evaluating Feynman diagrams (see **S matrix, evaluation of**) imply that three types of divergences can occur in evaluating an n^{th} order diagram consisting of F_e external and F_i internal electron lines, P_e external and P_i internal photon lines, and n_s vertices at which the **mass renormalization** term act. Of these, those arising because the integrand does not fall off rapidly enough for large values of the momentum of one of the internal lines are called ultraviolet divergences and are the ones with which the **renormalization** technique is designed to eliminate. The other divergences are connected with the fact that photons have zero mass (infrared divergences) or the onset of inelastic processes and can be handled in a known fashion. Any ultraviolet divergence will be removed if a sufficient number of the internal momenta are held fixed. A *primitive divergent* is defined as a divergent graph made convergent by the cutting of any internal line. Dyson has shown that any graph for which $\frac{3}{2}F_e + P_e + n_s > 4$ has the matrix element which is convergent. The number of primitive Feynman divergent graphs in quantum electrodynamics are finite and are indicated in Figure 1. In that figure,

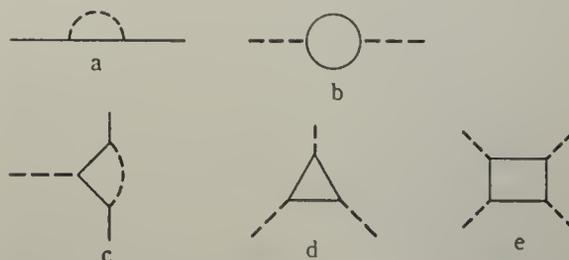

Fig. 1.

a and b are an electron and a photon self-energy diagram, respectively. Diagram a gives rise to a possible linearly divergent contribution, b , to a possibly quadratically divergent contribution, though in fact the quadratically divergent contribution vanishes by **gauge invariance**. Diagram c is a vertex part, and

is at most logarithmically divergent. The diagram d actually gives a zero contribution to the S -matrix (Furry's theorem) and therefore need not be considered. Diagram e correspond to the scattering of light by light and is potentially logarithmically divergent. However, due to gauge invariance it is in fact convergent. There are therefore just three primitive divergents in quantum electrodynamics. (In meson theory with a coupling of the form $(G\bar{\psi}\lambda\gamma\phi)$ diagram e is divergent and must be compensated by a counter term $\delta\phi^4$ in \mathcal{L} , diagram d vanishes if ϕ is a pseudoscalar field, otherwise it is divergent and must also be compensated.)

The possible divergences of the theory having been isolated, the next stage is to devise a prescription for the removal of these divergences. Consider an arbitrary graph G . Associated with this graph is a skeleton graph G_o formed by omitting all self-energy and vertex parts from G . A graph which is its own skeleton is irreducible. Starting from an irreducible graph, the insertion of self-energy and vertex parts in all possible ways give rise to a set Γ , of diagrams. It is possible to give a prescription to find the contribution of $M(\Gamma)$ of Γ to S from a specification of G_o . This has the consequence that only irreducible diagrams need be considered.

To establish this prescription, consider the effect of the insertion of an electron self-energy part into the internal electron line of momentum p of any graph. By the rules previously established the effect of this insertion is to replace the factor $S_F(p)$ by

$$S_F(p) \frac{ie^2}{(2\pi)^4} \left\{ \int d^4k D_F(k) \gamma^\mu S_F(p+k) \gamma_\mu \right\} S_F(p),$$

i.e., $S_F(p)$ by $S_F(p) \Sigma^{(2)}(p) S_F(p)$. The factor

$$\begin{aligned} \Sigma^{(2)}(p) &= \frac{e^2}{(2\pi)^4} \int d^4k D_F(k) \gamma^\mu S_F(p+k) \gamma_\mu \\ &= \int d^4k R(p,k) \end{aligned}$$

is at most linearly divergent. Therefore, the integrand $R(p,k)$ when expanded into a **Taylor series**

$$R(p,k) = R(0,k) + p \frac{\partial}{\partial p} R(0,k) + R_c(p,k)$$

is such that $\int R_c(p,k) d^4k$ converges. Relativistic invariance further asserts that

$$\begin{aligned} \Sigma^{(2)}(p) &= A^{(2)} + B^{(2)}(\gamma p - m) \\ &\quad + (\gamma p - m) S_c^{(2)}(p) \end{aligned}$$

where $A^{(2)}$ and $B^{(2)}$ are infinite constants and $S_c^{(2)}(p)$ vanishes for $\gamma p = m$, i.e., if p corresponds to a free electron line. For a free electron $\Sigma^{(2)}$ reduces to $A^{(2)}$, which corresponds to the change in mass of the electron due to its interaction with the radiation field. The only physical change which can occur for a single particle with the radiation field is a change of mass so that one would expect the modified propagator to be derived in this case to be S_F the function corresponding to the mass $m_o + \delta m$. Since

$$\begin{aligned} &\frac{1}{\gamma p - (m_o + \delta m)} \\ &= \frac{1}{\gamma p - m_o} + \delta m \frac{1}{\gamma p - m_o} \cdot \frac{1}{\gamma p - m_o} + \dots \\ &= S_F(p) + \delta m S_F(p) \cdot S_F(p) + \dots \end{aligned}$$

$A^{(2)}$ is equal to δm to order e^2 .

Now in the Lagrangian formulation of the theory, the mass m_o which one writes down for the mass of the electron-positron field is the bare mass. The experimentally determined mass, m is equal to $m_o + \delta m$ where δm is the correction to the mass due to the interaction with the radiation field. One can formulate the theory in terms of m , by writing for the mass term in the Hamiltonian, $m_o \bar{\psi}\psi = m \bar{\psi}\psi - \delta m \bar{\psi}\psi$ and include the $\delta m \bar{\psi}\psi$ term with the interaction term $\bar{\psi}\gamma_\mu \psi A^\mu$. H_I is then equal to $j^\mu A_\mu - \delta m \bar{\psi}\psi$. If this formulation is adopted there will also arise an insertion into the internal electron line due to the action of the $\delta m \bar{\psi}\psi$ term. The contribution of this graph is obtained by replacing S_F (which is now expressed in terms of the mass m) by $S_F \delta m S_F$. The contribution of both these insertions thus requires S_F to be replaced by

$$\begin{aligned} S_F(p) &\rightarrow S_F(p) + S_F(p)[(A^{(2)} - \delta m) \\ &\quad + B^{(2)}(\gamma p - m) + (\gamma p - m) S_c] S_F(p). \end{aligned}$$

Therefore if δm to order e^2 is set equal to $A^{(2)}$, this divergence is eliminated. This is called **mass renormalization**. Since

$$S_F(p)(\gamma p - m) = 1,$$

after mass renormalization to order e^2

$$S_F(p) \rightarrow (1 + B^{(2)})S_F(p) + S_F(p)(\gamma p - m)S_c(p)S_F(p).$$

The $B^{(2)}$ divergence has the effect of multiplying S_F by a factor $1 + B$, which renormalization is usually called *wave function renormalization*.

A similar treatment holds for the replacement of a simple vertex by the diagram c . The vertex factor γ_μ is found to be modified by the replacement of γ_μ by $\Lambda_\mu(p, p')$ with

$$\Lambda_\mu^{(2)}(p, p') = \frac{e^2}{(2\pi)^4} \int D_F(k) \{ \gamma^\lambda S_F(p + k) \gamma_\mu S_F(p' + k) \gamma_\lambda \}$$

which is at most logarithmically divergent. Relativistic invariance asserts that $\Lambda_\mu^{(2)}$ can be written in the form $\Lambda_\mu^{(2)}(p, p') = L^{(2)}\gamma_\mu + \Lambda_{\mu c}^{(2)}(p, p')$ with $\Lambda_{\mu c}^{(2)}$ convergent and equal to zero for $\gamma p = \gamma p' = m$. It can be shown that $-L^{(2)} = B^{(2)}$. This is a special case of the theorem proved by Ward that $-L = B$ to all orders.

Finally the insertion of a photon self-energy part (figure 1b) into an internal photon line of momentum k implies the replacement of $D_F(k)$ by $D_F(k)\Gamma(k)D_F(k)$ where to second order

$$\begin{aligned} \Pi^{(2)}k &= \frac{e^2}{(2\pi)^4} \int d^4p \text{Tr} \{ \gamma_\mu S_F(p) \gamma^\mu S_F(p + k) \} \\ &= \frac{e^2}{(2\pi)^4} \int d^4p P(p, k) \end{aligned}$$

is at most quadratically divergent. The Taylor expansion of P , then yields for Π an expression of the form $\Pi(k) = C^{(2)} + D^{(2)}k^2 + k^2\Pi_c^{(2)}(k^2)$ since from relativistic invariance $\Pi = \Pi(k^2)$ where Π_c is convergent and vanishes for $k^2 = 0$. The term $C^{(2)}$ vanishes by gauge invariance. The divergent term $D^{(2)}$ gives rise by renormalization of the electromagnetic field strength or equivalently to a renormalization of the charge. The remaining convergent term leads to observable effects and is the physical manifestation of the **polarization of the vacuum**.

The above rules outlined for the e^2 correction can be generalized for arbitrary insertions and lead to the following rules to obtain from G^o the complete contribution of the graphs of Γ to $S^{(n)}$. For every internal electron line of the irreducible diagram G_o from which Γ is ob-

tained, make the replacement $S_F(p)$ by $S'_F(p)$ where

$$S'_F(p) = S_F(p) + S_F(p)\Sigma(p)S_F(p)$$

where $\Sigma(p)$ denotes the sum of contributions of all possible self-energy diagrams. For the photon lines, replaces D_F by D'_F , where

$$D'_F(R) = D_F(k) + D_F(k)\Pi(k)D_F(k)$$

and each vertex factor γ_μ by $\Gamma_\mu(p, p')$ where

$$\Gamma_\mu(p, p') = \gamma_\mu + \Lambda_\mu(p, p').$$

The removal of the divergences from self-energy diagrams which are more complicated than the irreducible ones drawn above is somewhat more involved, but consistent rules can nonetheless be given. For example, the diagram in Figure 2

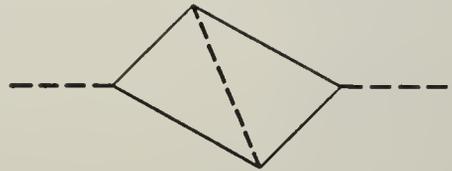

Fig. 2.

obtained by adding a vertex part to an irreducible photon self-energy diagram gives rise to "overlapping" divergences. As stated above, consistent rules for subtracting these divergences can be given.

The culmination of these rules due to Dyson and Salam is the proof that the finite contributions D'_{F1} , S'_{F1} , $\Gamma_{\mu 1}$ left after the subtraction of infinities are related to the complete quantities Γ_μ , S'_F , D'_F by multiplicative constants, i.e.,

$$\Gamma_\mu = Z_1^{-1}\Gamma_{\mu 1}(e_1)$$

$$S'_F = Z_2 S'_{F1}(e_1)$$

$$D'_F = Z_3 D'_{F1}(e_1)$$

where

$$e_1 = Z_1^{-1}Z_2Z_3^{1/2}e.$$

Charge conservation, or equivalently gauge invariance implies that $Z_1 = Z_2$ (Ward's identity). The quantity e_1 is called the renormalized charge.

The above has the result that for any irreducible diagram G_I^n of order n which gives rise to a finite contribution to S_n , one can obtain the complete radiative connections to this diagram by the replacement $S_F \rightarrow S'_F$, $D_F \rightarrow D'_F$, $\gamma_\mu \rightarrow \Gamma_\mu$. These contributions are divergent. However, if the integrand of G_I^n is $e^n \mathbf{I}(D'_F, S'_F, \gamma_\mu)$ then it can be shown that

$$e^n \mathbf{I}(D'_F, S'_F, \Gamma_\mu) = (eZ_1^{-1}Z_2Z_3^{1/2})^n \mathbf{I}(D'_{F1}S'_{F1}\Gamma_{\mu1}) \\ = e_1^n \mathbf{I}(D'_{F1}S'_{F1}\Gamma_{\mu1})$$

where $\mathbf{I}(D'_{F1}, S'_{F1}, \Gamma_{\mu1})$ leads to a convergent integral. Thus a finite result is obtained for the graph considered with all its added radiative corrections. The quantity e_1 can be identified with the experimentally measured charge of the electron, since the above rules lead to the conclusion that two slowly moving electrons separated by a large distance r interact according to a potential e_1^2/r . Thus all the infinities in quantum electrodynamics are isolated in two infinite constants, the mass and charge parameters of the electron.

DIVERGENT. Not convergent.

DIVIDED DIFFERENCES. For *interpolation* with unequally spaced abscissae, let $f(x)$ be the function to be interpolated, and let its values be given at

$$x_0, x_1, \dots, x_n,$$

where it is not required that they be in order or even distinct. Form the table as follows:

x_0	$f(x_0)$				
x_1	$f(x_1)$	$f(x_0, x_1)$			
x_2	$f(x_2)$	$f(x_1, x_2)$	$f(x_0, x_1, x_2)$		
x_3	$f(x_3)$	$f(x_2, x_3)$	$f(x_1, x_2, x_3)$	$f(x_0, x_1, x_2, x_3)$	\dots
x_4	$f(x_4)$	$f(x_3, x_4)$	$f(x_2, x_3, x_4)$	$f(x_1, x_2, x_3, x_4)$	

where

$$f(x_i, x_j) = [f(x_i) - f(x_j)]/(x_i - x_j);$$

$$f(x_i, x_j, x_k) = [f(x_i, x_j) - f(x_j, x_k)]/(x_i - x_k);$$

.....

When there are coincident abscissae they should be placed in adjacency, and then

$$f(x, x) = f'(x),$$

$$f(x, x, x) = f''(x)/2!,$$

.....

It can be shown that any divided difference is a symmetric function of all its arguments, which means that

$$f(\dots, x_i, \dots, x_j, \dots) = f(\dots, x_j, \dots, x_i, \dots),$$

it being understood that dots represent arguments that are the same on the two sides.

In terms of divided differences one can write the following interpolation formula due to Newton:

$$f(x) = f(x_0) + (x - x_0)f(x_0, x_1) \\ + (x - x_0)(x - x_1)f(x_0, x_1, x_2) + \dots \\ + (x - x_0) \dots (x - x_n)f(x_0, x_1, \dots, x_n, x),$$

where the last term written is the **remainder** and previous ones constitute the interpolation formula.

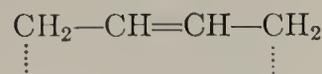

DOMAIN. The domain of a function or operator is the **set** of its arguments, i.e., the values that the independent variable (or variables) may assume. An *integral domain* is a **ring** with unit element in which division, when it exists, is unique. An **open non-empty** (connected) **point-set** is called a domain.

DOMINANT MODE. In a **waveguide**, that characteristic field configuration (mode) having the lowest **cutoff frequency**. For excitation frequencies between this cutoff and the next higher, this is the only mode by which energy will be propagated along the waveguide.

DOMINANT WAVELENGTH. Dominant wavelength (of a colored light, not purple) is the wavelength of the **spectrum** light that, when combined in suitable proportions with the specified **achromatic** light, yields a match with the light considered. When the dominant wavelength cannot be given (this applies to purples) its place is taken by the **complementary wavelength**.

DONNAN MEMBRANE EQUILIBRIUM. Suppose two solutions α, β to be separated by a membrane permeable to some of the ions present and to the solvent, but not to all of the ions. The equilibrium which is eventually reached is called the Donnan membrane equilibrium.

DONOR BOND. A double or triple bond which has a tendency to share some of its multiple bond character with a neighboring bond. The latter is an *acceptor bond*. For example, in the fundamental state of butadiene: $\text{CH}_2=\text{CH}-\text{CH}=\text{CH}_2$, the 1-2 and 3-4 bonds are donor bonds, while the 2-3 bond is an acceptor bond. Compare the two resonant formulas:

.....

The dotted line in the second configuration represents a bond between two unpaired electrons of opposite spin on the terminal C atoms. (See also **bond character**.)

DOOLITTLE METHOD. A particular scheme of recording intermediate results in applying triangularization to solve a system of normal equations. (See **matrix inversion**.)

DOPPLER EFFECT. The effects upon the apparent frequency of a wave train produced (1) by motion of the source toward or away from the stationary observer, and (2) by motion of the observer toward or from the stationary source; the motion in each case being with reference to the (supposedly stationary) medium.

For sound waves, the observed frequency f_0 , in cycles/sec, is given by

$$f_0 = \frac{v + w - v_0}{v + w - v_s} f_s$$

where v is the velocity of sound in the medium, v_0 is the velocity of the observer, v_s is the velocity of source, w is the velocity of wind in the direction of sound propagation, and f_s is the frequency of source.

For optical waves

$$f_0 = f_s \sqrt{\frac{c + v}{c - v}}$$

where v is the velocity of the source relative to the observer and c is the speed of light.

DOPPLER WIDTH OF A SPECTRAL LINE.

The contribution to the total line width of the Doppler shifts due to the thermal motions of the absorbing or emitting atoms.

The whole Doppler width ($2 \times$ Doppler half width) of a spectral line is given by

$$2(\Delta\lambda)_D = \frac{2\xi_0\lambda}{c}$$

where λ is the wavelength at the center of the line, c the velocity of light, and

$$\xi_0 = \sqrt{\frac{2RT}{\mu}}$$

the most probable thermal velocity of the atoms of atomic weight μ at temperature T . (R stands for the gas constant.)

DOPPLER WIDTH OF BREIT-WIGNER CROSS-SECTION. In the theory of the resonant capture of neutrons by heavy nuclei, the temperature motion of the nuclei causes a broadening of the Breit-Wigner cross-section profile (see **cross-section, Doppler broadened**). The broadening is characterized by the quantity

$$\theta = \frac{4E_0kT}{A\Gamma^2},$$

while $2\sqrt{\theta}$ is the Doppler width, w . Strongly perturbed widths have Gaussian form and fall to $1/e$ of their maximum when $|E - E_0| = w\Gamma$.

DOT PRODUCT OF VECTORS. See **vector multiplication**.

DOUBLE EXPONENTIAL DISTRIBUTION. See **exponential distribution**.

DOUBLE INTEGRATION PROCEDURE. The name given to the straightforward but often cumbersome method of finding **beam deflections** by integrating

$$d^2y/dx^2 = M/EI$$

with support and junction conditions taken into account.

DOUBLE MODULUS. See **modulus, reduced or double**.

DOUBLE REFRACTION. When a beam of light traverses an anisotropic medium, double refraction occurs so that the beam is separated into two components, polarized at right angles to each other, having different velocities within the medium and usually being propagated in different directions. The two components are distinguished as the *ordinary* and the *extraordinary rays*.

DOUBLE SOUND SOURCE. See **sound source, double**.

DOUBLE STARS. A celestial object that appears to be a single star to the unaided eye, but in a telescope is found to be two, or more, stars apparently very close together. If long-continued observation of the system indicates no evidence of relative motion it is safe to assume that the system is merely an optical double, i.e., it appears because the line of sight from one star is close to the line of sight from one very much farther away. If relative

motion of one star to the other is observed, the star is assumed to be a physically connected pair known as a binary system. (See **binary stars**.)

DOUBLE SYSTEM. See **indicial notation**.

DOUBLET. (1) Two electrons which are shared by two atoms so as to form a non-polar valence bond. (2) A pair of spectral lines resulting from transitions between a common state and two states which differ only in total angular momentum (**J**), i.e., have identical values of orbital (**L**) and spin (**S**) angular momenta. (3) Two stationary states having common values of (**L**) and (**S**), but different values of (**J**). (4) A **lens**, particularly an **achromat**, having two components. (5) In fluid mechanics, a source of strength m and a sink of strength $-m$ at distance δx apart constitute a doublet. The potential of the velocity due to a doublet is obtained by differentiating the potential of a source in the direction in which the doublet is oriented. For a doublet of moment $M_1 = m\delta x$, the potential, at distance r at angle θ from the axis of the doublet, is

$$\phi = \frac{M \cos \theta}{r^2}.$$

The potential of a fixed doublet in a uniform stream U , for which $\phi = Ur \cos \theta$, is

$$\phi = \left(Ur + \frac{M}{r^2} \right) \cos \theta$$

which, beyond a distance a , where $a^3 = \frac{2M}{U}$, is the same as the potential for inviscid flow round a sphere of radius a fixed in a uniform stream U .

In two-dimensional flow a line source of strength m per unit length and a parallel line sink of equal strength at distance δx constitute a line doublet of moment $\mu = m\delta x$. The complex potential of a line doublet is

$$\phi + i\psi = \frac{\mu}{2} = \frac{\mu}{r} (\cos \theta + i \sin \theta).$$

DOUBLE TENSOR. See **tensor, double**.

DOUBLING, INVERSION. See **inversion doubling**.

DOUBLING, LAMBDA-TYPE. See **Λ -type, doubling**.

DOUBLING, I-TYPE. See **i-type doubling**.

DRAG (FLUID). The resultant force exerted by the fluid on a body in a uniform stream may be resolved into two components, the *drag* in the direction of the stream and the *lift* perpendicular to the stream.

The force exerted by the fluid on an *element* of the body surface may be resolved into two components, normal and tangential to the surface. The drag due to the integrated effect of the normal components over the whole body surface is the *normal-pressure drag*, while that due to the tangential components is the *surface-friction drag*. In an inviscid fluid, of course, the latter is always zero.

In the absence of shock waves and trailing vortices the normal-pressure drag is also zero for an inviscid fluid, so that the total drag is zero. In a real fluid there is a drag due to effects of viscosity, which appears partly as a normal-pressure drag (sometimes called form drag) and partly as surface-friction drag. For a body of good "streamline shape," with no separation of the boundary layer, the normal-pressure drag is usually very small and most of the drag is due to surface friction, especially at high Reynolds numbers. On a bluff body, separation of the boundary layer leads to a large normal-pressure drag, and the surface-friction drag is then a small proportion of the total.

When lift is produced by a wing or other body, trailing vortices are formed. Kinetic energy must be continually added to the trailing-vortex system, and this energy can only be derived from work done against an associated drag, the *trailing-vortex drag*. Trailing vortex drag has often been called "induced drag," but the latter term has also been used commonly with another meaning, and it is therefore not recommended.

At transonic and supersonic speeds, shock waves are formed and there is then an additional component of drag, the *wave drag*, associated with the dissipation of energy in the shock waves. (See also **drag coefficient; trailing-vortex drag; profile drag of a wing**.)

DRAG (IONIC). The effect of interionic attraction in reducing the freedom of an ion to move in an electrical field, because of the interference of the ions of opposite charge by which a given ion is surrounded. The drag effect is an essential part of the explanation

of the Debye-Hückel theory of the anomalous properties of concentrated solutions of strong electrolytes.

DRAG (OPTICAL). See Fresnel coefficient of drag.

DRAG COEFFICIENT. If D is the drag of a body in a uniform stream of density ρ and velocity V , the drag coefficient is

$$C_D = \frac{D}{\frac{1}{2}\rho V^2 S},$$

where S is a representative area of the body. For bodies of revolution and for bluff bodies, S is usually taken as the "frontal area," i.e., the area of the body's projection on a plane normal to the stream. For a wing, S is usually the plane area, while for a complete airplane it is usually the gross wing area.

For a two-dimensional airfoil, if D' is the drag per unit span, the drag coefficient is

$$C_D = \frac{D'}{\frac{1}{2}\rho v^2 c},$$

where c is the chord. (See also drag.)

DRAG OF A WING, PROFILE. See profile drag of a wing.

DRAG, PROFILE. See profile drag of a wing.

DRAG, TRAILING-VORTEX. See trailing-vortex drag.

DRAG, WING. See slender-body theory.

DRIVING-POINT IMPEDANCE. See impedance, driving point.

DRIVING SYSTEM, ELECTRODYNAMIC.

A driving system in which the mechanical forces are developed by the interaction of currents in a conductor and the magnetic field in which it is located. The system is depicted in the figure. The force f_M , in dynes, due to the interaction of the current in the voice coil and the polarizing magnetic field is

$$f_M = Bli \quad (1)$$

where B is the flux density, in gauss, l is the length of the conductor, in centimeters, and i is the current, in abamperes.

The electromotive force e , in abvolts, developed by the motion of the conductor is

$$e = Bl\dot{x} \quad (2)$$

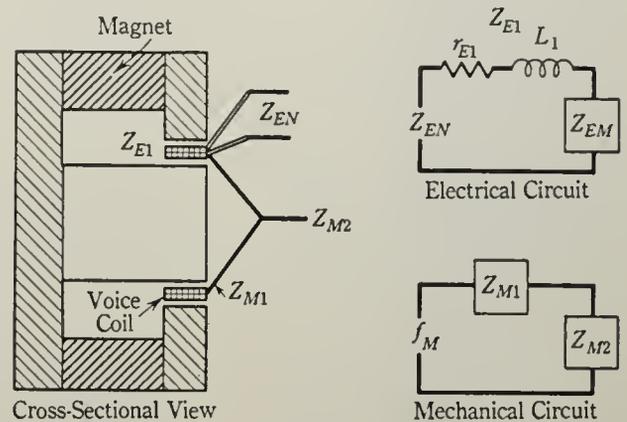

where \dot{x} is the velocity, in centimeters per second.

From Equations 1 and 2

$$\frac{e}{i} = (Bl)^2 \frac{\dot{x}}{f_M} \quad (3)$$

$$\frac{e}{i} = z_{EM} \quad (4)$$

where z_{EM} is the electrical impedance, in abohms, due to motion, termed motional electrical impedance.

Electrodynamic driving system. In the electrical circuit: z_{EN} , the normal electrical impedance of the voice coil. z_{EM} , the motional electrical impedance of the voice coil. z_{E1} , the damped electrical impedance of the voice coil. $z_{E1} = r_{E1} + j\omega L_1$. L_1 and r_{E1} , the damped inductance and electrical resistance of the voice coil. In the mechanical circuit: f_M , the driving force. z_{M1} , the mechanical rectilinear impedance of the voice coil. z_{M2} , the mechanical rectilinear impedance of the load.

From the mechanical circuit of the figure, the mechanical rectilinear impedance of the vibrating system at the voice coil is

$$z_M = z_{M1} + z_{M2} \quad (5)$$

where z_M is the total mechanical rectilinear impedance at the conductor, in mechanical ohms, z_{M1} is the mechanical rectilinear impedance of the voice coil and suspension system, in mechanical ohms, and z_{M2} is the mechanical rectilinear impedance of the load, in mechanical ohms.

The mechanical rectilinear impedance z_M , in mechanical ohms, at the voice coil is

$$z_M = \frac{f_M}{\dot{x}} \quad (6)$$

The electrical impedance due to motion from Equations 3, 4 and 6 is

$$z_{EM} = \frac{(Bl)^2}{z_M} \tag{7}$$

The motional electrical impedance of a transducer is the vector difference between its normal and blocked electrical impedance.

The normal electrical impedance of a transducer is the electrical impedance measured at the input to the transducer when the output is connected to its normal load.

The blocked electrical impedance of a transducer is the electrical impedance measured at the input when the mechanical rectilinear system is blocked, that is, in the absence of motion.

The normal electrical impedance z_{EN} , in abohms, of the voice coil is

$$z_{EN} = z_{E1} + z_{EM} \tag{8}$$

where z_{E1} is the damped electrical impedance of the voice coil, in abohms, and z_{EM} is the motional impedance of the voice coil, in abohms.

The motional electrical impedance as given by Equation 8 may be represented as in series with the blocked or damped electrical impedance of the conductor, as depicted by the electrical circuit in the figure.

The dynamic driving system is almost universally used for all types of direct radiator and horn loud speakers.

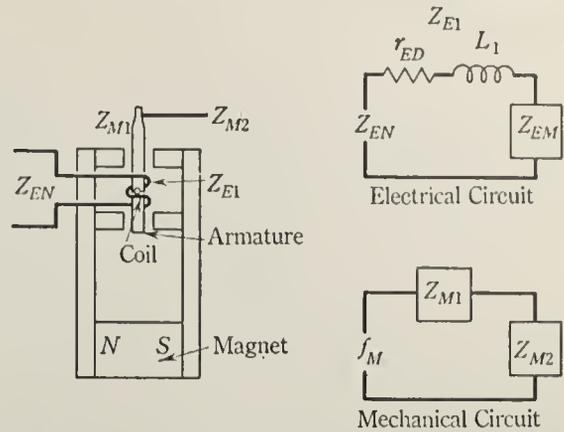

DRIVING SYSTEM, ELECTROMAGNETIC.

A driving system in which the mechanical forces result from magnetic reaction. A typical balanced armature magnetic driving system is shown in the figure. The steady field is usually supplied by a permanent magnet. The armature is located so that it is in the equilibrium with the steady forces. The alternating current winding is wound around the armature.

The result of the forces f_M , in dynes at the four poles acting upon the armature due to a current in the coil is

$$f_M = \frac{4\phi_1 Ni}{R_2 A} \tag{1}$$

where ϕ_1 is the total flux, in maxwells, at each pole due to the permanent magnet, A is the effective area, in square centimeters, of the pole piece, N is the number of turns in the coil, i is the current in the coil, in abamperes,

Polarized balanced armature electromagnetic driving system. In the electrical circuit: z_{EN} is the normal electrical impedance of the coil; z_{EM} , the motional electrical impedance of the coil; z_{E1} , the damped electrical impedance of the coil; $z_{E1} = r_{E1} + j\omega L_1$; L_1 and r_{E1} , the damped inductance and electrical resistance of the coil. In the mechanical circuit: f_M is the driving force; z_{M1} , the mechanical rectilinear impedance of the armature; z_{M2} , the mechanical rectilinear impedance of the load; z_{M1} and z_{M2} are referred to a point on the armature directly over a pole piece.

and R_2 is the reluctance of the magnetic circuit, in oersteds, which the coil energizes.

The electromotive force, e , in abvolts, generated in the coil is

$$e = \frac{NMA}{a^2} \dot{x} \tag{2}$$

where \dot{x} is the velocity of the armature, in centimeters per second, M is the magnetomotive force, in gilberts, of the steady field, a is the spacing between the armature and pole, in centimeters, and A is the effective area of a pole piece, in square centimeters.

From the mechanical circuit of the figure, the mechanical rectilinear impedance of the vibrating system is

$$z_M = z_{M1} + z_{M2} \tag{3}$$

where z_M is the total mechanical rectilinear impedance, in mechanical ohms, z_{M1} is the mechanical rectilinear impedance of the armature, in mechanical ohms, and z_{M2} is the mechanical rectilinear impedance of the load, in mechanical ohms.

The mechanical rectilinear impedance z_M , in mechanical ohms, at the armature directly over a pole piece is

$$z_M = \frac{f_M}{\dot{x}} \tag{4}$$

Combining Equations 1 and 2

$$\frac{e}{i} = \frac{4N^2\phi_1 M}{a^2 R_2} \frac{\dot{x}}{f_M} \quad (5)$$

From Equations 3, 4 and 5

$$z_{EM} = \frac{4N^2\phi_1 M}{a^2 R_2 z_M} \quad (6)$$

where z_{EM} is the motional electrical impedance, in abohms, and z_M is the total mechanical rectilinear impedance including the armature with reference to a point on the armature directly over one of the pole pieces.

If the entire reluctance is assumed to reside in the air gap, Equation 6 may be written

$$z_{EM} = \frac{4N^2\phi_1^2}{a^2 z_M} \quad (7)$$

The normal electrical impedance z_{EN} , in abohms, of the coil is

$$z_{EN} = z_{E1} + z_{EM} \quad (8)$$

where z_{E1} is the damped electrical impedance of the coil, in abohms, and z_{EM} is the motional electrical impedance of the coil, in abohms.

The motional electrical impedance as given by Equation 7 may be represented as in series with the blocked or damped electrical impedance of the coil as depicted by the electrical circuit in the figure.

DRIVING SYSTEM, ELECTROSTATIC. A driving system in which the mechanical forces result from electrostatic reactions. Consider the system of the figure consisting of a vibrating surface moving normal to its plane and separated from a fixed conductor. The force f_M , in dynes, between the plates is

$$f_M = \frac{e_0 e}{4\pi a^2} A \quad (1)$$

where e is the alternating electromotive force between plates, in statvolts, e_0 is the polarizing electromotive force between the plates, in statvolts, a is the normal distance between the plates, in centimeters, and A is the area of the plate, in square centimeters.

The generated current i , in statamperes due to the motion of the movable plate or diaphragm is

$$i = \frac{e_0 A}{4\pi a^2} \dot{x} \quad (2)$$

where \dot{x} is the velocity of the diaphragm, in centimeters per second.

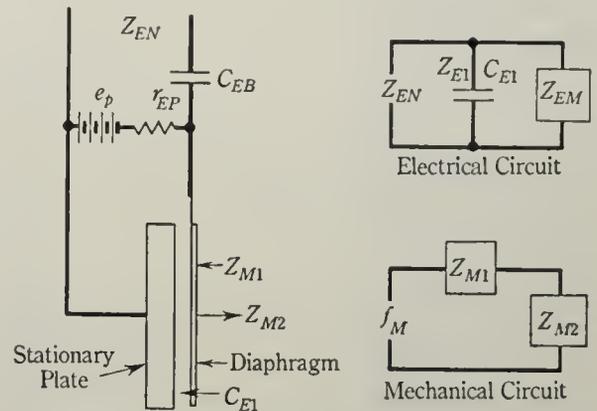

The mechanical rectilinear z_M , in mechanical ohms impedance at the movable plate is

$$z_M = \frac{f_M}{\dot{x}} \quad (3)$$

From the mechanical circuit of the figure, the mechanical rectilinear impedance of the vibrating system is

$$z_M = z_{M1} + z_{M2} \quad (4)$$

where z_M is the total mechanical rectilinear impedance of the vibrating system, in mechanical ohms, z_{M1} is the mechanical rectilinear

Electrostatic driving system. In the electrical network: z_{EN} is the normal electrical impedance of the condenser; z_{EM} , the motional electrical impedance of the condenser; z_{E1} , the damped electrical impedance of the condenser; $z_{E1} = 1/j\omega C_{E1}$; C_{E1} , the damped electrical capacitance of the condenser. In the mechanical circuit: f_M is the driving force; z_{M1} , the mechanical rectilinear impedance of the movable plate; z_{M2} , the mechanical rectilinear impedance of the load.

impedance of the vibrating plate, in mechanical ohms, and z_{M2} is the mechanical rectilinear impedance of the load, in mechanical ohms.

From Equations 1 and 2

$$\frac{e}{i} = \frac{16\pi^2 a^4 f_M}{e_0^2 A^2 \dot{x}} \quad (5)$$

From Equations 3, 4 and 5

$$z_{EM} = \frac{16\pi^2 a^4}{e_0^2 A^2} z_M \quad (6)$$

where z_{EM} is the motional electrical impedance, in statohms, and z_M is the total mechanical rectilinear impedance presented to the vibrating surface including the vibrating surface.

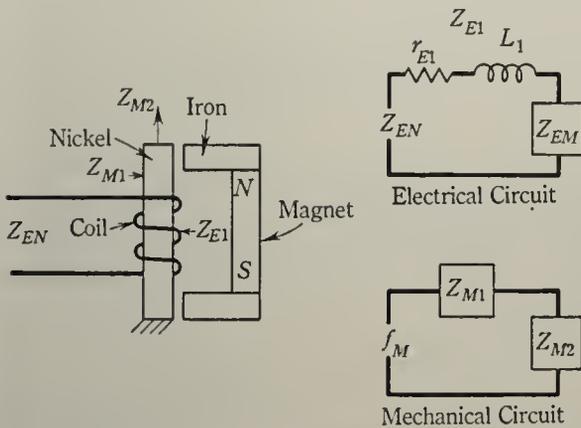

The normal electrical impedance z_{EN} , in statohms, of the condenser is

$$z_{EN} = \frac{z_{E1}z_{EM}}{z_{E1} + z_{EM}} \quad (7)$$

where z_{E1} is the damped electrical impedance of the condenser, in statohms, and z_{EM} is the motional electrical impedance of the condenser, in statohms.

The motional electrical impedance as given by Equation 6 may be represented as in parallel with the blocked or damped electrical impedance of the condenser as depicted by the electrical network in the figure.

DRIVING SYSTEM, MAGNETOSTRICTION. A driving system in which the mechanical forces result from the deformation of a ferromagnetic material having magnetostriction properties. The term "Joule effect" is applied to the phenomena in which a change in linear dimensions occurs when a magnetic field is applied along a specified direction. The term "Villari effect" is applied to the phenomena in which a change in magnetic induction occurs when a mechanical stress is applied along a specified direction.

Magnetostriction driving system. In the electrical circuit: z_{EN} is the normal electrical impedance of the coil; z_{EM} , the motional electrical impedance of the coil; z_{E1} , the damped electrical impedance of the coil; $z_{E1} = r_{E1} + j\omega L_1$; L_1 and r_{E1} , the damped inductance and electrical resistance of the coil. In the mechanical circuit: f_M is the driving force. z_{M1} , the mechanical rectilinear impedance of the rod. z_{M2} , the mechanical rectilinear impedance of the load.

Consider the system shown in the figure. Assume that the rod is clamped so that no motion is possible and that a current is applied to the winding; then the mechanical stress f_M , in dynes, due to the Joule effect, is

$$f_M = \frac{4\pi NiK}{R} \quad (1)$$

where K is the constant representing the dynamical Joule magnetostriction effect, R is the reluctance of the magnetic circuit, N is the number of turns in the coil, and i is the current in the coil, in abamperes.

The induced voltage, e in abvolts, due to a change in dimensions of the rod is

$$e = \frac{4\pi NK}{R} \dot{x} \quad (2)$$

where \dot{x} is the velocity of the change in the longitudinal dimension of the rod, in centimeters per second.

Combining Equations 1 and 2

$$\frac{e}{i} = \frac{16\pi^2 N^2 K^2}{R^2} \frac{\dot{x}}{f_M} \quad (3)$$

In the above consideration it has been assumed that the stress and driving force are uniform over the length of the rod. Under these conditions the rod is a compliance given by

$$C_{M1} = \frac{l}{EA} \quad (4)$$

where C_{M1} is the compliance of the rod, in centimeters per dyne, A is the cross-sectional area of the rod, in square centimeters, l is the length of the rod, in centimeters, and E is Young's modulus.

The mechanical rectilinear impedance z_{M1} , in mechanical ohms, of the rod is

$$z_{M1} = \frac{1}{j\omega C_{M1}} \quad (5)$$

For the conditions under consideration the mechanical rectilinear impedance of the vibrating system, from the mechanical circuit of the figure, is

$$z_M = z_{M1} + z_{M2} \quad (6)$$

where z_M is the total mechanical rectilinear impedance, in mechanical ohms, z_{M1} is the mechanical rectilinear impedance of the rod, in mechanical ohms, and z_{M2} is the mechanical rectilinear impedance of the load, in mechanical ohms.

The mechanical rectilinear impedances z_M , z_{M1} and z_{M2} are referred to one end of the rod with the other end rigidly fixed. The dimensions of the rod are assumed to be small compared to the wavelength.

The mechanical rectilinear impedance at the end of the rod is

$$z_M = \frac{f_M}{\dot{x}} \tag{7}$$

From Equations 3, 6 and 7

$$z_{EM} = \frac{16\pi^2 N^2 K^2}{R^2 z_M} \tag{8}$$

where z_{EM} is the motional electrical impedance, in abohms, and z_M is the total mechanical rectilinear impedance load upon the rod, including the effective mechanical rectilinear impedance of the rod, in mechanical ohms.

The normal impedance of the coil is

$$z_{EN} = z_{E1} + z_{EM} \tag{9}$$

where z_{E1} is the damped impedance of the voice coil, in abohms, and z_{EM} is the motional impedance, in abohms—Equation 8.

The damped impedance of the coil of most magnetostriction systems comprises a resistance in series with an inductance (see figure). The damped impedance and the motional impedance are effectively in series, as shown by Equation 9 and depicted by the electrical circuit in the figure.

In the above considerations the length of the rod is assumed to be a small fraction of the wavelength. In general, magnetostriction driving systems are operated at resonance. The three most common systems are as follows: a rod fixed on one end and loaded on the other, a rod free on one end and loaded on the other and a free rod.

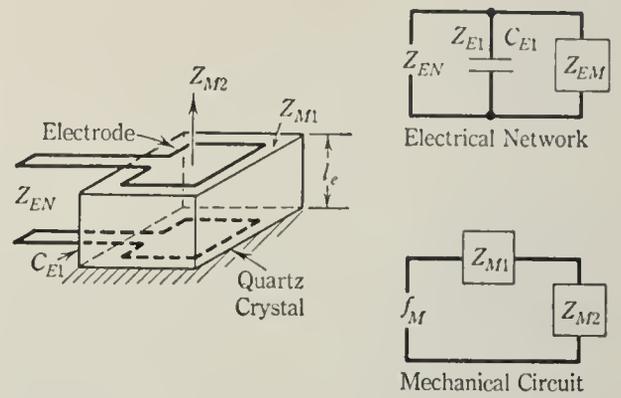

DRIVING SYSTEM, PIEZOELECTRIC. A driving system in which the mechanical forces result from the deformation of a crystal having converse piezoelectric properties. Among the crystals that exhibit piezoelectric phenomena are quartz, tourmaline, and Rochelle salt.

The consideration will be that of an X cut quartz crystal as shown in the figure.

The force f_M , in dynes, due to the application of an electromotive force is

$$f_M = \frac{KEAe}{l_e} \tag{1}$$

where K is the constant of the crystal, 6.4×10^{-8} for quartz, e is the applied voltage, in statvolts. l_e is the length of the crystal, in centimeters, E is Young's modulus, and A is the cross-sectional area, in square centimeters.

Piezoelectric driving system. In the electrical network: z_{EN} is the normal electrical impedance of the crystal; z_{EM} , the motional electrical impedance of the crystal; z_{E1} , the damped electrical impedance of the crystal; $z_{E1} = 1/j\omega C_{E1}$. C_{E1} , the damped electrical capacitance of the crystal. In the mechanical circuit: f_M is the driving force; z_{M1} , the mechanical rectilinear impedance of the crystal; z_{M2} , the mechanical rectilinear impedance of the load.

The generated current i , in statamperes due to a change in dimension of the crystal is

$$i = \frac{KEA\dot{x}}{l_e} \tag{2}$$

where \dot{x} is the velocity of the change in the longitudinal dimension of the crystal.

From Equations 1 and 2

$$\frac{e}{i} = \frac{l_e^2 f_M}{K^2 E^2 A^2 \dot{X}} \tag{3}$$

In the above consideration it has been assumed that the stress and driving force are uniform over the length l_e of the crystal. Under these conditions the crystal has a compliance given by

$$C_{M1} = \frac{l_e}{EA} \tag{4}$$

where A is the cross-sectional area of the crystal, in square centimeters, l_e is the length of the crystal, in centimeters, and E is Young's modulus.

The mechanical rectilinear impedance of the crystal is

$$z_{M1} = \frac{1}{j\omega C_{M1}} \tag{5}$$

For the conditions under consideration the mechanical rectilinear impedance of the vibrating system, from the mechanical circuit of the figure is

$$z_M = z_{M1} + z_{M2} \tag{6}$$

where z_M is the total mechanical rectilinear impedance, in mechanical ohms, z_{M1} is the mechanical rectilinear impedance of the crystal, in mechanical ohms, and z_{M2} is the mechanical rectilinear impedance of the load, in mechanical ohms.

The mechanical rectilinear impedances z_M , z_{M1} and z_{M2} are referred to one end of the crystal with the other end rigidly fixed. The dimensions of the crystal are assumed to be small compared to the wavelength.

The mechanical rectilinear impedance at the end of the crystal is

$$z_M = \frac{f_M}{\dot{x}} \quad (7)$$

From Equations 3, 6 and 7

$$z_{EM} = \frac{l_e^2}{K^2 E^2 A^2} z_M \quad (8)$$

The normal electrical impedance of the crystal system is

$$z_{EN} = \frac{z_{EM}}{1 + j\omega C_{E1} z_{EM}} \quad (9)$$

where z_{EM} is the motional impedance and C_{E1} is the capacitance of the crystal in the absence of motion.

The damped impedance and the motional impedance are effectively in parallel as shown by Equation 9 and depicted by the electrical circuit in the figure.

In the above considerations the length of the crystal is assumed to be a small fraction of the wavelength. In general, piezoelectric driving systems are operated at resonance. The three most common systems are as follows: a crystal fixed on one end and loaded on the other, a crystal free on one end and loaded on the other and a free crystal.

DROP-WISE CONDENSATION. When a vapor is cooled by a solid surface at sufficiently low temperature to cause condensation, the process of condensation may occur in one of two modes. Discrete drops may be formed on the surface, a process called drop-wise condensation. Alternatively, all drops may coalesce into a continuous film covering the solid surface. This is called *film-wise condensation*. In the case of drop-wise condensation, the coefficient of heat transfer is much higher than in the case of film-wise condensation, sometimes by factors as high as 1000.

DRUDE EQUATION. A relationship between the specific rotation of an optically-active substance and the wavelength of the light, of the form:

$$[\alpha] = \frac{k}{\lambda^2 - \lambda_0^2}$$

where $[\alpha]$ is the specific rotation, λ the wavelength, and k and λ_0^2 are constants, known as the rotation constant and the dispersion constant of the substance.

DRUDE THEORY OF ELECTRONS IN METALS. The original form of the free electron theory of metals in which the electrons were treated as a gas of classical particles. This theory is capable of explaining the high electrical conductivity of metals, but attributes to them far too large a specific heat, and has to be supplemented by the postulate that the electrons obey **Fermi-Dirac**, rather than **Maxwell-Boltzmann** statistics.

DRY-ADIABATIC LAPSE RATE. A special process lapse rate of temperature, defined as the rate of decrease of temperature with height of a parcel of **dry air** lifted adiabatically through an atmosphere in **hydrostatic equilibrium**. This lapse rate is g/c_{pd} , where g is the acceleration of gravity and c_{pd} is the specific heat of dry air at constant pressure; numerically equal to 9.767°C per km or about 5.4°F per thousand feet.

Potential temperature is constant with height in an atmosphere with this lapse rate.

DRY-BULB TEMPERATURE. See **adiabatic saturation**.

DRY COMBUSTION GASES. See **combustion**.

DRY GASES. See **combustion**.

DRY (SATURATED) STEAM. See **dry (saturated) vapor**.

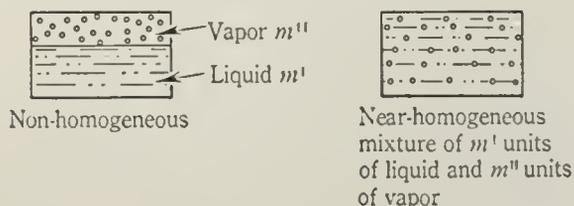

DRY (SATURATED) VAPOR. The vapor in a two-phase system which is in equilibrium with its own liquid, in contrast with superheated vapor. The pressure p and temperature T of dry, saturated vapor are not independent but lie on the vapor-pressure curve for the substance.

DRYNESS FRACTION. In a two-phase, vapor-liquid mixture (for example, in wet

steam), the ratio x of the mass of the vapor m'' to that of the whole system m ; thus

$$x = m''/m, \quad m = m' + m''$$

(where m' is the mass of liquid). The concept is applied to two-phase systems irrespective of whether or not they are homogeneous.

The extensive thermodynamic properties are determined by the dryness fraction. If ϕ is any extensive property, then

$$\begin{aligned} \phi &= \phi' + x(\phi'' - \phi') \\ &= \phi'' - (1 - x)(\phi'' - \phi'). \end{aligned}$$

Here ϕ' refers to the liquid and ϕ'' to the vapor. The intensive properties have the same values for both components in equilibrium.

The dryness fraction of the saturated liquid $x' = 0$, and of saturated vapor $x'' = 1$.

D²-STATISTIC. In multivariate analysis, a statistic which measures the "distance" between two populations with identical dispersions. If (α_{ij}) is the dispersion matrix of a p -variate complex, (α^{ij}) is its inverse and δ_i is the difference of means of the i^{th} variate, the distance Δ is defined by

$$\Delta^2 = \sum_{i,j=1}^p \alpha^{ij} \delta_i \delta_j$$

and for a sample the definition of the squared distance is similar with estimated means and dispersions on the right.

DUAL-COMBUSTION CYCLE. See diesel engine.

DUAL CYCLE. See diesel engine.

DUAL GRAPHS. See graphs, dual.

DUAL NETWORK. See network, dual.

DUAL TENSORS, RELATION TO SPINORS. See spinor calculus.

DUANE AND HUNT LAW. X-rays generated by electrons striking a target cannot have a frequency greater than eV/h where e is the electronic charge, V the exciting voltage and

h is Planck's constant. This is a simple consequence of quantum theory.

DUCT, FLOW OF GAS IN. See nozzle or duct, flow of gas in.

DUCTILITY. The ability of material to undergo large plastic deformation without cracking. It varies greatly with the conditions of test or fabrication. Quite brittle materials become ductile at high hydrostatic pressures and elevated temperatures. Ductile materials become brittle at low temperatures and with triaxial tension.

DUFFIN-KEMMER MATRICES. Matrices β_μ ($\mu = 1, 2, 3, 4$) satisfying

$$\beta_\mu \beta_\nu \beta_\sigma + \beta_\sigma \beta_\nu \beta_\mu = \delta_{\mu\sigma} \beta_\sigma + \delta_{\nu\sigma} \beta_\mu.$$

The equation $\left[\sum \beta_\mu \frac{\partial}{\partial x_\mu} + \frac{mc}{\hbar} \right] \psi = 0$ then describes particles of spin 0 or \hbar .

DUHAMEL INTEGRAL. See transient response of a dynamical system to an arbitrary force.

DUHEM-MARGULES EQUATION. The partial pressures p_1 and p_2 of the components of a binary solution are related by the equation

$$(1 - x_2) \left(\frac{\partial \ln p_1}{\partial x_2} \right)_T + x_2 \left(\frac{\partial \ln p_2}{\partial x_2} \right)_T = 0 \quad (1)$$

where x_2 is the mole fraction of component 2 in the solution. This equation, called the Duhem-Margules equation, is valid for ideal and non-ideal solutions as long as the gas phase may be considered as a perfect gas mixture, and as the total pressure remains sufficiently small not to affect the properties of the condensed phase.

This relation which is a form of the Gibbs-Duhem equation yields important information about one of the partial pressures if the other is known.

By combining it with the equation

$$p = p_1 + p_2 \quad (2)$$

one may calculate the partial pressures p_1, p_2 when the total pressure is known as a function of composition.

DUHEM THEOREM. The state of a thermodynamic system formed by ϕ phases is com-

pletely determined if one knows: (1) The physico-chemical state of each phase, defined for example by the intensive variables

$$T, p, x_1^1 \cdots x_c^1, x_1^2 \cdots x_c^{\phi} \quad (1)$$

where x_i^α is the mole fraction of component i in phase α ; (2) The extensive variables for each system. One may take as the independent extensive variables, the masses

$$m^1 \cdots m^{\phi} \quad (2)$$

of the different phases.

Duhem's theorem states that whatever the number of phases, of components, or of chemical reactions, the equilibrium state of a **closed system** for which one knows the initial masses is completely determined by *two independent variables*.

The basic difference between the Duhem theorem and the Gibbs **phase rule** is that the phase rule is concerned only with *intensive* variables while Duhem's theorem is a statement about the *total* number of variables (intensive + extensive) determining the state of a *closed* system. (See also **Saurel's theorem**.)

DULONG-PETIT RULE. A rule, discovered in 1819, which states that the product of the specific heat per unit mass of a crystalline solid element and its atomic weight (=atomic specific heat) is approximately the same for all such elements and has a value of about 6.2 kcal/C = 6.2 Btu/F. According to statistical mechanics this rule is an asymptotic one and is valid for temperatures T which are large compared with a characteristic temperature Θ ($T \gg \Theta$), different for each element. See **Debye temperature**, **Debye T^3 law**.

DUMMY. In experimental design it is sometimes convenient to regard certain plots as subject to treatment when no treatment is, in fact, applied. Such a "treatment" is then called dummy. Likewise, in certain forms of analysis it is convenient to regard constants as dummy variables.

DUMMY INDEX. See **summation convention**.

DUMMY UNIT LOAD METHOD. A method of finding deflection of a structure at a given point in a given direction by placing a unit load at the point in the direction desired. In essence it is a special application of the general method of virtual work in which the ac-

tual system is chosen as the compatible one, and the unit load system as the equilibrium one. Therefore, any system of forces and stresses in equilibrium with the unit load is permissible.

DUPIN INDICATRIX. See **indicatrix**.

DUPIN THEOREM. See **Euler theorem on normal curvature**.

DYADIC OPERATOR. A symbolic operator containing functions of a **dyadic**.

DYADIC. In ordinary **vector** analysis no meaning is attached to a symbol such as **AB**, where neither dot nor cross stands between two vectors. Such a quantity is called a **dyad** and the symbolic sum of two or more dyads is a dyadic **polynomial** or, more briefly, a **dyadic**. It is useful in the study of linear vector functions and has applications to theories of rotation and strain, electromagnetism, and optical phenomena in non-isotropic solids.

Consider the vector function $\mathbf{r}' = \mathbf{i}(c_1\mathbf{i}\cdot\mathbf{r}) + \mathbf{j}(c_2\mathbf{j}\cdot\mathbf{r}) + \mathbf{k}(c_3\mathbf{k}\cdot\mathbf{r})$, which is readily interpreted since the quantities in parentheses are scalars. The same equation, however, can be more simply written as $\mathbf{r}' = (\mathbf{i}c_1\mathbf{i} + \mathbf{j}c_2\mathbf{j} + \mathbf{k}c_3\mathbf{k})\cdot\mathbf{r}$ or, generally, if $\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3, \dots, \mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3, \dots$ are two sets of vectors, as $\mathbf{r}' = (\mathbf{a}_1\mathbf{b}_1 + \mathbf{a}_2\mathbf{b}_2 + \mathbf{a}_3\mathbf{b}_3 + \dots)\cdot\mathbf{r} = \Phi\cdot\mathbf{r}$. In the last equation, the direct or scalar product of the dyadic Φ and the vector \mathbf{r} yields a new vector \mathbf{r}' . The scalar product is not always commutative, for it does not follow that $\Phi\cdot\mathbf{r} = \mathbf{r}\cdot\Phi$. A special dyadic is the idempfactor, $\mathbf{I} = \mathbf{ii} + \mathbf{jj} + \mathbf{kk}$, which has the property that $\mathbf{I}\cdot\mathbf{r} = \mathbf{r}\cdot\mathbf{I} = \mathbf{r}$.

Nine fundamental dyads can be formed from unit vectors $\mathbf{i}, \mathbf{j}, \mathbf{k}$. The nonian form of any dyadic can be written in terms of them and scalar quantities a_{mn} as

$$\begin{aligned} \Phi = & a_{11}\mathbf{ii} + a_{12}\mathbf{ij} + a_{13}\mathbf{ik} + a_{21}\mathbf{ji} + a_{22}\mathbf{jj} \\ & + a_{23}\mathbf{jk} + a_{31}\mathbf{ki} + a_{32}\mathbf{kj} + a_{33}\mathbf{kk}. \end{aligned}$$

One can continue the algebra of dyadics, defining several kinds of products, reciprocals, conjugates, and other properties. They are discussed at length in Gibbs-Wilson, *Vector Analysis*, Yale University Press, New Haven, Conn., 1925, or, as related to a special physical problem, by W. H. Zachariasen, *Theory of X-Ray Diffraction in Crystals*, John Wiley and Sons, Inc., New York, 1945. A more sophisticated approach to the dyadic regards

it as a special kind of **tensor** with nine components. Each of them is a function of three coordinates and they transform from one coordinate system to another according to rules which can be derived. A dyadic can also be written in **matrix** form and can be generalized to the concept of triad, tetrad, polyad, and polyadic.

DYNAMICAL ANALOGIES, CLASSICAL.

The fundamental electrical elements of **electrical resistance, inductance, and electrical capacitance**; the mechanical rectilinear elements of **mechanical rectilinear resistance, mass and compliance**; the mechanical rotational elements of **mechanical rotational resistance, moment of inertia, and rotational compliance**; and the acoustical elements of **acoustical resistance, inertance, and acoustical capacitance** are defined by means of the fundamental equations. These equations establish the analogies between the three fundamental elements in the four dynamical systems. The consideration of electrical, mechanical rectilinear, mechanical rotational, and acoustical systems of one degree of freedom establishes further analogies between the elements and the quantities in the four systems. Electrical, mechanical rectilinear, mechanical rotational, and acoustical wave filters provide additional data on the analogies in the four systems. The subject of analogies is extended further by treatment of the **reciprocity theorems** in the four systems.

The analogies between the elements and quantities in the four systems are shown in the table.

Mathematically the elements in an electrical network are the coefficients in the differential equations describing the network. When the electric circuit theory is based upon Maxwell's dynamics the network forms a dynamical system in which the currents play the role of velocities. In the same way the coefficients in the differential equations of a mechanical or acoustical system may be looked upon as mechanical or acoustical elements. Kirchhoff's electromotive force law plays the same role in setting up the electrical equations as d'Alembert's principle does in setting up the mechanical and acoustical equations. That is to say, every electrical, mechanical or acoustical system may be considered as a combination of electrical, mechanical or acoustical elements.

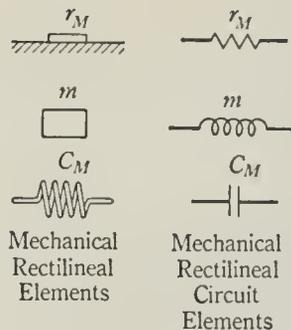

Fig. 1.

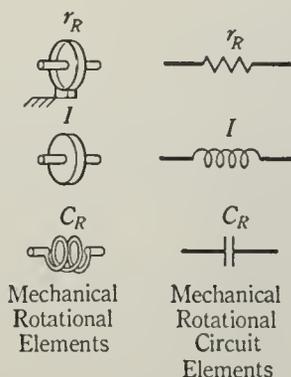

Fig. 2.

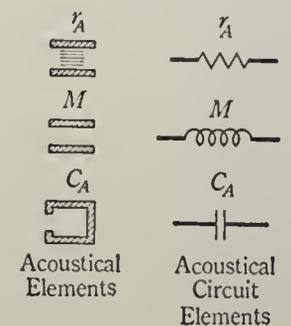

Fig. 3.

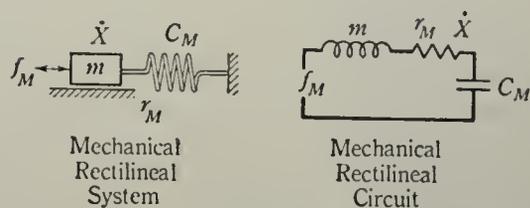

Fig. 4.

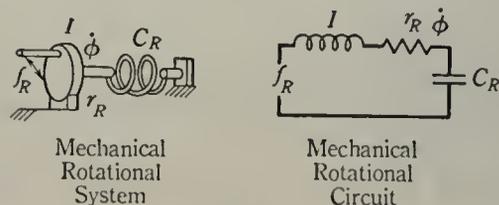

Fig. 5.

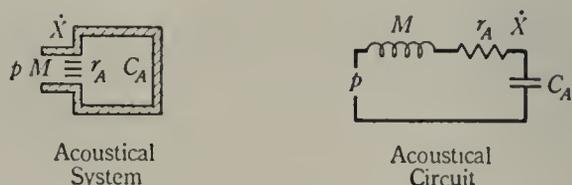

Fig. 6.

Therefore, any mechanical or acoustical system may be reduced to an electrical network and the problem may be solved by electrical circuit theory.

In view of the tremendous amount of study which has been directed towards the solution of circuits, particularly electrical circuits, and the engineer's familiarity with electrical circuits, it is logical to apply this knowledge to the solution of vibration problems in other fields by the same theory as that used in the solution of electrical circuits.

To carry out the solution of a problem in a **mechanical rectilinear, mechanical rotational or acoustical system**, the elements in these systems are converted to mechanical rectilinear circuit elements, mechanical rotational cir-

cuit elements or acoustical circuit elements, as shown in Figures 1, 2, and 3. The procedure is illustrated in Figures 4, 5, and 6 for the solution of a mechanical rectilinear, mechanical rotational, and acoustical systems. In Figure 4, the mechanical rectilinear system of one degree of freedom is converted to an acoustical circuit. The constants of the elements and quantities used in the mechanical rectilinear, mechanical rotational and acoustical circuits are shown in the table. The performance of the circuits is obtained by the application of electrical circuit theory. The equations for the performance of the systems of Figures 4, 5, and 6 will be found in **mechanical rectilinear, mechanical rotational, and acoustic systems of one degree of freedom**.

QUANTITIES AND ELEMENTS IN ELECTRICAL, MECHANICAL RECTILINEAL, MECHANICAL ROTATIONAL, AND ACOUSTICAL SYSTEMS

Electrical			Mechanical Rectilinear			Mechanical Rotational			Acoustical		
Quantity	Unit	Sym- bol	Quantity	Unit	Sym- bol	Quantity	Unit	Sym- bol	Quantity	Unit	Sym- bol
Electromotive Force	Volts $\times 10^8$	e	Force	Dynes	f_M	Torque	Dyne Centimeter	f_R	Pressure	Dynes per Square Centimeter	p
Charge or Quantity	Coulombs $\times 10^{-1}$	q	Linear Displacement	Centimeters	x	Angular Displacement	Radians	ϕ	Volume Displacement	Cubic Centimeters	X
Current	Amperes $\times 10^{-1}$	i	Linear Velocity	Centimeters per Second	\dot{x} or v	Angular Velocity	Radians per Second	$\dot{\phi}$ or θ	Volume Current	Cubic Centimeters per Second	\dot{X} or U
Electrical Impedance	Ohms $\times 10^9$	z_E	Mechanical Impedance	Mechanical Ohms	z_M	Rotational Impedance	Rotational Ohms	z_R	Acoustical Impedance	Acoustical Ohms	z_A
Electrical Resistance	Ohms $\times 10^9$	r_E	Mechanical Resistance	Mechanical Ohms	r_M	Rotational Resistance	Rotational Ohms	r_R	Acoustical Resistance	Acoustical Ohms	r_A
Electrical Reactance	Ohms $\times 10^9$	x_E	Mechanical Reactance	Mechanical Ohms	x_M	Rotational Reactance	Rotational Ohms	x_R	Acoustical Reactance	Acoustical Ohms	x_A
Inductance	Henries $\times 10^9$	L	Mass	Grams	m	Moment of Inertia	(Gram) (Centimeter) ²	I	Inertance	Grams per (Centimeter) ⁴	M
Electrical Capacitance	Farads $\times 10^{-9}$	C_E	Compliance	Centimeters per Dyne	C_M	Rotational Compliance	Radians per Dyne per Centimeter	C_R	Acoustical Capacitance	(Centimeter) ⁵ per Dyne	C_A
Power	Ergs per Second	P_E	Power	Ergs per Second	P_M	Power	Ergs per Second	P_R	Power	Ergs per Second	P_A

DYNAMICAL ANALOGIES, MOBILITY.

The analogies which have been presented in the section on classical dynamical analogies

mechanical mobility is defined as the complex ratio of velocity to force. Although the mobility dynamical analogy can be applied to all types of vibrating systems, the most direct and useful application of the mobility dynamical analogy resides in the field of mechanical vibrating systems.

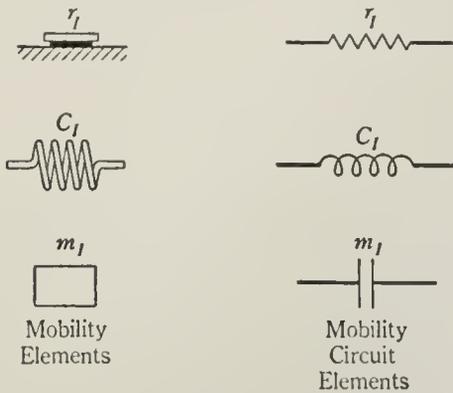

Fig. 1.

(see dynamical analogies, classical) and related sections have been formal ones due to the similarity of the differential equations of the electrical, mechanical, and acoustical systems. For this reason these analogies have been termed the classical impedance dynamical analogies. These are, however, not the only ones possible of development for useful applications. In this connection, the **mobility** analogy has been developed and used on a wide scale to solve problems in mechanical vibrating systems. In the mobility analogy,

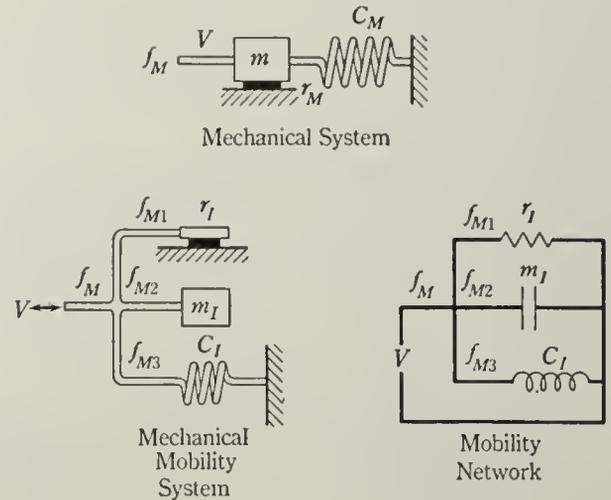

Fig. 2.

As in the case of the solution of a problem in a mechanical vibrating system by applying the principles of classical dynamical analogies, the mechanical elements in the mechanical sys-

Electrical			Mechanical Rectilinear Mobility		
Quantity	Unit	Symbol	Quantity	Unit	Symbol
Electromotive Force	Volts $\times 10^{-8}$	e	Velocity	Centimeters per Second	\dot{x} or v
Charge or Quantity	Coulombs $\times 10^{-1}$	q	Impulse or Momentum	Gram Centimeter per Second	Q
Current	Amperes $\times 10^{-1}$	i	Force	Dynes	f_M
Electrical Impedance	Ohms $\times 10^9$	z_E	Mechanical Mobility	Mechanical Mhos	z_I
Electrical Resistance	Ohms $\times 10^9$	r_E	Responsivity	Mechanical Mhos	r_I
Electrical Reactance	Ohms $\times 10^9$	x_E	Excitability	Mechanical Mhos	x_I
Inductance	Henries $\times 10^9$	L	Compliance or Mobility Inertia	Centimeters per Dyne	C_I
Electrical Capacitance	Farads $\times 10^9$	C_E	Mass or Mobility Capacitance	Grams	m_I
Power	Ergs per Second	P_E	Power	Ergs per Second	P_I

tem are converted to mobility circuit elements as depicted in Figure 1.

The analogies between the elements and the quantities in the electrical and mechanical rectilinear mobility systems are shown in the table.

The procedure for the application of the mobility analogy is illustrated in Figure 2. The mechanical system is converted to a mechanical mobility system. Then it is a simple matter to convert the mechanical mobility system to a mobility network. The performance of the network is obtained by the application of electrical circuit theory.

DYNAMICAL EQUATIONS OF LIGHT RAYS. The optical paths, or rays, in a medium of refractive index $n = n(x, y, z)$ are the solutions of the system of dynamical equations

$$\ddot{x} = \frac{\partial}{\partial x} \left(\frac{1}{2}n^2 \right),$$

$$\ddot{y} = \frac{\partial}{\partial y} \left(\frac{1}{2}n^2 \right),$$

$$\ddot{z} = \frac{\partial}{\partial z} \left(\frac{1}{2}n^2 \right),$$

which satisfy

$$\dot{x}^2 + \dot{y}^2 + \dot{z}^2 = n^2,$$

where one dot denotes the first derivative with respect to time, and two dots, the second. Thus, the rays are paths of "corpuseles" moving in a potential field $\phi = -\frac{1}{2}n^2$ with velocity n . This last conclusion is in conflict with Foucault's measurements of the relative velocities of light in air and water.

Descartes proved **Snell's law** on the basis of the corpuscular theory using the continuity of the tangential component of velocity.

DYNAMICAL SIMILARITY. Two systems are dynamically similar if the ratio of corresponding forces is the same. This requires that all possible **Froude numbers** must be the same in the two systems. The inertia forces, gravity forces, viscous forces, etc., must be in the same ratio.

In making model experiments the **Reynolds number** is usually the most important when gravity does not directly affect the flow, but the **Richardson** and ordinary Froude numbers are important in modeling flows of stratified

fluids, and the **Rayleigh number** in Stokes flows which transfer buoyancy (or heat).

DYNAMICAL SURFACE TENSION. In a surface phase whose age is low with respect to the characteristic times involved in diffusion, the adsorption (see **Gibbs division surface**) may be taken equal to zero. The surface tension of such a "fresh" surface is called the dynamical surface tension.

DYNAMICAL VARIABLES. Those variables in terms of which classical mechanics is built up, and which can be given an operational definition. Examples are the coordinates and components of velocity, momentum, and angular momentum of particles, and functions of these quantities.

DYNAMIC BOUNDARY CONDITION. The condition that the pressure must be continuous across an internal boundary or **free surface** in a fluid.

DYNAMIC EQUILIBRIUM. See **equilibrium, dynamic**.

DYNAMIC LOADING. The loading applied as a consequence of the motion of a live load and often expressed as a multiple of the static value of that load. A suddenly applied load such as would be exerted by the release of a weight in contact with a horizontal elastic beam gives a dynamic load that is twice the static load.

DYNAMIC PARALLAX (OF BINARY STARS). If the masses of the two components of a visual **binary star**, m_1 and m_2 , are found from the **mass-luminosity relation**, it is possible to determine the parallax of the system. From the Kepler laws, one can write

$$m_1 + m_2 = \frac{a^3}{P^2 \pi^3}$$

in which π is the parallax of the system in seconds of arc, and P is given in sidereal years. In a visual binary, a is the separation of the components and this can be measured in seconds of arc. π is the only remaining unknown and therefore

$$\pi = \frac{a}{\sqrt[3]{P^2(m_1 + m_2)}}.$$

DYNAMIC PRESSURE. The dynamic pressure at a given point in a fluid is the difference

between the total pressure p_o and the static pressure p at that point. For an incompressible fluid, **Bernoulli's equation** shows that the dynamic pressure is equal to $\frac{1}{2}\rho v^2$, where ρ is the density of the fluid and v is the velocity. For a compressible fluid the dynamic pressure ($p_o - p$) is given by

$$\frac{p_o - p}{p} = \left[1 + \left(\frac{\gamma - 1}{2} \right) M^2 \right]^{\frac{\gamma}{\gamma - 1}} - 1.$$

(See also **Pitot tube**.)

DYNAMICS. The science that deals with the motion of systems of particles under the influence of forces. Dynamics deals with the causes of motion, as opposed to **kinematics**, which deals with its geometrie description, and to **statics**, which deals with the conditions for lack of motion.

DYNAMICS OF A FREE MASS POINT (RELATIVITY). The relativistic force **F** acting on an accelerated mass point can be defined, just as in classical mechanics, as the time rate of change of linear momentum.

$$\mathbf{F} = \frac{d}{dt} \left(\frac{m_o v}{\sqrt{1 - v^2/c^2}} \right)$$

m_o is the rest mass. If the force is parallel to the velocity, its magnitude is

$$\left(1 - \frac{v^2}{c^2} \right)^{-3/2} m_o \frac{d^2x}{dt^2}.$$

If the force is perpendicular to the velocity, its magnitude is

$$\left(1 - \frac{v^2}{c^2} \right)^{-1/2} m_o \frac{d^2y}{dt^2} \quad \text{or} \quad \left(1 - \frac{v^2}{c^2} \right)^{-1/2} m_o \frac{d^2z}{dt^2}.$$

(It is assumed that the velocity is parallel to the x -direction.) The coefficients

$$\left(1 - \frac{v^2}{c^2} \right)^{-3/2} m_o \quad \text{and} \quad \left(1 - \frac{v^2}{c^2} \right)^{-1/2} m_o$$

are called the "longitudinal" and the "transversal" mass.

DYNAMICS, RAREFIED GAS. See **rarefied gas dynamics**.

DYNAMIC UNBALANCE. See **balancing**.

DYNAMIC VISCOSITY. See **viscosity, dynamic**.

DYNE. The cgs unit of force. See **mechanical units**.

DYSON REPRESENTATION. Consider two fields $A(x)$ and $B(x)$ obeying the **causality condition**

$$[A(x), B(y)] = 0 \quad \text{for } (x - y)^2 < 0 \quad (1)$$

where x, y are four vectors and the scalar product is defined by

$$x \cdot y = x_\mu y^\mu = x_0 y_0 - \mathbf{x} \cdot \mathbf{y}. \quad (2)$$

An important problem is to determine the analytic form of the (**generalized**) function

$$\tilde{f}(x) = \langle P, \alpha | \left[A \left(\frac{x}{2} \right), B \left(-\frac{x}{2} \right) \right] | Q, \beta \rangle \quad (3)$$

or its Fourier transform

$$f(q) = \frac{1}{(2\pi)^4} \int d^4x e^{-iqx} \tilde{f}(x) \quad (4)$$

where $|P, \alpha\rangle$ and $|Q, \beta\rangle$ are any two physical states specified by the energy momentum vectors P and Q and by other quantum numbers α and β . By (1) the function \tilde{f} in x space has the property

$$\tilde{f}(x) = 0 \quad \text{for } x^2 < 0. \quad (5)$$

From Equation (3) and the assumption that the physical states of the system are complete in \mathcal{H} and that they can be characterized in part by energy momentum four-vectors $p^{(n)}$ for which $p^{(n)} p^{(n)} \geq 0, p_o^{(n)} \geq 0$, the function f in q space also has the property of vanishing in a large region. In the coordinate system in which

$$\frac{1}{2}(P + Q) = (a, 0, 0, 0) \quad a > 0. \quad (6)$$

$f(q) = 0$ for all $q = (q_0, q)$ satisfying

$$a - [\mathbf{q}^2 + b^2]^{1/2} < q_0 < [\mathbf{q}^2 + c^2]^{1/2} - a \quad (7)$$

where b and c are the lowest masses of the possible intermediate states $|n\rangle, |m\rangle$ in the decomposition

$$\begin{aligned} \langle P\alpha | A \left(\frac{x}{2} \right) B \left(-\frac{x}{2} \right) | Q\beta \rangle &= \sum_n \langle P\alpha | A \left(\frac{x}{2} \right) | n \rangle \langle n | B \left(-\frac{x}{2} \right) | Q\beta \rangle \\ \langle P\alpha | B \left(-\frac{x}{2} \right) A \left(\frac{x}{2} \right) | Q\beta \rangle &= \sum_m \langle P\alpha | B \left(-\frac{x}{2} \right) | m \rangle \langle m | A \left(\frac{x}{2} \right) | Q\beta \rangle. \end{aligned} \quad (8)$$

Jost and Lehmann have shown that the class of generalized function $f(q)$ which vanish in the region

$$|q_0| > [\mathbf{q}^2 + c^2]^{1/2} - a \quad (9)$$

and have Fourier transforms vanishing for $x^2 < 0$ is identical with the class of functions of the form

$$f(q) = \int d^3u \int d\kappa^2 \epsilon(q_0) \delta[q_0^2 - (\mathbf{q} - \mathbf{u})^2 - \kappa^2] \\ \times [\Phi_1(\mathbf{u}, \kappa^2) + q_0 \Phi_2(\mathbf{u}, \kappa^2)] \quad (10)$$

with the functions $\Phi_1(\mathbf{u}, \kappa^2)$ and $\Phi_2(\mathbf{u}, \kappa^2)$ each vanishing except in the region

$$|\mathbf{u}| < a \quad \kappa \geq c - (a^2 - \mathbf{u}^2)^{1/2}. \quad (11)$$

This theorem provides a representation for functions $f(q)$ vanishing in the region (7) for the case $b = c$. An important Lemma also due to Jost and Lehmann is that the class of func-

tion $f(q)$ satisfying $\tilde{f}(x) = 0$ for $x^2 < 0$ and vanishing in the region

$$|q_0| + |\mathbf{q} - \mathbf{v}| < \lambda$$

is identical with the class represented by (10) with the functions Φ_1 , and Φ_2 vanishing in $\kappa^2 + (\mathbf{u} - \mathbf{v})^2 < \lambda^2$.

Dyson has given the solution to general case in the following theorem: for a function $f(q)$ to vanish in the region $h(\mathbf{q}) < q_0 < g(\mathbf{q})$ and to have a Fourier transform vanishing for $x^2 < 0$ it is necessary and sufficient that

$$f(q) = \int d^4u \int ds \epsilon(q_0 - u_0) \delta[(q - u)^2 - s] \Psi(u, s)$$

where $\Psi(u, s)$ is a function vanishing outside the region S defined by

$$m(\mathbf{u}, s) \leq u_0 \leq M(\mathbf{u}, s)$$

with

$$m(\mathbf{u}, s) = \max_{\mathbf{q}} \{g(\mathbf{q}) - [(\mathbf{q} - \mathbf{u})^2 + s]^{1/2}\}$$

$$M(\mathbf{u}, s) = \min_{\mathbf{q}} \{h(\mathbf{q}) + [(\mathbf{q} - \mathbf{u})^2 + s]^{1/2}\}.$$

E

e (THE NUMBER). A transcendental number, used as the base of the system of natural or Napierian logarithms. It is defined by

$$e = \lim_{n \rightarrow \infty} \left(1 + \frac{1}{n}\right)^n$$

or by

$$e = \lim_{x \rightarrow 0} (1 + x)^{1/x}.$$

It is represented by the infinite series

$$e = 1 + \frac{1}{1!} + \frac{1}{2!} + \frac{1}{3!} + \frac{1}{4!} + \cdots + \frac{1}{n!} + \cdots$$

and has the approximate value of 2.71828.

EARNSHAW THEOREM. No charge can be in stable equilibrium in an electric field under the influence of electric forces alone.

EARTHQUAKE RESISTANCE. Resistance to failure due to horizontal motion of the supports of a structure. Building codes may call for design against a static horizontal force of between 0.025 and 1.0 times the **dead load**, depending upon location and part of structure. The actual problem involves the dynamic response of a structure to a random sequence of forced motions at its base and is still under study.

EARTHQUAKE SCALES. The intensity and magnitude of an earthquake is rated by a number of scales. The Rossi-Forel intensity scale from the barely felt I to the disaster X and the Mercalli scale from 1 to total damage 12 are in common use.

EBULLIOSCOPIC CONSTANT. See **boiling constant**.

ECCENTRIC LOADING. A force applied parallel to the axis of a bar (line of centroids of the cross sections) but at some distance from it, produces both direct stress and bending. (See **kern**.)

ECHELON. A highly specialized form of **diffraction grating**. It consists of a row of glass plates of exactly equal thickness, packed

together to form a miniature stairway of equal risers. The light enters normally to the largest plate at one end (see figure) and emerges at various deviations through the low "risers." It is easily shown that if the thickness of the plates is a , the height of the "risers" b , and the

refractive index of the glass n , the equivalent path difference between successive emergent streams for any angle of deviation Δ is $na - a \cos \Delta + b \sin \Delta$; or since Δ is in practice always small, $\cos \Delta = 1$ and $\sin \Delta = \Delta$ (in radians), giving $(n - 1)a + b\Delta$. This must be equal to an integral multiple, N , of the wavelength λ for any spectrum line, the deviation of which is therefore

$$\Delta = N \frac{\lambda}{b} - (n - 1) \frac{a}{b}.$$

The smallest value N can have (for $\Delta = 0$) is $(n - 1) \frac{a}{\lambda}$, which, since a is usually several mm. and $(n - 1)$ is 0.5 or more, is of the order of several thousand. The **dispersion**, viz.,

$$D = \frac{d\Delta}{d\lambda} = \frac{N}{b} - \frac{a}{b} \frac{dn}{d\lambda},$$

is correspondingly large. The echelon is thus especially adapted to the study of the **hyper-fine structure** of spectrum lines.

ECKERT NUMBER. See **dimensionless groups**.

ECLIPSING BINARY STARS. An eclipsing binary star is both a **binary star** and also a **variable star**. The light curve is characterized by a relatively sharp and symmetric drop to minimum. The curve is not always flat at maximum, but may show a slow rise and then a decline to a point at which the drop to minimum occurs. In some cases there are two minima, one deeper than the other. It is believed that, in this class of variable star, there

are two stars that differ in size and brightness, and that are revolving about the center of gravity of the system in elliptic orbits, with the plane of the orbit passing through or relatively close to the sun, i.e., with inclination close to 90° . If the inclination differs appreciably from 90° the eclipse will be only partial. All available evidence points to this type of variability.

When the masses and relative dimensions of the components are known from the orbit, light curve, and parallax, the mass of the system is

$$m_b + m_f = \frac{(a_b + a_f)^3}{25P^2}$$

with a in millions of kilometers and P in days.

The radius of the brighter component is given by $(a_1 + a_2)r_b$ where r_b is given by the photometric data. The volume of this star in terms of the volume of the sun, is $2.98 (a_1 + a_2)^3 r_b$. Therefore, the density of the brighter star, in terms of the density of the sun as unity, is given by

$$\rho_b = \frac{m_b}{V_b} = \frac{1}{74.4P^2 r_b^3} \cdot \frac{m_b}{m_b + m_f}$$

In the second right-hand member of this equation, $\frac{m_b}{m_b + m_f}$ may be estimated with considerable accuracy from the mass-luminosity relation:

$$\frac{m_b}{m_f} = \left(\frac{L_b}{L_f} \right)^{2/5}$$

Much more information about the atmospheres of the two stars may be determined by spectrophotometric observations of the changes as one star passes over the photosphere of the other and leaves just the atmosphere exposed. This and other information is needed for the development of various theories relative to stellar structure.

ECLIPTIC. The great circle on the celestial sphere cut out by the plane containing the orbit of the earth. The ecliptic intersects the **celestial equator** at the vernal and autumnal equinoxes. The angle between the plane of the ecliptic and the plane of the equator is known as the *obliquity of the ecliptic* and is about 23.5° , but is slowly changing. The accurate value of the obliquity is published in almanacs. The celestial latitudes and longitudes of astronomic objects are referred to the

plane of the ecliptic and the equinoxes. (C.f. **precession**.)

ECONOMISER. See **air-preheating**.

EDDY. (1) By analogy with a molecule, a "glob" of fluid within the fluid mass that has a certain integrity and life history of its own; the activities of the bulk fluid being the net result of the motion of the eddies.

The concept is applied with varying results to phenomena ranging from the momentary spasms of the wind to storms and anticyclones.

(2) Any circulation drawing its energy from a flow of much larger scale, and brought about by pressure irregularities as in the lee of a solid obstacle.

EDDY CONDUCTIVITY. See **turbulent transfer coefficient**.

EDDY CURRENT. See **current, eddy**.

EDDY FLUX. (Or turbulent flux.) The rate of transport (or flux) of fluid properties such as momentum, mass, heat, or suspended matter by means of **eddies** in a turbulent motion; the rate of turbulent exchange. (See **mixing length, exchange coefficients, interaction**.)

EDDY HEAT CONDUCTION. (Or eddy heat flux; also called eddy conduction.) The transfer of heat by means of **eddies** in turbulent flow, treated analogously to molecular conduction.

If temperature is represented by the sum of the mean temperature of the fluid plus its instantaneous departure from the mean, substituted into the Fick equation and the mean value taken, then the form of the resulting equation for the mean temperature is unchanged except that the molecular heat transfer terms

$$K_x \frac{\partial T}{\partial x}, \quad K_y \frac{\partial T}{\partial y}, \quad \text{and} \quad K_z \frac{\partial T}{\partial z}$$

are replaced by

$$K_x \frac{\partial \bar{T}}{\partial x} - c_p \overline{\rho u' T'}, \quad K_y \frac{\partial \bar{T}}{\partial y} - c_p \overline{\rho v' T'}$$

and

$$K_z \frac{\partial \bar{T}}{\partial z} - c_p \overline{\rho w' T'},$$

where ρ is the density, c_p is the specific heat at constant pressure, and u' , v' , w' , and T' the departures of the velocity components and the

temperature. These are analogous to the **Reynolds stresses** of the correlation term as expressed as an **exchange coefficient**. Then (considering only one-dimensional variability)

$$-\overline{w'T''} = K_z \frac{\partial \bar{T}}{\partial z},$$

where K is the eddy conductivity coefficient (see **turbulent transfer coefficient**) and, unlike the molecular coefficient, is usually a function of the coordinates.

On the basis of the **mixing length** theory, the mean rate of transfer of heat q in an incompressible fluid normal to the direction of z is

$$q = -c_p \rho l^2 \sqrt{w'^2} \frac{\partial T}{\partial z},$$

where l is the mixing length. Because the atmosphere is compressible, temperature is not conservative and in the previous equations the **potential temperature** must be used when the transfer is considered in the vertical direction. Another expression for the transfer of heat, now across an isobaric surface, is

$$q = -K c_p \rho \left(\Gamma + \frac{\partial T}{\partial z} \right),$$

where Γ is the dry- or saturation-adiabatic lapse rate, as the circumstance requires.

EDDY KINETIC ENERGY. (Also called turbulent energy.) The **kinetic energy** of that component of fluid flow which represents a departure from the average kinetic energy of the fluid, the mode of averaging depending on the particular problem. This eddy kinetic energy is represented by $\overline{\rho u'^2}$ where ρ is the density, u' is the **eddy velocity**, and the superior bar denotes an average.

In general circulation studies, for example, the zonal average along a fixed latitude circle is usually considered. As another example, in small-scale turbulence studies it is frequently desirable to consider the average with respect to time at a fixed point in the fluid.

EDDY SPECTRUM. The distribution of the frequency of **eddies** of various sizes or scales in a turbulent flow, or the distribution of kinetic energy among eddies of various frequencies or sizes.

EDDY STRESS. See **Reynolds stress**.

EDDY TRANSPORT (EDDY TRANSFER). See **turbulent transfer coefficient**.

EDDY VELOCITY. (Also called fluctuation velocity.) The difference between the **mean velocity** of fluid flow and the instantaneous velocity at a point. For example,

$$u' = u - \bar{u},$$

where u' is the eddy velocity, u is instantaneous velocity, and \bar{u} is mean velocity.

Over the same interval which defines the mean velocity, the average value of the eddy velocity is necessarily zero.

EDDY VISCOSITY. See **turbulent transfer coefficient**.

EDGE. Two distinct points (endpoints) and a line segment joining them. Considering the edge as point-closed (including endpoints) is the conventional procedure although open line segments are also used by some authors. Similarly the insistence upon the distinctness of the endpoints of an edge is motivated by the desire to exclude closed "loops" in which the endpoints coincide.

EDGE CONDITION. A condition introduced in problems involving diffraction of electromagnetic waves by obstacles with sharp edges. The edge must be a **singularity** of the field with the following characteristics: (1) No energy is radiated from the edge itself. (2) The field components parallel to the edge shall be bounded.

EDGE FORCE. Surface traction applied to the cylindrical bounding surface of a plate or shell. Usually measured per unit length along the periphery of the plate or shell, the detailed distribution on the bounding surface in the thickness direction being unspecified. Also called *edge traction*.

EDGE MULTIPLICITY. The number of times an **edge** appears in an **edge sequence**.

EDGE OF REGRESSION. The locus of the points of intersection of successive characteristics of a one-parameter family of surfaces as the parameter is varied. If $f(x, y, z, a) = 0$ is the one-parameter family of surfaces then the equations for the edge of regression can be obtained by eliminating a from the equation

$$f(x, y, z, a) = 0, \quad \partial f(x, y, z, a) / \partial a = 0,$$

$$\partial^2 f(x, y, z, a) / \partial a^2 = 0.$$

EDGE SEQUENCE. A **subgraph** whose edges admit an ordering possessing the following property: Each edge has one **vertex** in common with the preceding **edge** and the other vertex in common with the succeeding edge. The words "preceding" and "succeeding" are defined with respect to the ordering imposed on the edges.

EDGE TRAIN. An **edge sequence** in which each **edge** has **multiplicity** one.

EDGE TRAIN, CLOSED. An **edge train** whose **terminal** vertices coincide.

EDGE TRAIN, OPEN. An **edge train** whose **terminal** vertices do not coincide.

EDGEWORTH SERIES. A form of expansion of a frequency function in terms of derivatives of the **normal distribution**. For a distribution in standard form (i.e., with zero mean and unit variance) the expansion is

$$f(x) = \left[\exp \left\{ \sum_{j=3}^{\infty} \kappa_j \frac{(-D)^j}{j!} \right\} \right] \alpha(x),$$

where κ_j is the j^{th} **cumulant**, D is the operator $\frac{d}{dx}$ and $\alpha(x)$ is the normal function $e^{-\frac{1}{2}x^2}/\sqrt{(2\pi)}$.

(See also **Gram-Charlier series**.)

EFFECTIVE ANGULAR VELOCITY, EFFECTIVE FORCE, ETC. See entries under **angular velocity**, **effective**, etc.

EFFECTIVE AREA (ANTENNA). The square of the wavelength times the **power gain** (or **directive gain**) in a specified direction, and divided by 4π . When power gain is used, the effective area is that for power reception; when directive gain is used, the effective area is that for **directivity**.

EFFECTIVE BANDWIDTH. See **bandwidth**, **effective**.

EFFECTIVE EXHAUST VELOCITY. See **exhaust velocity**, **effective**.

EFFECTIVE HEIGHT (ANTENNA). In its present usage, this term means the height of the antenna center of radiation above the effective ground level. For an antenna with a symmetrical current distribution, the center of radiation is the center of the distribution. For an antenna with an asymmetrical current distribution, the center of radiation is the

center of current moments when viewed from directions near the direction of maximum radiation.

EFFECTIVE MASS. A parameter of the dimensions of a mass which is often used in the band theory of solids. An exact definition covering all its uses is impossible, but one may say that electrons at the bottom of a band, and holes near the top of a band, behave in many respects as if they were free particles with masses rather different from the mass of a free electron.

EFFECTIVE MULTIPLICATION. See **multiplication**, **effective**.

EFFECTIVE PHASE RETARDATION. See **partial coherence**.

EFFECTIVE POWER OF A LENS. The reciprocal of the **back foal length**.

EFFECTIVE PRINCIPAL QUANTUM NUMBER. The quantity

$$n^* = n + \mu$$

in the **Rydberg equation** for the line series in atomic spectra.

EFFECTIVE RADIUS OF CONTROL ROD. See **radius**, **effective**, of **control rod**.

EFFECTIVE VALUE. A term used in electricity, mechanics, etc., to denote the root-mean square value of a periodically-variable (usually sinusoidal) quantity.

EFFECTIVE WAVELENGTH. The wavelength of a monochromatic beam having the same penetration in a given medium as a beam of complex radiation.

EFFECTIVE WIDTH. See **width**, **effective**.

EFFICIENCY. (1) A ratio used to assess the performance of a machine or a prime mover in relation to its idealized version. (2) The ratio of some desired output quantity, such as work, to the (usually larger) equivalent which must be supplied to a device or prime mover, for example, heat. (3) The ratio of energy or work input to output in a transformation process. Thus, in a power cycle, the ratio of work done, W , to the heat required Q . Or

$$\eta = \frac{W}{Q}$$

Since some heat, say Q_o , must always be rejected, the efficiency is also

$$\eta = 1 - \frac{Q_o}{Q}$$

because by the first law of thermodynamics $W = Q - Q_o$ for a cycle. Efficiencies are so defined as to give a number smaller than unity for real engines. (4) In the theory of statistical estimation, the efficiency of an estimator is measured by its **dispersion** about the parameter under estimate or by its **variance**; the smaller the dispersion the more efficient the estimator. If there exists an optimum estimator, i.e., one with minimum dispersion, the efficiency of any other estimator is measured by the inverse ratio of their variances.

Measures of efficiency of an experimental design can similarly be set up in terms of the smallness of the experimental error.

EFFICIENCY, AVAILABLE POWER. Of an electroacoustic transducer used for sound reception, the ratio of the electric power available at the electric terminals of the **transducer** to the **acoustic power** available to the transducer. For an electroacoustic transducer which obeys the **reciprocity principle**, the available power efficiency in sound reception is equal to the transmitting efficiency. In a given narrow-frequency band, the available power efficiency is numerically equal to the fraction of the open-circuit mean-square thermal noise voltage present at the electric terminals which is contributed by thermal noise in the acoustic medium.

EFFICIENCY, CONVERSION. In vacuum tube **amplifier** and **oscillator** circuits, the a-c (usually radio frequency) power output divided by the d-c power input to the plate circuit. It is also called the plate efficiency. It varies quite widely with different classes of amplifiers, running as high as about 80% in some class C amplifiers, from 30 to 70% (depending upon conditions) in class B and being of the order of 20% in the usual class A amplifier.

EFFICIENCY, FROUDE. See **Froude momentum theory**.

EFFICIENCY, INDICATED. See **indicated efficiency**.

EFFICIENCY, LUMINOUS. The ratio of the luminous flux to the radiant flux.

EFFICIENCY OF A DIFFUSER. See **diffuser**.

EFFICIENCY OF ROCKET ENGINE. The efficiency of a rocket motor may be expressed as the product of a number of factors. One relationship between these factors is the following:

$$\eta = \eta_d \eta_F \eta_v$$

where η is the (overall) efficiency of the motor, η_d is the discharge correction factor, η_F is the thrust correction factor and η_v is the velocity correction factor. These factors are expressed, in turn, by the following relationships:

$$\eta_d = (dm/dt)/(dm/dt)_{th}$$

$$\eta_F = F/F_{th} = \eta_v/\eta_d$$

$$\eta_v = c/c_{th}$$

where (dm/dt) is the mass flow rate, F is the thrust, c is the effective exhaust velocity, and subscript *th* denotes the theoretical values. The ideal efficiency of a rocket motor is found from the relationship

$$\eta_i = 1 - (p_e/p_c)^{\frac{\gamma-1}{\gamma}} = 1 - T_e/T_c$$

where η_i is the ideal efficiency, p_e is the exhaust pressure, p_c is the chamber pressure, γ is the ratio of specific heats, T_e is the exhaust temperature and T_c is the chamber temperature. The efficiency of any jet engine can be regarded as the product of its thermal efficiency, η_T , its mechanical efficiency, η_M , and its propulsive efficiency, η_P , provided that these terms are defined as follows: thermal efficiency (η_T) = energy input to nozzle / energy in fuel; mechanical efficiency (η_M) = energy available for propulsion / energy input to nozzle; propulsive efficiency (η_P) = propulsive work / energy available for propulsion.

EFFICIENCY, QUANTUM. See **quantum efficiency**.

EFFICIENCY RATIO. Ratios of indicated work W_i to ideal work W . The ideal work is calculated on the basis of an idealized diagram, for example, an air-standard cycle in the case of internal combustion engines.

$$\eta_r = W_i/W.$$

It is equal to the so-called **diagram factor**. It is also equal to the ratio of indicated thermal efficiency, η_i , to the thermal efficiency of the ideal cycle, η_{th} :

$$\eta_r = \eta_i / \eta_{th}$$

It is sometimes also called the relative efficiency.

EHRENFEST ADIABATIC LAW. See **adiabatic law for quantized states (Ehrenfest)**.

EHRENFEST RELATIONS. The Ehrenfest relations describe the influence of pressure on a lambda-point considered as a second order transition (see **transitions of higher order**).

Using the superscripts $-$ and $+$ to denote the value of quantities immediately below and immediately above the temperature T of the λ -point, the Ehrenfest relations are

$$\frac{dT_\lambda}{dp} = \frac{(\alpha^- - \alpha^+)V_\lambda T_\lambda}{C_p^- - C_p^+} \quad (1)$$

$$\frac{dT_\lambda}{dp} = \frac{\kappa^- - \kappa^+}{\alpha^- - \alpha^+} \quad (2)$$

where C_p is the molar heat capacity, α , the thermal expansion coefficient and κ , the compressibility coefficient.

EHRENFEST THEOREM. See **adiabatic law for quantized states (Ehrenfest)**.

EIGENFUNCTION. If a differential or integral equation possesses solutions satisfying the given boundary conditions for only certain values of a parameter λ , such a value of λ is an **eigenvalue** and the corresponding solution is the eigenfunction belonging to the eigenvalue. If the set of all eigenfunctions of a linear operator are non-degenerate they will form an **orthogonal** set which is **normalizable**. No specific case has been found where the set is not also complete.

(2) As used in quantum mechanics, the eigenfunctions of a quantum mechanical operator (see **operators, quantum mechanical**).

(3) Often used as a synonym for **energy eigenfunction**.

EIGENFUNCTIONS, ELECTRONIC OF MOLECULES. See **molecular eigenfunctions**.

EIGENFUNCTIONS, MOLECULAR. See **molecular eigenfunctions**.

EIGENFUNCTIONS, MOLECULAR, SYMMETRY PROPERTIES OF. See **symmetry properties of molecular eigenfunctions**.

EIGENFUNCTIONS, ROTATIONAL. See **molecular eigenfunctions**.

EIGENFUNCTIONS, VIBRATIONAL. See **molecular eigenfunctions**.

EIGENSTATE. In quantum mechanics, measurable quantities correspond to linear operators. An eigenstate of a linear operator A is an **eigenvector** of A . The corresponding **eigenvalue** gives the result of a measurement, if the quantity A is measured in the eigenstate.

EIGENVALUE (PROPER VALUE). The concept described by this hybrid word has become extremely important in pure and applied mathematics, and in engineering, physics and chemistry. The German word "*eigen*" means "characteristic," a term already overburdened in mathematical English. The "characteristic values" of a physical system are numbers which describe, for example, the critical frequencies of a suspension bridge or of a rotating shaft, the critical load of a supporting column, or the energy levels of a system in quantum mechanics. In corresponding mathematical language, we shall define the eigenvalues of a square **matrix**, of the kernel of an **integral equation**, of a **differential equation** with **boundary conditions**, and of an **operator** or **transformation**, the last case including all the others.

If $\mathbf{A} = \{a_{ik}\}$ is a square matrix, then the number λ is an eigenvalue (also called a characteristic number, a proper value, a latent root, etc.) of the matrix \mathbf{A} if the **determinant**

$$\begin{vmatrix} a_{11} - \lambda & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} - \lambda & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} - \lambda \end{vmatrix}$$

is equal to zero. In other words, an eigenvalue of a matrix is a root of the **characteristic equation** of the matrix.

As a physical example, consider a suspension bridge which is vibrating with n degrees of freedom about a position of stable equilibrium. Its potential energy at any time will be a function, call it $A(q_1, q_2, \dots, q_n)$, of its n position coordinates q_1, q_2, \dots, q_n , which is approxi-

mated by the quadratic form $\Sigma a_{ik}q_iq_k$, the constants a_{ik} being given by $a_{ik} = \frac{1}{2}(\partial^2 A / \partial q_i \partial q_k)$ evaluated at the position of equilibrium. Then, the eigenvalues of the matrix $\{a_{ik}\}$ are the squares of the critical frequencies of the bridge, namely the frequencies at which an impressed force will cause dangerous resonance.

From the theory of linear equations it follows that this definition of the eigenvalues of a matrix can be restated as follows. The constant λ is an eigenvalue of the matrix $\{a_{ik}\}$ if the n homogeneous linear equations in the n unknowns q_1, q_2, \dots, q_n

$$\begin{aligned} a_{11}q_1 + a_{12}q_2 + \dots + a_{1n}q_n &= \lambda q_1 \\ a_{21}q_1 + a_{22}q_2 + \dots + a_{2n}q_n &= \lambda q_2 \\ \vdots & \\ a_{n1}q_1 + a_{n2}q_2 + \dots + a_{nn}q_n &= \lambda q_n \end{aligned}$$

have a non-trivial solution (i.e., one for which not all the q_i vanish). In other words, regarding the matrix as a linear operator in n -dimensional Euclidean space, the constant λ is an eigenvalue of the operator A which transforms a vector $\mathbf{q} = (q_1, q_2, \dots, q_n)$ into a vector denoted by $A\mathbf{q}$, if there exists a non-zero vector $\mathbf{q} = (q_1, q_2, \dots, q_n)$ such that $A\mathbf{q} = \lambda\mathbf{q}$. Such a non-zero vector is called an *eigenvector* (of the operator A) belonging to the eigenvalue λ .

Similarly, let $A(x,y)$ be a continuous function of two variables (the infinite-dimensional analogue of a matrix with rows and columns) defined for $a \leq x, y \leq b$, and let A be the integral operator which transforms a function $\phi(x)$ into a function $f(x)$ according to the formula $f(x) =$

$\iint A(x,y)\phi(y)dy$, where the integration is taken over the square $a \leq x, y \leq b$ and the functions $\phi(x)$ and $f(x) = A\phi(x)$ are infinite-dimensional analogues (in **Hilbert space**) of the above vectors \mathbf{q} and $A\mathbf{q}$. Then the constant λ is defined to be an eigenvalue of the integral operator A if the integral equation

$$\iint A(x,y)\phi(y)dy = \lambda\phi(x),$$

which we may also write in the form $A\phi = \lambda\phi$, has a non-trivial solution $\phi(x)$. The solution $\phi(x)$ is called an eigensolution, or **eigenfunction** belonging to λ .

The type of eigenvalue problem occurring most frequently in practical applications involves a **differential operator**. For example, the critical frequencies of a vibrating plate (im-

portant in the theory of microphones and elsewhere) are the squares of the eigenvalues of the biharmonic operator discussed below.

In general, let A be any differential operator acting on functions ϕ of any number of variables; e.g., for the clamped plate, $\phi = \phi(x,y)$ and A is the biharmonic operator defined by the formula

$$A\phi = \partial^4\phi/\partial x^4 + 2\partial^4\phi/\partial x^2\partial y^2 + \partial^4\phi/\partial y^4.$$

Also, let us consider as admissible only those functions ϕ which satisfy certain boundary conditions; e.g., for the clamped plate, ϕ and its normal derivative must vanish on the boundary. Then the constant λ is an eigenvalue of the operator A if there exists an admissible function ϕ , called an eigenfunction of A , such that $A\phi = \lambda\phi$. Differential eigenvalue problems of this sort are of fundamental importance in the theory of vibrations and buckling and in quantum mechanics.

EIGENVALUE EQUATION. An equation of the form $P\psi = \lambda\psi$ where P is a linear operator and λ is a constant. ψ is called the eigenfunction of the operator P corresponding to the **eigenvalue**, λ .

EIGENVALUE EQUATION OF TENSOR. For a covariant second-order **tensor** t_{ij} , the equation $|t_{ij} - \lambda g_{ij}| = 0$. For a contravariant second-order tensor t^{ij} , the equation $|t^{ij} - \lambda g^{ij}| = 0$. For a mixed second-order tensor t_j^i , the equation $|t_j^i - \lambda \delta_j^i| = 0$. g_{ij} and g^{ij} are the covariant and contravariant **metric tensors** respectively and δ_j^i is the **Kronecker delta**. For a second-order Cartesian tensor t_{ij} , the equation $|t_{ij} - \lambda \delta_{ij}| = 0$, where δ_{ij} is the Kronecker delta. The solutions for λ of the eigenvalue equation are called the **eigenvalues**, *characteristic values*, or *principal values of the tensor*.

EIGENVALUES AND EIGENVECTORS OF MATRICES, METHODS OF COMPUTING.

For a given square matrix \mathbf{A} (singular or not), non-null vectors \mathbf{x} exist satisfying $\mathbf{A}\mathbf{x} = \lambda\mathbf{x}$ only when the scalar λ satisfies $\det(\lambda\mathbf{I} - \mathbf{A}) = \phi(\lambda) = 0$, called the characteristic equation (cf., the entry **eigenvalue**) where $\phi(\lambda)$ is a polynomial of degree n , the order of \mathbf{A} , called the characteristic polynomial (see **matrix**). Any root λ of this equation is called an eigenvalue; associated with any root λ there is at least one non-null vector \mathbf{x} called eigenvector belonging to λ . The number of independent

eigenvectors belonging to an eigenvalue may equal, but cannot exceed, the multiplicity of λ as a root of the characteristic equation. For normal matrices, including **Hermitian**, the number equals the multiplicity. For a non-normal matrix, if λ is a root of multiplicity $\nu > 1$, and if fewer than ν independent vectors belong to λ , then there are principal vectors $\mathbf{y} \neq 0$ satisfying $(\lambda \mathbf{I} - \mathbf{A})^\mu \mathbf{y} = 0$ for $1 < \mu \leq \nu$. It is always true that $\phi(\mathbf{A}) = 0$. If there is a polynomial $\psi(\lambda)$ of degree $m < n$ for which $\psi(\mathbf{A}) = 0$, then that polynomial of lowest degree for which this is true is a minimal polynomial, and \mathbf{A} is said to be derogatory; otherwise nonderogatory. The condition for being derogatory is rather stringent and not often satisfied in practice, and the same is true for the presence of principal vectors, but when the conditions are nearly satisfied the corresponding eigenvectors are poorly defined and computational difficulties arise, possibly even insurmountable.

Implicitly or explicitly, to evaluate an eigenvalue requires the solution of an algebraic equation of degree n . The problem is much simpler for a **Hermitian matrix**, and for these is discussed under that heading. Some of these methods can also be adapted to normal matrices. Here the general case is considered. A method may purport to yield only the characteristic, or possibly the minimal, polynomial, leaving this to be solved by any of the standard methods for solving algebraic equations. Such a method is called direct. Once an eigenvalue is known, an eigenvector belonging to it can be found by solving a system of homogeneous equations (see **matrix inversion**). A direct expansion of the determinant is unthinkable when n is at all large.

Since any $n + 1$ vectors in n -space are linearly dependent, if $\mathbf{b} = \mathbf{b}_1 \neq 0$, then in the sequence

$$\mathbf{b}_{i+1} = \mathbf{A}\mathbf{b}_i$$

there is a smallest index $m \leq n$ such that \mathbf{b}_{m+1} is linearly dependent upon those preceding:

$$\mathbf{b}_{m+1} + \beta_1 \mathbf{b}_m + \beta_2 \mathbf{b}_{m-1} + \dots + \beta_m \mathbf{b}_1 = 0. \tag{1}$$

This represents n equations in $m \leq n$ unknowns, and they are consistent by hypothesis, even if $m < n$. But this is

$$(\mathbf{A}^m + \beta_1 \mathbf{A}^{m-1} + \dots + \beta_m \mathbf{I})\mathbf{b} = 0. \tag{2}$$

Hence, if

$$\psi(\lambda) \equiv \lambda^m + \beta_1 \lambda^{m-1} + \dots + \beta_m, \tag{3}$$

then $\psi(\mathbf{A})\mathbf{b} = 0$ and $\psi(\lambda)$ is either a minimal polynomial or a factor of it, and except for very special choices of \mathbf{b} , $\psi(\lambda)$ is a minimal polynomial.

If one forms the matrix

$$\mathbf{B} = (\mathbf{b}_1, \mathbf{b}_2, \dots, \mathbf{b}_m) \tag{4}$$

whose columns are the \mathbf{b}_i , then

$$\mathbf{A}\mathbf{B} = \mathbf{B}\mathbf{F} \tag{5}$$

where \mathbf{F} is the companion matrix whose form is

$$\mathbf{F} = \begin{pmatrix} 0 & 0 & \dots & 0 & -\beta_m \\ 1 & 0 & \dots & 0 & -\beta_{m-1} \\ & & \dots & & \\ & & & & \\ 0 & 0 & \dots & 1 & -\beta_1 \end{pmatrix}. \tag{6}$$

Its characteristic polynomial is $\psi(\lambda)$. With $\mathbf{b}_1 = \mathbf{c}_1$, the first column of \mathbf{I} , this is the method of *Krylov*.

This method is effective for matrices of fairly low order. For matrices of high order the equations to be solved for the β_i tend to become ill-conditioned. A method due to *Hessenberg* yields a matrix \mathbf{B} such that

$$\mathbf{A}\mathbf{B} = \mathbf{B}\mathbf{G}, \tag{7}$$

where \mathbf{G} is not the companion matrix, but whose form is such that the characteristic polynomial can be expanded directly, and from which it is rather easy to solve for the eigenvectors. To apply this method one selects auxiliary vectors $\mathbf{c}_1, \mathbf{c}_2, \mathbf{c}_3, \dots$ subject to two mild restrictions but otherwise arbitrary. Ordinarily one can take (with *Hessenberg*) each $\mathbf{c}_i = \mathbf{e}_i$, a column of \mathbf{I} . One starts again with a vector \mathbf{b} , possibly \mathbf{c}_1 . Now \mathbf{b}_2 is a linear combination of \mathbf{b}_1 and $\mathbf{A}\mathbf{b}_1$ orthogonal to \mathbf{c}_1 ; \mathbf{b}_3 a linear combination of $\mathbf{b}_1, \mathbf{b}_2$, and $\mathbf{A}\mathbf{b}_2$ orthogonal to both \mathbf{c}_1 and \mathbf{c}_2 ; \dots . The restrictions on the \mathbf{c}_i are, first, linear independence, and, second,

$$\mathbf{c}_i^* \mathbf{b}_i \neq 0.$$

With these conditions fulfilled one forms

$$\mathbf{A}\mathbf{b}_1 = \mathbf{b}_1 \gamma_{11} + \mathbf{b}_2$$

where

$$\mathbf{c}_1^* \mathbf{A}\mathbf{b}_1 = \mathbf{c}_1^* \mathbf{b}_1 \gamma_{11}.$$

Hence γ_{11} is obtained, and therefore \mathbf{b}_2 . Next

$$\mathbf{A}\mathbf{b}_2 = \mathbf{b}_1 \gamma_{12} + \mathbf{b}_2 \gamma_{22} + \mathbf{b}_3,$$

where

$$\begin{aligned} \mathbf{c}_1^* \mathbf{A} \mathbf{b}_2 &= \mathbf{c}_1^* \mathbf{b}_1 \gamma_{12}, \\ \mathbf{c}_2^* \mathbf{A} \mathbf{b}_2 &= \mathbf{c}_2^* \mathbf{b}_1 \gamma_{12} + \mathbf{c}_2^* \mathbf{b}_2 \gamma_{22}. \end{aligned}$$

From the first of these one obtains γ_{12} , from the second γ_{22} , and finally \mathbf{b}_3 . The process continues, and \mathbf{G} is seen to have the form

$$\mathbf{G} = \begin{pmatrix} \gamma_{11} & \gamma_{12} & \gamma_{13} & \cdots \\ 1 & \gamma_{22} & \gamma_{23} & \cdots \\ 0 & 1 & \gamma_{33} & \cdots \\ & & \dots & \dots \end{pmatrix}. \tag{8}$$

It may be observed that when the choice $\mathbf{c}_i = \mathbf{c}_i$ is made, then the first element of \mathbf{b}_2 is null as are the first two elements of \mathbf{b}_3 , the first three of \mathbf{b}_4 , \dots .

A further refinement of the method is the biorthogonalization method of *Lanczos*. In this method only \mathbf{b}_1 and \mathbf{c}_1 are arbitrary. Thereafter, just as \mathbf{b}_2 is a linear combination of \mathbf{b}_1 and $\mathbf{A}\mathbf{b}_1$ orthogonal to \mathbf{c}_1 , so is \mathbf{c}_2 a linear combination of \mathbf{c}_1 and $\mathbf{A}^*\mathbf{c}_1$ orthogonal to \mathbf{b}_1 , and so for the others. The matrix \mathbf{G} is then tridiagonal, being null everywhere except along, just below, and just above the diagonal. The recursion then never contains more than three terms in any equation.

Another modification is due to *Arnoldi*, who chooses $\mathbf{b}_i = \mathbf{c}_i$ and requires \mathbf{B} to be an orthogonal matrix. Then (7) is satisfied, but with a matrix \mathbf{G} of the form

$$\mathbf{G} = \begin{pmatrix} \gamma_{11} & \gamma_{12} & \gamma_{13} & \cdots \\ \gamma_{21} & \gamma_{22} & \gamma_{23} & \cdots \\ 0 & \gamma_{32} & \gamma_{33} & \cdots \\ & & \dots & \dots \end{pmatrix} \tag{9}$$

similar to (8) but with elements other than ones on the subdiagonal. The development of the characteristic polynomial from \mathbf{G} is almost equally straightforward.

When only one, or few, of the eigenvalues of largest modulus are required a simple iteration scheme is advisable, and is preferred by some even for a complete reduction of rather large matrices. If there is a single proper value exceeding all others in modulus, λ_1 , vectors \mathbf{b}_ν in the continued sequence

$$\mathbf{b}_{\nu+1} = \mathbf{A} \mathbf{b}_\nu$$

approach the eigenvector belonging to λ_1 , so that for large ν ,

$$\mathbf{b}_{\nu+1} \doteq \lambda_1 \mathbf{b}_\nu.$$

Hence, with any vector \mathbf{u} , an approximate value of λ_1 is given by

$$\mathbf{u}^* \mathbf{A} \mathbf{b}_\nu = \lambda_1 \mathbf{u}^* \mathbf{b}_\nu.$$

Convergence, when it occurs, can be accelerated by application of the **delta-square process** termwise to the vectors in the sequence.

In the case of a pair of complex roots, convergence does not occur, but in the limit \mathbf{b}_ν becomes parallel to the plane of the two eigenvectors. Then if

$$\mu_\nu = \mathbf{u}^* \mathbf{b}_\nu$$

the roots of the equation

$$\begin{vmatrix} 1 & \mu_\nu & \mu_{\nu+1} \\ \lambda & \mu_{\nu+1} & \mu_{\nu+2} \\ \lambda^2 & \mu_{\nu+2} & \mu_{\nu+3} \end{vmatrix} = 0$$

approach these roots λ_1 and λ_2 as ν increases. In fact, whether or not λ_1 and λ_2 are equal in modulus, but provided only both exceed all others in modulus, the statement is true. Moreover, the roots of

$$\begin{vmatrix} 1 & \mu_\nu & \mu_{\nu+1} & \mu_{\nu+2} \\ \lambda & \mu_{\nu+1} & \mu_{\nu+2} & \mu_{\nu+3} \\ \lambda^2 & \mu_{\nu+2} & \mu_{\nu+3} & \mu_{\nu+4} \\ \lambda^3 & \mu_{\nu+3} & \mu_{\nu+4} & \mu_{\nu+5} \end{vmatrix} = 0$$

approach the three proper values of largest modulus, if such exist (cf. **Bernoulli method**).

Returning to the two roots, for large ν ,

$$\mathbf{b}_\nu \doteq \mathbf{v}_1 + \mathbf{v}_2,$$

$$\mathbf{b}_{\nu+1} \doteq \lambda_1 \mathbf{v}_1 + \lambda_2 \mathbf{v}_2,$$

approximately, where \mathbf{v}_1 and \mathbf{v}_2 are eigenvectors belonging to λ_1 and λ_2 . Knowing λ_1 and λ_2 , as well as \mathbf{b}_ν and $\mathbf{b}_{\nu+1}$, these equations can be solved for \mathbf{v}_1 and \mathbf{v}_2 .

When any eigenvalue and eigenvector are known it is possible to apply *deflation* as follows: The matrix

$$\mathbf{A} - \lambda_1 \mathbf{v}_1 \mathbf{u}^*,$$

where \mathbf{u} is any vector satisfying $\mathbf{u}^* \mathbf{v}_1 = 1$ has the same eigenvalues as \mathbf{A} except that instead of λ_1 the new matrix has a zero. Moreover, if \mathbf{w} is an eigenvector of $\mathbf{A} - \lambda_1 \mathbf{v}_1 \mathbf{u}^*$, belonging to the eigenvalue λ , then $(\mathbf{A} - \lambda_1 \mathbf{I}) \mathbf{w}$ is a proper vector of \mathbf{A} belonging to the eigenvalue λ . And finally, it is possible to choose \mathbf{u}^* so that every element but the first in the first row

of $\mathbf{A} - \lambda_1 \mathbf{v}_1 \mathbf{u}^*$ is zero. To do this, normalize \mathbf{v}_1 to have 1 as the first element (should this be zero, permute rows and corresponding columns of \mathbf{A} , and the same elements of \mathbf{v}_1 to make the first element non-null). Choose the last $n - 1$ elements of \mathbf{u}^* to be $1/\lambda_1$ times the corresponding elements of the first row of \mathbf{A} , and choose the first element of \mathbf{u}^* to satisfy $\mathbf{u}^* \mathbf{v}_1 = 1$. It remains now to consider only a matrix of order $n - 1$, and further reductions are made as further eigenvalues and eigenvectors are found.

In case μ is an approximation to a particular eigenvalue λ_i , closer than to any other λ_j , then $\mu - \lambda_i$ is the numerically largest eigenvalue of $(\mathbf{A} - \mu \mathbf{I})^{-1}$. Hence the solution of the system

$$(\mathbf{A} - \mu \mathbf{I}) \mathbf{x}_1 = \mathbf{x}_0$$

for an almost arbitrary \mathbf{x}_0 will give a good approximation to the eigenvector belonging to λ_i , and $\mathbf{x}_1^* \mathbf{A} \mathbf{x}_1 / \mathbf{x}_1^* \mathbf{x}_1$ will be a better approximation to λ_i . This is *Wielandt's broken iteration*.

Unless it is known a priori that a matrix has **principal vectors** that are not eigenvectors, and has auxiliary conditions available for determining them, rounding errors will almost inevitably conceal them, but the problem may turn out to be highly unstable. If $\mathbf{A} = \mathbf{P} \mathbf{\Lambda} \mathbf{P}^{-1}$ where $\mathbf{\Lambda}$ is diagonal, the **numerical stability** decreases as $\|\mathbf{P}\| \|\mathbf{P}^{-1}\|$ increases in some **norm**, hence this seems to be an appropriate **condition number** with respect to this problem. But as \mathbf{A} approaches the nondiagonalizable form, this number becomes infinite, hence at least some of the eigenvalues and eigenvectors become ill defined.

EIGENVECTOR. See **eigenvalue**.

EIKONAL. H. Brun's term for the **eigenfunction** of an optical system. Bruns in 1895 developed a **Hamiltonsion theory** for geometric optics. At the time continental Europe was well aware, through Jacobi, of Hamilton's contributions to classical mechanics but was apparently unaware that Hamilton first developed these methods in optical theory. The alternative spelling *ikonal* is now sometimes used.

EIKONAL EQUATION. The differential equation of geometrical optics

$$V_x^2 + V_y^2 + V_z^2 = n^2$$

is referred to either as the eikonal equation, or as the characteristic equation. The solutions are the eikonal or Hamilton's characteristic of the optical system with refractive index $n = n(x, y, z)$.

EINSTEIN COEFFICIENTS. Discussed under **transition probabilities**, **Einstein**.

EINSTEIN CONDENSATION. A perfect gas obeying **Bose-Einstein statistics** will show at low temperatures a third order phase transition which in many respects resembles the condensation of an imperfect gas. The condensed phase consists of particles in their ground state. This phenomenon has been studied extensively in connection with a possible relation to the **lambda-transition** of liquid helium.

EINSTEIN DIFFUSION EQUATION. An equation for the mean square displacement of spherical colloidal particles in a gas or liquid, due to Brownian movement. The mean square displacement from its original position after a time τ is

$$\overline{x^2} = \frac{RT}{3\pi\eta r N} \tau,$$

where R is the gas constant, T is the absolute temperature, r is the radius of the particle, η is the viscosity, N is Avogadro's number. This relationship is only valid for particles of such size that they obey Stokes' resistance law.

EINSTEIN EFFECTS. See **relativity**, **general**.

EINSTEIN EQUATION FOR HEAT CAPACITY. See **Einstein specific heat function**.

EINSTEIN MASS-ENERGY RELATIONSHIP. See **mass-energy relationship**.

EINSTEIN PHOTOELECTRIC EQUATION. An equation giving the kinetic energy of an electron ejected from a system in the **photoelectric effect**, where the electron is ejected by an incident photon, absorbing all the energy of the latter. This equation is:

$$E_k = h\nu - \omega$$

where E_k is the kinetic energy of the ejected electron, h is the Planck constant, ν is the frequency associated with the absorbed photon, and ω is the energy necessary to remove the electron from the system.

EINSTEIN RELATIONSHIP BETWEEN MOBILITY AND DIFFUSION COEFFICIENT. The mobility μ of charges in a semiconductor, or ionic solution is related to the diffusion coefficient D_e by

$$\mu = eD_e/kT$$

where e is the magnitude of the charge, k is the Boltzmann constant, and T is the absolute temperature.

EINSTEIN SPECIFIC HEAT FUNCTION. The heat capacity of an assembly of N simple harmonic oscillators, all having the same frequency is given by

$$c_v = Nk(h\nu/kT)^2 e^{h\nu/kT} / (e^{h\nu/kT} - 1)^2,$$

where h and k are the Planck and Boltzmann constants. This type of function represents the contribution of the optical modes to the specific heat of a solid, which is otherwise more accurately given by a Debye heat capacity equation. By replacing Nk in the equation by $3R$, where R is the gas constant, its value is C_v , the heat capacity at constant volume of one gram-atomic weight of an element.

EINSTEIN TRANSITION PROBABILITY. See transition probability, Einstein.

EISNER-LACHS THEOREM. The theorem, proved by Eisner and Lachs in 1947, stating that in a nuclear reaction produced with an unpolarized beam of given orbital angular momentum incident on an unpolarized target, the angular distribution of the outgoing intensity cannot be more complicated than that of the incoming intensity.

EKMAN LAYER. (Sometimes called spiral layer.) The layer of transition between the surface boundary layer, where the shearing stress is constant, and the free atmosphere, where the atmosphere is treated as an ideal gas in approximate geostrophic equilibrium. In Ekman's analysis, the coefficient of eddy viscosity is assumed constant within this layer; subsequent calculations have relaxed this assumption.

EKMAN SPIRAL. The equiangular spiral of 45° traced out by a point whose position vector is the steady horizontal ocean current vector (with varying depth) produced by a steady surface stress due to the wind. The water at great depth is at rest and is represented by the

center of the spiral. The surface water moves in a direction at 45° to the wind (to the right in the northern hemisphere). The total momentum of any column of ocean is at right angles to the wind, and the total momentum below any depth is at right angles to the direction of shear at that depth.

ELASTANCE. The reciprocal of capacitance, measured in darafs.

ELASTICA. A plane curve into which the central line of a thin, initially cylindrical, elastic rod can be bent by means of forces and couples applied to its ends only.

ELASTIC AFTER EFFECT. See after effect, elastic.

ELASTICA, INFLEXIONAL. An elastica on which there are one or more points of inflexion.

ELASTICA, NON-INFLEXIONAL. An elastica on which there are no points of inflexion.

ELASTIC AXIS. The line joining the shear centers of the cross sections of an elastic beam.

ELASTIC CENTER. The point on the rigid extension from one end of, or a cut through, an elastic arch or frame which will not translate when a moment is applied there. Correspondingly a force applied at the elastic center will not rotate the rigid extension. It is, therefore, also the centroid in the plane of the M_s/EI diagram erected perpendicular to the plane of the structure, where M_s is the moment due to the applied loads with zero force and moment at the elastic center.

ELASTIC COEFFICIENTS, LATTICE THEORY OF. The elastic constants and elastic moduli of crystals may be calculated on the assumption that the only forces are those between near neighbors in the lattice. Such a calculation gives reasonable results for ionic crystals, but is quite unsatisfactory for metals, where the Cauchy relations are not obeyed. The free electron gas in a metal is not easily compressed but scarcely opposes shear.

ELASTIC CONSTANTS. Physical constants occurring in the strain-energy function or stress-deformation relation for a homogeneous, elastic material, which characterize the elastic behavior for the material, e.g., the Lamé con-

stants in the case when the material is isotropic and obeys the **generalized Hooke's law**.

Two independent elastic constants characterize the small strain behavior of a linearly elastic isotropic material having the same properties in tension and compression. Four related elastic constants are in common use. The modulus of elasticity in simple tension or compression given by the ratio of axial stress to strain is called **Young's modulus**. The ratio of transverse strain magnitude to longitudinal strain magnitude is called **Poisson's ratio**. The ratio of shear stress to strain in simple shear is the *shear modulus* or *modulus of rigidity* and the ratio of pressure to unit volume change is the *bulk modulus*.

ELASTIC CURVE. The curve of the neutral surface of a structural member subjected to loads which cause bending is called the elastic curve. The ordinates between this curve and the original position of the neutral surface represent the deflections due to bending.

ELASTIC FOUNDATION. The term elastic foundation generally means linearly elastic, and usually refers to the simplest type in which the local foundation reaction is proportional to the local deflection.

ELASTIC HYSTERESIS CONSTANT. The ratio of the area (expressed in energy units) of the stress-strain loop, for a unit volume of the material, to the square of the maximal strain.

ELASTICITY, DELAYED. Mechanical behavior which is elastic for slow changes, but **anelastic** for changes at finite stress and strain rates. It is represented by the **Kelvin** or **Voigt viscoelastic model**.

ELASTICITY, HIGH. Viscoelastic deformation of polymers.

ELASTICITY, RECIPROCITY THEOREM FOR. See **Maxwell and Betti reciprocity theorem**.

ELASTICITY, RETARDED. See **elasticity, delayed**.

ELASTICITY THEORY. See **classical elasticity theory; finite elasticity theory**.

ELASTIC LIMIT. In simple tension or compression the maximum stress which can be carried without measurable plastic deformation

is called the elastic limit. More generally it is a limiting state of stress σ_{ij} such that $K\sigma_{ij}$, where $K > 1$, will cause plastic deformation. Actually, the more precise the measuring instruments, the lower the stress at which plastic deformation is observed. An offset **yield strength** or a **tangent modulus** limitation gives a repeatable and more useful definition.

ELASTIC LINE. See **elastic curve; elastic axis**.

ELASTIC LOAD METHOD. A conjugate beam or truss procedure in which the loads are M/EI or similar quantities and the forces and moments in the conjugate structure are slopes and deflections.

ELASTIC MATERIAL. A material for which the work done by the applied forces in a quasi-static **deformation** is a single-valued function of the initial and final states of deformation.

ELASTIC WEIGHTS. Although sometimes employed as an alternate term for elastic loads, elastic weights denote ds/EI where s is the distance along the structure.

ELASTOSTATIC. Adjective describing condition in elastic or perfectly elastic material in which neither the **displacement field** nor the **stress field** varies with time. Hence, *elastostatic problem*.

ELECTRIC(AL) CAPACITANCE. See **capacitance**.

ELECTRIC CIRCUITS. Electric charges, at rest and/or in motion, are the fundamental sources of electric and magnetic **fields**. Broadly speaking, there are three more or less distinct situations involving the spatial distribution of the fields produced by distributions of charge and current. Many important instances arise where these fields are distributed throughout a region of space of vast extent and differ accordingly at separated points in the region. On the other hand, important applications are made of devices in which the electric and magnetic fields are confined to a much more limited region of space although the fields still undergo a significant variation in magnitude from point to point throughout the region, as in a transmission line. Here the fields are confined to the immediate vicinity of the line conductors but the fields vary significantly as one moves along the line.

Finally, however, there are applications utilizing pieces of apparatus in which the electric and magnetic fields are confined to regions of space which are so restricted in spatial extent that one may speak of an electric or magnetic field as having an essentially constant value in the immediate region of the device which is very much greater than at all other points of space.

It is found, however, that when one deals with changing currents (charges in motion with varying velocity), the spatial dimension alone is not an adequate measure to establish which of the three situations suggested above is involved in a particular application. For sinusoidally varying currents one can define a quantity known as the wavelength which in free space is numerically equal to the velocity of light divided by the frequency of the sinusoidal variation. If spatial extent is measured in wavelengths, then an assemblage of apparatus which is confined to a region which is less than about one tenth of a wavelength in greatest dimension results in a good approximation to the third situation considered above. This possibility, one in which the electric fields and the magnetic fields may be considered to be concentrated in individual pieces of apparatus, is the domain of electric circuits. An electric circuit may be defined as a characterization of an electrical system in terms of the integrated effects of the electric and magnetic fields present in the system. The characterization is an approximation to the actual field problem in which one replaces the actual system by elements having **resistance**, **capacitance**, and **inductance** and by sources of **electric potential** and **electric current**. Systems in which the approximation cited is permissible are sometimes called "lumped constant" circuits. Antennas and transmission lines, on the other hand, are often referred to as "distributed constant" circuits. The distinction between these two designations comes from the spatial variation of the electric and magnetic fields as outlined above.

As may be inferred from their definitions, the parameters of resistance, capacitance, and inductance are not necessarily independent of the currents and voltages impressed upon the elements of an electrical system. Whether the resistance of an element is a function of the current through it or not, the relation $v = Ri$ (R is resistance in ohms) is still valid for the

connection between the voltage across an element and the current through it. On the other hand, corresponding relations for the coil and the capacitor become more involved if their parameters are dependent on current or voltage. For constant parameters of inductance (L in henrys) and capacitance (C in farads), the voltages and currents in pure inductive and capacitive components assume the form

$$v = L \frac{di}{dt} \quad \text{or} \quad i = \frac{1}{L} \int v dt$$

and

$$i = C \frac{dv}{dt} \quad \text{or} \quad v = \frac{1}{C} \int i dt$$

respectively. If the parameters L and C vary with impressed voltage and current, the above relations are not valid and recourse must be made to the basic law of **electromagnetic induction** when coils are involved and to the expression for electric current as the rate of change of charge (derivative of charge with respect to time) for circuits containing capacitors.

Whether elements with constant or variable parameters are involved, one may employ **Kirchhoff laws of networks** to formulate equations representing conditions of equilibrium between the applied voltages and/or currents and the quantities that result. The equilibrium equations may be formulated on the basis of voltages as independent variables and currents as dependent quantities, the system of equations being known as the mesh equations for the circuit. Alternatively, they may be written on the nodal basis, where the sources are current generators and the dependent quantities are nodal voltage differences with respect to a reference node. As an example of the process involved, consider the simple series circuit shown in Figure 1 and the simple parallel circuit shown in Figure 2 (page 291). The single mesh equation characterizing the series circuit and the single nodal equation describing equilibrium in the parallel circuit are, respectively

$$V(t) = Ri(t) + L \frac{di(t)}{dt} + \frac{1}{C} \int i(t) dt$$

and

$$I(t) = \frac{1}{R} v(t) + \frac{1}{L} \int v(t) dt + C \frac{dv(t)}{dt}$$

The mesh and nodal equations for more complicated circuits have a form similar to these equations with added dependent variable terms and, in general, additional independent

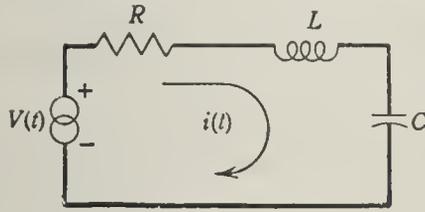

Fig. 1.

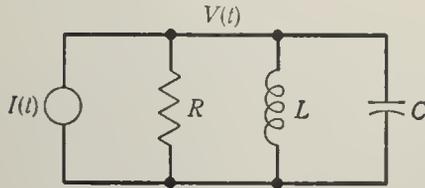

Fig. 2.

variable terms. The equations may be solved by various mathematical means to yield the desired unknown quantities, currents for mesh equations and voltages for nodal equations.

If the applied voltage sources are batteries or alternative sources of electric potential which are constant with time, the solution to the network equations described above will consist of constant terms (including zero as a special case) plus terms which decay exponentially with time. The latter terms are called the transient terms or the transient solution. They correspond to the solution of the homogeneous **differential equations**. The constant terms represent the **steady state** solution of the problem. In the case of **direct currents**, these particular solutions may be obtained in terms of the resistances involved, that is, in the computation of the steady state response for circuits with constant potential applied, inductors may be replaced by elements of zero resistance and capacitors by resistors of infinite resistance. If, on the other hand, the applied sources vary sinusoidally with time, the solution to the network problems which have been considered will have transient terms which decay with time, as was stated above, but the steady state terms will be sinusoidally varying quantities. The steady state solutions will involve all elements, those having inductance and capacitance as well as the resistive elements.

ELECTRIC CONSTANT. (Symbol ϵ_0 or γ_e . The electric constant pertinent to any system

of units in the scalar dimensional factor ϵ_0 appearing in the **Coulomb law of force** between two charges in vacuo:

$$F = q_1 q_2 / n \epsilon_0 r^2$$

where $n = 1$ for unrationalized units, and $n = 4\pi$ for rationalized units.

In the esu system, ϵ_0 is assigned the value unity, with no dimensions. In all systems, $\epsilon_0 \mu_0 = 1/c^2$, where c is the velocity of light in the appropriate system. Note that c is dimensional. (See **magnetic constant**.) In the mksa system, ϵ_0 has the dimensions: farad/meter.

ELECTRIC CURRENT. See **current, electric; alternating currents; direct currents**.

ELECTRIC DIPOLE. See **dipole, electric**.

ELECTRIC(AL) DIPOLE MOMENT. See **dipole, electric**.

ELECTRIC DISPLACEMENT VECTOR. In a polarizable medium, (see **dielectric constant**), the measured **electric field vector** is due both to **free charges** and to the **bound charges** resulting from the polarization of the medium. Since the electric field vector is the fundamental measurable quantity, it is convenient to express it in terms of two auxiliary field quantities associated respectively with the free and bound charges. The field associated with the free charges is called the electric displacement vector, **D**, and satisfies the equation $\nabla \cdot \mathbf{D} = \rho$, where ρ is the free charge density (see **Maxwell equations**). The field associated with the bound charges is the **polarization vector P**. These three vectors are related as follows:

$$\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P},$$

where ϵ_0 is the **electric constant**. The vector **D** is sometimes called the **electric induction**, or the **electric flux density**, and defined by $\mathbf{D} = \epsilon \mathbf{E}$, ϵ being the dielectric constant. (See **constitutive relations**.)

ELECTRIC FIELD. The field of force having its source either in **electric charges**, or in time-varying **magnetic fields**.

ELECTRIC FIELD STRENGTH (INTENSITY). The magnitude of the **electric field vector**. In the mksa system of units it is measured in newtons/coulomb, or equivalently

in volts/meter. For its units in other systems, see **electromagnetic units**. The magnitude of the electric field strength at a distance r from a point of charge Q is, from Coulomb's law, $E = Q/4\pi\epsilon_0 r^2$ and its direction along \mathbf{r} , outward from the charge Q , if Q is positive. The electrostatic field strength due to a number of stationary charges is

$$\mathbf{E} = \sum_i q_i \mathbf{r}_i / 4\pi\epsilon_0 r_i^3$$

where the summation is a vector sum. The field due to stationary charges is a conservative field and the field strength may therefore be represented as the negative gradient of a potential V , $\mathbf{E} = -\text{grad } V = -\nabla V$. An electric field is also produced by a changing magnetic field, and is then given by

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t},$$

or alternatively

$$\phi \mathbf{E} \cdot d\mathbf{s} = -\frac{d}{dt} \int \mathbf{B} \cdot d\mathbf{A}.$$

(See Maxwell equations; Faraday law of electromagnetic induction.)

ELECTRIC FIELD VECTOR. The fundamental electric field quantity, defined as the force per unit charge on a positive charge in the limit as the charge approaches zero. This quantity has the dimensions newtons per coulomb, or volts per meter, and is denoted by \mathbf{E} .

ELECTRIC FLUX DENSITY. See **electric displacement vector**.

ELECTRIC(AL) IMPEDANCE. See **impedance; impedance, electrical**.

ELECTRIC(AL) INDUCTION. See **electric displacement vector**.

ELECTRIC INTENSITY. See **electric field strength**.

ELECTRICITY. (1) Under certain conditions physical objects separated in space can exert non-gravitational forces on each other. The source of these forces was originally thought to reside in an excess or deficiency of some substance possessed by all bodies. This substance, called "electricity," was later found to consist of discrete particles (charges) individually capable of "electrical" behavior. (2) A term loosely applied to physical phenomena associated with **electric charges**.

ELECTRIC(AL)-MECHANICAL-ACOUSTICAL RECIPROCITY THEOREM. See **reciprocity theorem, electric(al)-mechanical-acoustical**.

ELECTRIC(AL)-MECHANICAL RECIPROCITY THEOREM. See **reciprocity theorem, electric(al)-mechanical**.

ELECTRIC MULTIPOLES. The potential due to a static charge distribution ρ can be written

$$\phi(\mathbf{R}) = \frac{1}{4\pi\epsilon_0} \int_V \frac{\rho(\mathbf{R}') dV'}{r}$$

where $r = |\mathbf{R} - \mathbf{R}'|$ and the integral extends over the volume of the charge. (See **electrostatics, laws of**.) At distances $R = |\mathbf{R}|$ far from the charge distribution, $1/r$ can be expanded in a **Taylor series** as follows:

$$\begin{aligned} \frac{1}{r} &= \frac{1}{R} + \sum_{j=1}^3 x'_j \left[\frac{\partial}{\partial x'_j} \left(\frac{1}{r} \right) \right]_{r=R} \\ &+ \frac{1}{2!} \sum_{j,k=1}^3 x'_j x'_k \left[\frac{\partial^2}{\partial x'_j \partial x'_k} \left(\frac{1}{r} \right) \right]_{r=R} + \dots \end{aligned}$$

Inserting into the integral yields the multipole expansion,

$$\begin{aligned} \phi(\mathbf{R}) &= \frac{1}{4\pi\epsilon_0} \left\{ \frac{1}{R} \int_V \rho dV' \right. \\ &+ \sum_{j=1}^3 \left[\frac{\partial}{\partial x'_j} \left(\frac{1}{r} \right) \right]_{r=R} \int_V x'_j \rho dV' \\ &+ \frac{1}{2!} \sum_{j,k=1}^3 \left[\frac{\partial^2}{\partial x'_j \partial x'_k} \left(\frac{1}{r} \right) \right]_{r=R} \int_V x'_j x'_k \rho dV' + \dots \end{aligned}$$

The integral coefficients in this expansion represent the moments of the charge distribution: $\int_V \rho dV'$ is the total charge, $\int_V x'_j \rho dV'$ is the j^{th} component of the **dipole moment**, $\int_V x'_j x'_k \rho dV'$ is the jk^{th} component of the **quadrupole moment**, etc.

ELECTRIC NETWORK, LAWS OF. See **Kirchhoff laws; reciprocity theorem, electric network; Thévenin theorem**.

ELECTRIC(AL) NETWORK RECIPROCITY THEOREM. See **reciprocity theorem, electric(al) network**.

ELECTRIC(AL) POTENTIAL. See **potential, electric.**

ELECTRIC(AL) QUANTUM NUMBERS. See **Stark effect.**

ELECTRIC(AL) RESISTANCE. See **resistance.**

ELECTRIC(AL) SYSTEM OF ONE DEGREE OF FREEDOM. An electrical system of one degree of freedom is shown in Figure 1. In one degree of freedom the activity in

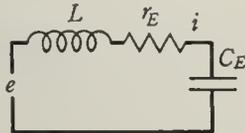

Fig. 1. Electric(al) system of one degree of freedom.

every element of the system may be expressed in terms of one variable. In the electrical system an electromotive force e acts upon an inductance L , an electrical resistance r_E and an electrical capacitance C_E connected in series.

The principle of the conservation of energy states that the total store of energy of all forms remains constant if the system is isolated so that it neither receives nor gives out energy; in the case of transfer of energy the total gain or loss from the system is equal to the loss or gain outside the system. The sum of the kinetic, potential and heat energy during an interval of time is, by the principle of conservation of energy, equal to the energy delivered to the system during that interval. In the electrical system of Fig. 1, there are three forms of energy, namely, kinetic, potential, and heat energy.

In the following derivations, the symbol, ϵ , is used for the base of natural logarithms, to avoid confusion with electromotive force, e .

Kinetic Energy. The kinetic energy T_{KE} stored in the magnetic field of the electrical circuit is

$$T_{KE} = \frac{1}{2} Li^2 \quad (1)$$

where L is the inductance, in abhenries, and i is the current through the inductance L , in abamperes.

Potential Energy. The potential energy V_{PE} stored in the electrical capacitance of the electrical circuit is

$$V_{PE} = \frac{1}{2} \frac{q^2}{C_E} \quad (2)$$

where C_E is the capacitance, in abfarads, and q is the charge on the capacitance, in abcoulombs.

Kinetic and Potential Energy. The total energy stored in the system is

$$W_E = T_{KE} + V_{PE} = \frac{1}{2} Li^2 + \frac{1}{2} \frac{q^2}{C_E} \quad (3)$$

The rate of change of energy in the system is

$$\frac{dW_E}{dt} = Li \frac{di}{dt} + \frac{q\dot{q}}{C_E} = Lq\dot{q} + \frac{q\dot{q}}{C_E} \quad (4)$$

Dissipation of Energy. The rate at which electromagnetic energy D_E is converted into heat is

$$D_E = r_E i^2 \quad (5)$$

where r_A is the electrical resistance, in abohms, and i is the current, in abamperes.

Equation of Motion. The power delivered to the system must be equal to the rate of kinetic energy storage plus the rate of potential energy storage plus the power loss due to dissipation. The rate at which work is done or power delivered to the electrical system by the applied electromotive force is $\dot{q}E\epsilon^{j\omega t} = e\dot{q}$.

The rate of increase of energy ($T_{KE} + V_{PE}$) of the system plus the rate at which work is done on the system or power delivered to the system by the external forces must be equal to the rate of dissipation of energy D_E . Writing this sentence mathematically yields the equation of motion for the electrical system of Figure 1.

$$Lq\dot{q} + r_E \dot{q}^2 + \frac{q\dot{q}}{C_E} = E\epsilon^{j\omega t} \dot{q} \quad (6)$$

$$L\dot{q} + r_E \dot{q} + \frac{q}{C_E} = E\epsilon^{j\omega t} \quad (7)$$

Solution of Equation of Motion. The steady state solution of the differential Equation 7 is

$$\dot{q} = i = \frac{E\epsilon^{j\omega t}}{r_E + j\omega L - \frac{j}{\omega C_E}} = \frac{e}{z_E} \quad (8)$$

Electrical Impedance. From Equation 8 the vector electrical impedance z_E in abohms, is

$$z_E = r_E + j\omega L - \frac{j}{\omega C_E} \quad (9)$$

Electrical Reactance. Electrical reactance x_E is the imaginary part of the electrical imped-

ance z_E , of Equation 9. The electrical reactance x_E , in abohms, is

$$x_E = \omega L - \frac{1}{\omega C_E}. \quad (10)$$

Response. The response of the electrical system of Figure 1 can be obtained from Equation 8. The response is the current i , in abamperes, for a constant applied voltage e , in abvolts. A typical response frequency characteristic is shown in Figure 2.

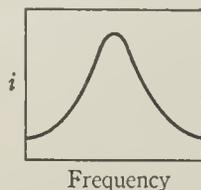

Fig. 2. Response frequency characteristic of the electric(al) system of Fig. 1.

Resonant Frequency. For a certain value of L and C_E , there will be a certain frequency at which the imaginary component of the electrical impedance is zero. This frequency is called the resonant frequency. At this frequency the ratio of the current to the applied voltage is a maximum. At the resonant frequency the current and voltage are in phase. The resonant frequency f_r , in cycles per second, is given by

$$f_r = \frac{1}{2\pi\sqrt{LC_E}}. \quad (11)$$

Power. The power P_E , in ergs per second, dissipated in the electrical system of Figure 1 is given by

$$P_E = r_E i^2. \quad (12)$$

ELECTROACOUSTICAL RECIPROcity THEOREM. See reciprocity theorem, electroacoustical.

ELECTROCHEMICAL CELL. The essential characteristic of an electrochemical cell is that a chemical process involving ions can take place in it in such a manner that the process is accompanied by a transfer of charge from one terminal to the other. (See **electromotive force**.)

ELECTROCHEMICAL POTENTIAL. The expression

$$\mu_i = \mu_i + z_i \mathfrak{F} \phi \quad (1)$$

is called the electrochemical potential. It consists of the ordinary **chemical potential**

μ_i , and the electrical part $z_i \mathfrak{F} \phi$, z_i is the charge number (see **electroneutrality**), ϕ , the electrostatic potential and \mathfrak{F} , the Faraday ($= 0.9649 \times 10^5$ coulombs, the electrical charge associated with one gram of a species having a charge number 1).

The electrochemical potential determines the thermodynamic equilibrium between phases α and β at different electric potentials and having different compositions. At equilibrium we have for all components i which may be transferred from α to β ,

$$\mu_i^\alpha = \mu_i^\beta \quad (2)$$

ELECTRODYNAMICS, MINKOWSKI. See Minkowski electrodynamics.

ELECTRODYNAMICS, QUANTUM. See quantum electrodynamics.

ELECTROKINETIC (ZETA) POTENTIAL. The difference in potential between the immovable liquid layer attached to the surface of a solid phase and the movable part of the diffuse layer in the body of the liquid.

ELECTROLYTES, STRONG. See limiting law for strong electrolytes.

ELECTROMAGNETIC CONSTANT. The speed of propagation of electromagnetic waves in a vacuum, commonly denoted by c . A long history of direct measurements culminated in the method which was perfected and refined by Michelson and others. Michelson's final value (1930) was 299,772 kilometers per sec. The most probable value, as of 1941, is given by Birge as 299,776 kilometers per sec. Later experiments using microwaves and other techniques indicate that 299,793 kilometers per sec is a better value.

ELECTROMAGNETIC DRIVING SYSTEM. See driving system, electromagnetic.

ELECTROMAGNETIC FIELD. According to the behavior of electric and magnetic fields described by the **Maxwell equations**, a time-varying **electric field** is always accompanied by a **magnetic field**, and conversely, a time-varying magnetic field is accompanied by an electric field. The **field of force** associated with these coupled electric and magnetic effects is called an electromagnetic field, and is considered to have an objective existence in space apart from the electric or magnetic

sources which may be considered to have generated it.

ELECTROMAGNETIC FIELD QUANTIZATION. See **quantization of electromagnetic field**.

ELECTROMAGNETIC FIELD TENSOR.

In terms of the covariant four-vector potential $\phi_i = (-c\mathbf{A}, \phi)$, the covariant electromagnetic field tensor is defined by

$$F_{ij} = \frac{\partial\phi_j}{\partial x^i} - \frac{\partial\phi_i}{\partial x^j}.$$

In terms of electric and magnetic field quantities, this antisymmetric tensor takes the form

$$F_{ij} = \begin{pmatrix} 0 & -cB_z & cB_y & -E_x \\ cB_z & 0 & -cB_x & -E_y \\ -cB_y & cB_x & 0 & -E_z \\ E_x & E_y & E_z & 0 \end{pmatrix}.$$

The corresponding contravariant tensor F^{ij} is obtained by changing the signs of the elements in the fourth row and fourth column.

ELECTROMAGNETIC FIELD, TRANSFORMATION EQUATIONS FOR. The Lorentz transformation equations for the electric and magnetic fields, \mathbf{E} and \mathbf{B} , are

$$\mathbf{B}'_{\parallel} = \mathbf{B}_{\parallel}$$

$$\mathbf{B}'_{\perp} = \gamma \left(\mathbf{B}_{\perp} - \frac{\mathbf{v} \times \mathbf{E}}{c^2} \right)$$

$$\mathbf{E}'_{\parallel} = \mathbf{E}_{\parallel}$$

$$\mathbf{E}'_{\perp} = \gamma (\mathbf{E}_{\perp} + \mathbf{v} \times \mathbf{B}),$$

where, for example, \mathbf{B}_{\parallel} and \mathbf{B}_{\perp} represents the components of \mathbf{B} parallel and perpendicular respectively to the direction of the velocity vector \mathbf{v} , and $\gamma = (1 - v^2/c^2)^{1/2}$.

When these transformed fields are used in Maxwell's equations, these equations are relativistically invariant.

ELECTROMAGNETIC GENERATING SYSTEM. See **generating system, electromagnetic**.

ELECTROMAGNETIC INDUCTION. See **Faraday law of electromagnetic induction**.

ELECTROMAGNETIC MASS. A charged particle in motion is accompanied by an elec-

tromagnetic field having a certain **electromagnetic momentum**. A force acting on the particle must change not only the momentum of the "bare" mechanical mass, but also the momentum of the electromagnetic field associated with the charge. The contribution of this latter effect to the total inertia of the particle is expressible as an **electromagnetic mass**.

ELECTROMAGNETIC MOMENTUM. See **energy-momentum tensor**.

ELECTROMAGNETIC RADIATION. The **electromagnetic field** associated with variable current and charge systems can generally be resolved into several components, each falling off with distance from the source according to a different power of distance R . (See the discussion under **field, radiation**.) The radiation field, which falls off as $1/R$, is the only component that contributes to the integral of the **Poynting vector** at large distances. It is this property of the electromagnetic field that is usually referred to as **electromagnetic radiation**.

ELECTROMAGNETIC RECIPROCITY THEOREM. See **reciprocity theorem, electromagnetic**.

ELECTROMAGNETIC SPECTRUM. The ordered array of all known electromagnetic radiations, extending from the shortest gamma rays, through x-rays, ultraviolet radiation, visible radiation, infrared radiation, and including microwave and all other wavelengths of radio energy.

The division of this continuum of wavelengths (or frequencies) into a number of named subportions is rather arbitrary and, with one or two exceptions, the boundaries of the several subportions are only vaguely defined.

ELECTROMAGNETIC STRESS. The **energy-momentum tensor** T_{ik} may be viewed as a **stress tensor** for the electromagnetic field of forces. If the forces between, say, two isolated charges are considered to be transmitted through the intervening space, then this space must be in a state of **stress** in the sense that the electromagnetic forces are transmitted across any element of surface located in it. From this point of view, the component dF_i of the force $d\mathbf{F}$ transmitted across a surface element

$d\mathbf{S}$ whose component in the k^{th} direction is dS_k is given by

$$dF_i = \sum_{k=1}^3 T_{ik} dS_k.$$

ELECTROMAGNETIC UNITS. At least eight or ten different systems of electrical and magnetic units are in common use. Each of these is based on a particular choice of a constant of proportionality in an experimentally verified physical law. Some systems start with Coulomb's law, which states that the force, f , between two electrical charges, q_1 and q_2 , separated by a distance r in empty space is directly proportional to the product of the charges and inversely proportional to the square of the distance between them, i.e.:

$$f = K_e q_1 q_2 / r^2,$$

where K_e is a constant that may be chosen for convenience. Such systems are known as electrostatic systems. The choice of K_e as unity and dimensionless, together with the use of the dyne and the centimeter as units of force and length, leads to the *cgs electrostatic system* in which the unit of charge, the *statcoulomb*, is the charge which repels an exactly similar charge, separated from it by one centimeter *in vacuo*, with a force of one dyne. This system is frequently called the *esu system*. Another choice, which is sometimes convenient, takes K_e as a dimensionless constant equal to $1/4\pi$. This leads to the *rationalized cgs electrostatic system*. In either of the two systems, charge has the dimensions of $\text{dyne}^{1/2} \text{cm}$, equivalent to $\text{cm}^{3/2} \text{gm}^{1/2} \text{sec}^{-1}$. All other electrical quantities also have identical dimensions in the two systems, although the sizes of their units differ.

In distinction to the electrostatic systems are the *electromagnetic systems* (emu systems), which start with the law of attraction between currents. If two currents of magnitudes I_1 and I_2 flow in long parallel wires, separated by a distance d *in vacuo*, they attract each other with a force per unit length, f_l , given by

$$f_l = K_m I_1 I_2 / d.$$

Here the constant of proportionality, K_m , may be chosen quite arbitrarily. The *cgs emu system* is based on the dyne and the centimeter as units of force and length and on the choice of K_m as a dimensionless constant of magni-

tude two. The emu of current, the *abampere*, then has the dimensions of $\text{dyne}^{1/2}$, or $\text{cm}^{1/2} \text{gm}^{1/2} \text{sec}^{-1}$.

The emu of charge, the *abcoulomb*, is defined as the charge which passes a given surface in one second if a steady current of one abampere flows across the surface. Its dimensions are therefore $\text{cm}^{1/2} \text{gm}^{1/2}$, which differ from the dimensions of the *statcoulomb* by a factor which has the dimensions of a speed. This relationship is connected with the fact that the ratio $2 K_e / K_m$ must have the value of the square of the speed of light in any consistent system of units. It follows further that

$$1 \text{ abcoulomb} = 2.998(10)^{10} \text{ statcoulomb},$$

the speed of light in *vacuo* being $2.998(10)^{10}$ cm/sec.

A *rationalized emu system*, in which K_m is taken as $1/2\pi$, has also been developed, but it is not widely used.

The electrostatic system is convenient for problems in which the principal equations may be deduced from Coulomb's law. Similarly, the electromagnetic system is convenient for problems involving the interactions between currents. In many physical problems, both electrical and magnetic interactions take place. Both systems suffer from certain inconveniences under the circumstances, and the *Gaussian system* of units has, as a result, gained wide popularity. In this system, magnetic quantities, such as magnetic field strength and magnetic flux density, are expressed in emu, while electric field strength, charge, and current are expressed in esu. To maintain self-consistency, it is essential that a factor c , the speed of light, be introduced into many of the equations which describe electromagnetic phenomena.

In all of the systems discussed thus far, *cgs mechanical units* have been employed. New systems of electrical units evolve if other sets of mechanical units are substituted. Only two such systems, both based on the *mks mechanical units*, have found wide acceptance. Of these two, only the *rationalized mksa system* is given here. The arbitrary choice which leads to this system is that of the unit of current. The *absolute ampere* is defined as exactly one-tenth of an abampere. With this choice, and with the newton and the meter as the units of force and length, the two constants which were chosen arbitrarily in the esu and

RELATIONS AMONG THE SYSTEMS OF ELECTRICAL AND MAGNETIC UNITS

emu systems are determined and have dimensions. They become:

$$K_e = 8.986(10)^9 \text{ km}^3\text{s}^{-4}\text{a}^2,$$

and

$$K_m = 2.000(10)^{-7} \text{ kms}^{-2}\text{a}^2.$$

One virtue of the mksa system is that nearly all of the electrical quantities expressed in it coincide closely with the *practical system* of units which grew up during the nineteenth century. Thus the volt, the ampere, the henry, the farad, and the ohm are all units in the mksa system. In fact, the legal electrical units have been fixed by international agreement since 1950 as the absolute mksa units. Prior to that time, the *International system* of electrical units had been used. This system had been intended to coincide with the absolute system, but had been defined in terms of fixed standards, which are slightly in error. There are therefore small differences between the two sets of electrical quantities, of the order of a few parts in ten thousand. Because many quantities stated in the literature are expressed in international units, these obsolescent definitions are included here.

One more remark needs to be made in regard to the dimensions of certain electromagnetic units. Two electrical quantities, the field strength \mathbf{E} and the displacement \mathbf{D} , are closely related, as are two magnetic quantities, the field strength \mathbf{H} and the flux density \mathbf{B} . In the electrostatic system, \mathbf{E} and \mathbf{D} have the same dimensions and are identical in magnitude in empty space; in the electromagnetic system, \mathbf{H} and \mathbf{B} have a corresponding relation. Thus in air, the electrical properties of which are practically those of empty space, the flux density is identical with the magnetic field strength if both are expressed in emu. The old unit of field strength, the *gauss*, has therefore been used to denote both \mathbf{H} and \mathbf{B} . In an attempt to avoid confusion, the name of the emu unit of \mathbf{H} was changed to the *oersted* about 30 years ago. The gauss had become so well established, however, that it is still used, and its meaning (either oersted or maxwell per square cm) must be judged from context.

The relations among the five systems of electrical units discussed are displayed in the table on page 297.

ELECTROMAGNETIC WAVES. Waves characterized by varying electric and mag-

netic fields. By differentiating Maxwell's equations and substituting from one equation to the other, the electric and the magnetic field vectors can be separated and each shown to satisfy the **wave equation**. Its solution is an electromagnetic wave. (See **electromagnetic spectrum**).

ELECTROMAGNETISM. A term generally used in reference to the generation of magnetic fields by electric currents. (See **Ampère law**, **Biot-Savart law** and **Maxwell equations**.)

ELECTROMOTIVE FORCE. Because of energy losses, a conservative electrostatic field cannot support a steady current. In order to account for steady currents, a non-conservative field having its origin in sources known as electromotive forces must be introduced. The electromotive force \mathcal{E} acting in a closed circuit may be defined as

$$\mathcal{E} = \oint \mathbf{E}' \cdot d\mathbf{l}$$

where \mathbf{E}' represents the non-conservative fields. Such fields can be produced by diffusion of ions in an electrolyte, for example, or by changing the magnetic flux through a circuit. (Cf. **Faraday law of electromagnetic induction**.) If the circuit is opened, the potential difference between the terminals is equal to the total electromotive force in the circuit.

The electromotive force of an **electrochemical cell** is equal to the affinity (see **chemical affinity**) of the chemical change associated with a flow of electricity of one **faraday**.

ELECTROMOTIVE FORCE, AVERAGE. For an alternating voltage (with no d-c component) the average value is zero. The term is often misused to mean the average absolute emf:

$$\frac{1}{T} \int_0^T |\mathcal{E}| dt.$$

For a sine wave, this is $2/\pi$ times the peak value.

ELECTROMOTIVE FORCE, MOTIONAL. The **electromotive force** induced in a circuit by virtue of motion of the conductor across a magnetic field:

$$\mathcal{E} = \int \mathbf{v} \times \mathbf{B} \cdot d\mathbf{l},$$

where \mathbf{V} is the velocity of the conductor, \mathbf{B} is the magnetic flux density, and the integral extends over the length of the conductor, $d\mathbf{l}$ being an element of length.

ELECTRON. An elementary particle of rest mass $m_e = 9.107 \times 10^{-28}$ g and charge of 4.802×10^{-10} statcoulomb, and a **spin** of one-half unit, i.e., of $\hbar/2 = \hbar/4\pi$. Its charge may be positive or negative, although the term electron is commonly used for the negative particle, which is also called the negatron. The positive electron is called the **positron**.

ELECTRON AFFINITY. The electron affinity of an atom or of a molecule X is the energy evolved in the reaction:

or, conversely, it is the energy of ionization of the negative ion X^- . In the above definition, the atom or molecule, and the atomic or molecular ion, are assumed in their fundamental state and without kinetic energy. X and e are initially at rest at an infinite distance from one another.

ELECTRON(S), ANTIBONDING. See molecular orbital theory of valence.

ELECTRON, BONDING. See molecular orbital theory of valence.

ELECTRON CONCENTRATION. The ratio of the number of valence electrons to the number of atoms in a molecule. This quantity is useful in studying the intermetallic compounds, where it is correlated with the crystal structure.

ELECTRON CONFIGURATION. The totality of the orbitals of the single electrons in an atom or molecule. One writes the electron configuration symbolically by giving the quantum numbers corresponding to the different orbitals, and indicating the number of electrons in each orbital by a right hand superscript. The lowest electron configuration of the Na atom, for instance, is $1s^2 2s^2 2p^6 3s$, that of the B_2 molecule $(\sigma_g 1s)^2 (\sigma_u 1s)^2 (\sigma_g 2s)^2 (\sigma_u 2s)^2 (\pi_u 2p)^2$. For atoms, as a rule, only the orbitals of electrons outside closed shells are given, i.e., $3s$ in the above case. For molecules, closed shells of the separate atoms which, to a first approximation, are not affected by the molecule formation (see **building-up principle**) are indicated only by the symbols $K, L,$

etc. (see **electron shells in an atom**), i.e., $KK(\sigma_g 2s)^2 (\sigma_u 2s)^2 (\pi_u 2p)^2$. (For the lowest electron configurations of atoms see *American Institute of Physics Handbook*, McGraw-Hill, Inc., 1957, 7-14, 15. For the lowest electron configurations of molecules see G. Herzberg, *Molecular Spectra and Molecular Structure. I. Spectra of Diatomic Molecules*. D. Van Nostrand Company, Inc., Princeton, 1950, pp. 341 and 343.)

ELECTRON ENERGY (CLASSICAL). An electron of charge $-e$ (emu) moving from point x_1 to point x_2 in an electric field E (emu) loses potential energy or gains kinetic energy according to

$$U = -e \int_{x_1}^{x_2} E dx = -e(V_1 - V_2) \text{ ergs,}$$

where V_1 and V_2 are the potentials in emu at x_1 and x_2 respectively.

The kinetic energy of an electron moving with velocity v cm/sec is

$$U = m_0 c^2 \left[\frac{1}{1 - (v/c)^2} - 1 \right] \text{ ergs}$$

$$= \frac{1}{2} m_0 v^2 \left[1 + \frac{3}{4} \left(\frac{v}{c} \right)^2 + \frac{5}{8} \left(\frac{v}{c} \right)^4 + \dots \right] \text{ ergs,}$$

where m_0 stands for the **rest mass** of the electron in gram and c for the velocity of light in cm/sec.

The transverse mass m_t and the longitudinal mass m_l of an electron moving with velocity v are given by

$$m_t = \frac{m_0}{[1 - (v/c)^2]^{1/2}}; \quad m_l = \frac{m_0}{[1 - (v/c)^2]^{3/2}}.$$

ELECTRONEUTRALITY. If one describes the properties of electrolytic solutions in terms of ionic species, one has to take account of the fact that the concentrations of all species are not independent because the solution as a whole is neutral.

One generally uses the symbol z_i to denote the charge on an ion measured in units of the charge of a proton (for example, for Na^+ , $z = 1$; for La^{3+} , $z = 3$; for PO_4^{3-} , $z = -3$); z is also called the *charge number* of the ion.

If n_i is the number of moles of the ionic species i , the condition of electrical neutrality is

$$\sum_i z_i n_i = 0. \quad (1)$$

Alternatively if one uses the subscript $+$ to denote positively-charged ions or *cations* and $-$ to denote negatively charged ions or *anions*, then one may write (1) in the form

$$\sum_{+} z_{+}n_{+} = \sum_{-} z_{-}n_{-}. \quad (2)$$

ELECTRON GAS, DEGENERATE. See **degenerate electron gas**.

ELECTRONIC CHARGE, SPECIFIC. The ratio e/m of the electronic charge to the rest mass of the electron, i.e.,

$$e/m = 5.2731 \times 10^{17} \text{ esu g}^{-1}.$$

ELECTRONIC CONFIGURATION. See **electron configuration**.

ELECTRONIC EIGENFUNCTIONS OF MOLECULES. See **molecular eigenfunctions**.

ELECTRONIC ENERGY LEVELS OF A MOLECULE. The different electronic states of a molecule are characterized by certain quantum numbers and symmetry properties of their eigenfunctions. For diatomic and linear polyatomic molecules the orbital angular momentum Λ about the internuclear axis is defined and has the magnitude $\Lambda h/2\pi$, where Λ is the corresponding quantum number which can assume only integral values. Depending on whether $\Lambda = 0, 1, 2, \dots$, we distinguish $\Sigma, \Pi, \Delta, \dots$ states. For nonlinear molecules different types (species) of electronic states arise depending on the symmetry properties of the nuclear frame. For example, if the molecule has a single plane of symmetry there are two species of electronic energy levels, those whose eigenfunctions are symmetric with respect to that plane and those whose eigenfunctions are antisymmetric with respect to it. They are designated A' and A'' , respectively. For a molecule with two mutually perpendicular planes of symmetry there are four species which may be characterized by $++, --, +-, -+$ where the two signs indicate the behavior with respect to the two planes. These four species are designated $A_1, A_2, B_1,$ and B_2 , respectively.

Each electronic state has a multiplicity $(2S + 1)$ depending on the value of the quantum number S of the resultant electron spin of the molecule.

No general formulas for the energies of the

electronic states of a molecule can be given except for those states in which one electron is excited to orbitals of increasing principal quantum number n . In this case one has to a good approximation

$$T_e = A - \frac{R}{(n - a)^2}$$

where A is the ionization potential, R the Rydberg constant, and a the Rydberg correction. (See also **fine structure**, **Λ -type doubling**.)

ELECTRONIC GYROMAGNETIC RATIO. See **gyromagnetic ratio, electronic**.

ELECTRONIC SPECIFIC HEAT. According to classical statistics, the *free* electrons in a metal should contribute an amount $3Nk$ to the specific heat, where N is the number of electrons per unit volume and k is Boltzmann's constant. The observed contribution is very much smaller than this, and the reason for this is that quantum statistics must be applied. Sommerfeld has pointed out that the electrons should be treated as a **Fermi-Dirac gas** for which the specific heat per unit volume is given by

$$c_v = \frac{1}{2}\pi^2 NKT/T_F$$

where T_F is the **Fermi temperature**. The contribution is thus only $(\pi^2/6) (T/T_F)$ of the value predicted classically, and at ordinary temperatures this fraction is very small. At very low temperatures, the specific heat resulting from lattice vibrations is proportional to T^3 so that, as the absolute zero is approached, the electronic contribution to the specific heat becomes relatively more important.

ELECTRONIC SPECTRA OF MOLECULES. The electronic spectrum of a molecule corresponds to the (allowed) transitions between the vibrational and rotational sub-levels of different electronic states.

A transition between the electronic states i and k is allowed as dipole radiation if there is at least one component of the dipole moment $M_x, M_y,$ or M_z which has the same symmetry properties as the product of the electronic eigenfunctions $\psi_e^i \psi_e^{k*}$. The electronic selection rules therefore are of the same form as the vibrational selection rules. The symmetry of the products $\psi_e^i \psi_e^{k*}$ can be determined from tables given by H. Sponer and E. Teller, *Rev.*

Mod. Phys. 13, 75 (1941) or by G. Herzberg, in *Molecular Spectra and Molecular Structure, II. Infrared and Roman Spectra of Polyatomic Molecules*, D. Van Nostrand Co., Inc., Princeton, 1945, though the latter were originally prepared for vibrational transitions.

For diatomic and linear polyatomic molecules the selection rule

$$\Delta\Lambda = 0, \pm 1$$

results from the above general rule.

(a) *Vibrational structure.* The totality of vibrational transitions for a given electronic transition is a band system. The wave numbers of the bands of a band system are represented by the formula

$$\nu = \nu_e + G'(v'_1, v'_2, \dots) - G''(v''_1, v''_2, \dots)$$

or in the case of diatomic molecules

$$\nu = \nu_e + \omega'_e(v' + \frac{1}{2}) - \omega'_e x'_e(v' + \frac{1}{2})^2 + \dots - [\omega''_e(v'' + \frac{1}{2}) - \omega''_e x''_e(v'' + \frac{1}{2})^2 + \dots]$$

where $\nu_e = T'_e - T''_e$ is the origin of the band system.

Which vibrational transitions are possible and what intensities they have is determined by the integral

$$\int \psi'_v \psi''_v d\tau_v.$$

As long as the interaction of vibration and electronic motion is negligible the relative intensities of the various vibrational transitions are proportional to the square of this integral. Only those vibrational transitions are possible for which the product $\psi'_v \psi''_v$ is symmetric with respect to all symmetry operations permitted by the symmetry of the molecule.

(b) *Rotational structure.* The rotational structure of the individual vibrational transitions (bands) of an electronic transition is essentially the same as that of rotation-vibration bands (see **rotation-vibration spectra of molecules**) as long as there is no spin splitting (see **fine structure**). If spin splitting is present, additional selection rules apply; for example, for diatomic and linear polyatomic molecules, if N the angular momentum apart from spin is defined, one has

$$\Delta N = 0, \pm 1.$$

For Σ — Σ transitions $\Delta N = 0$ does not occur. For details about the formulas for the branches in such cases, see G. Herzberg, *Molecular*

Spectra and Molecular Structure, I. Spectra of Diatomic Molecules, 2d ed., D. Van Nostrand Company, Inc., Princeton, 1950.

ELECTRONIC TRANSITIONS, VIBRATIONAL SUM RULE FOR. See vibrational sum rule for electronic transitions.

ELECTRON-OPTICAL INDEX OF REFRACTION. The path of an electron is determined by **Fermat's principle** using the electron-optical index of refraction n where

$$m_0 c n = m s - e A \cos \chi$$

where m is the mass, m_0 the rest mass, e , the charge of the electron, s the image distance (from the image principal plane to the image plane) and χ is the angle between the path of the electron and the magnetic vector potential A .

ELECTRON-OPTICAL LENS EQUATION. The general lens equation in electron optics is

$$\frac{f_i}{\rho_i} - \frac{f_o}{\rho_o} = 1, \quad \frac{f_i}{f_o} = \sqrt{\frac{\phi_i}{\phi_o}}, \quad \frac{\rho_i}{\rho_o} = M \sqrt{\frac{\phi_i}{\phi_o}}$$

where ρ_o is the object distance (from object principal plane to object plane), f_o is the object-side focal length, ϕ_o is the object-side electric potential along the axis of symmetry, and ρ_i , f_i , ϕ_i are the corresponding image-side quantities; finally, M is the **magnification**.

ELECTRON ORBIT (CLASSICAL). An electron having a velocity of v cm/sec in a magnetic field of flux density B moves in a stable circular orbit of radius r cm, when acted upon by a force

$$F = -m_t v^2 / r,$$

where $m_t = \frac{m_o}{1 - (v/c)^2}$ is the transverse mass of the electron (m_o represents the **rest mass** of the electron, c the velocity of light).

The cyclotron condition therefore is given by

$$\frac{m_t v}{r} = e B,$$

where e is the electronic charge in emu.

$$r = 10^4 \frac{2m_t V}{e B} \text{ cm,}$$

where V is the electron velocity v expressed in equivalent volts. The periodic time of one

revolution of an electron in the cyclotron orbit is

$$T = \frac{2\pi m_t}{eB}.$$

ELECTRON ORBITS IN AN ATOM (BOHR ORBITS). In the Bohr-Sommerfeld model of the atom the electrons described circular and elliptical orbits about the atomic nucleus. These orbits are selected from the continuum of classically possible orbits by means of certain quantum conditions. For hydrogen and the hydrogen-like ions the major and minor axes of these orbits are

$$a = \frac{h^2}{4\pi^2\mu e^2} \frac{n^2}{Z} = \frac{a_0}{Z} n^2$$

$$b = \frac{h^2}{4\pi^2\mu e^2} \frac{nk}{Z} = \frac{a_0}{Z} nk.$$

Here n is the principal quantum number, taking on the values

$$n = 1, 2, 3, \dots,$$

and k the azimuthal quantum number which, for a given n , can take the values

$$k = 1, 2, \dots, n.$$

h stands for Planck's constant, e , for the electronic charge, and Z , for the atomic number.

$$\mu = \frac{mM}{m + M}$$

is the reduced mass of the electron (m and M , electronic and nuclear mass respectively).

The energy of the electron orbits, neglecting relativistic effects, is given, for hydrogen and hydrogen-like ions by

$$E_n = \frac{2\pi^2\mu e^4}{h^2} \frac{Z^2}{n^2} = \frac{RZ^2}{n^2} hc$$

where R is the **Rydberg constant**. For hydrogen and the hydrogen-like ions therefore the energy is the same for all Bohr orbits with the same principal quantum number n , independently of the value of the azimuthal quantum number k . (For the effect of relativity corrections, see **hydrogen fine structure**.)

In the more general case of an electron moving in the field of an atomic core (nucleus plus p electrons) the orbits are ellipses whose axes rotate uniformly about the center of

gravity (rosette motion). In this case the energy of the electron orbits varies with both the quantum numbers n and k , and is given by the expression

$$E_{n,k} = \frac{R(Z - p)^2}{(n + a)^2} hc,$$

where a is the so-called **Rydberg correction** which depends on the azimuthal quantum number k and which rapidly approaches zero with increasing value of k .

ELECTRON, PI (π -ELECTRON). See **wave function, pi (π)**.

ELECTRON RADIUS, CLASSICAL. A quantity given by the equation,

$$r_0 = \frac{e^2}{mc^2} = 2.81785 \times 10^{-13} \text{ cm},$$

where e and m are respectively the charge and mass of the electron and c is the velocity of light.

ELECTRONS, EQUIVALENT. See **equivalent electron**.

ELECTRON SHELLS IN AN ATOM. The group of energy levels (**orbitals, orbits**) of the single electrons in an atom characterized by the same principal quantum number n . The number of electrons in a shell with a certain n is limited by the **Pauli principle**. A shell containing the maximum possible number of electrons is called a closed shell. Traditionally shells with $n = 1, 2, 3, \dots$ are designated K, L, M, \dots shells. (Sometimes the subgroups with the same values for both the quantum numbers n and l are referred to as shells (or subshells), e.g., L_1 (sub)shell for $n = 2, l = 0$; L_2 (sub)shell for $n = 2, l = 1$.) In general, energy levels belonging to the same shell lie close together, while successive shells differ considerably in their energy.

ELECTRON, SIGMA (σ -ELECTRON). See **wave function, sigma (σ)**.

ELECTRON SPIN. The intrinsic angular momentum s of the electron, that is, the rotation about its own axis. s has the magnitude

$$\sqrt{s(s + 1)} (h/2\pi) = \frac{1}{2} \sqrt{3} (h/2\pi)$$

where $s = \frac{1}{2}$ is the corresponding quantum number.

The magnetic moment associated with the electron spin is

$$\mu_e = 0.92837 \times 10^{-20} \text{ erg gauss}^{-1}$$

or

$$1.001145358 \mu_o$$

where μ_o is the **Bohr magneton**.

The ratio of μ_e to μ_o , the anomalous electron moment correction, is given by

$$\mu_e/\mu_o = 1 + \frac{\alpha}{2\pi} - 2.973 \frac{\alpha^2}{\pi^2}$$

(α is Sommerfeld's fine structure constant).

The **gyromagnetic ratio** of the spinning electron is

$$g_s \approx 2$$

("double magnetism" of electron spin).

ELECTRON THEORY, DIRAC. See **Dirac electron theory**.

ELECTRON THEORY OF METALS. A theory considering the system of conduction electrons to be a nearly **degenerate Fermi-Dirac gas**. When there are no external forces or temperature gradients the Fermi-distribution of the electrons will give rise to the correct order of magnitude of the electronic specific heat.

If there are electric or magnetic fields acting on the metal, or if there is a temperature gradient, the distribution function $f(x, y, z; u, v, w)$ (x, y, z : position coordinates; u, v, w : velocity components) is found as a solution of the **Boltzmann equation**. The electrical conductivity σ and the thermal conductivity k are thus obtained by evaluating the electrical current j and heat current w from the equations

$$j_x = \int f(x, y, z; u, v, w) e u \, du \, dv \, dw$$

$$w_x = \int f(x, y, z; u, v, w) \frac{1}{2} m (u^2 + v^2 + w^2) u \, du \, dv \, dw,$$

where m is the mass of the electrons and e their charge, and using the definitions of σ and k .

ELECTRON-VOLT (e.v.). An energy unit widely used in atomic and molecular physics. 1 electron volt is the energy equal to the kinetic energy of an electron which has been accelerated through a potential difference of 1 volt, or

$$1 \text{ e.v.} = 1.60206 \times 10^{-12} \text{ ergs/molecule.}$$

A photon of energy 1 e.v. has the wavelength

$$\lambda' = 12397.7 \text{ \AA}$$

and the wavenumber

$$\nu = \frac{1}{\lambda} = 8066.0 \text{ cm}^{-1}.$$

ELECTROPHILIC AGENT. See **inductive effect**.

ELECTROSTATIC DRIVING SYSTEM. See **driving system, electrostatic**.

ELECTROSTATIC FIELD. An electric field produced by stationary charges. (See **electrostatics; electric field strength**.)

ELECTROSTATIC GENERATING SYSTEM. See **generating system, electrostatic**.

ELECTROSTATIC INTERACTIONS AND VALENCE THEORY. See **bond types; atomic bonds**.

ELECTROSTATICS. That branch of electromagnetism that deals with the effects of stationary (as opposed to moving) electric charges. The basic law of electrostatics is the **Coulomb law** (see entry following). Materials are conveniently classed into conductors and non-conductors. In the former, charges are free to move within the conductor and any charge placed on a conductor will so distribute itself over the surface that the electric field within the conductor is zero and so that the conductor is an equipotential. When an uncharged conductor is placed in an electric field, produced, for example, by a neighboring charged body, a separation of charge on the surface will occur. A charge placed on a non-conductor will remain where it was placed. No material is a perfect non-conductor, but may approximate one very closely. When a non-conductor is placed in an electric field, **electric dipoles** are induced within it.

Static electric charges may be built up on a body by friction, by electrostatic induction, and by other means.

ELECTROSTATICS, LAWS OF. The laws of electrostatics are expressed in terms of electric charges, q , charge densities $\rho = dq/dV$, electric field strengths $\mathbf{E} = \mathbf{F}/q$, and electrostatic potentials $\phi = -\int \mathbf{E} \cdot d\mathbf{s}$. The basic law

of electrostatics is the Coulomb law of force between charges:

$$\mathbf{F} = \frac{q_1 q_2 \mathbf{r}}{4\pi\epsilon_0 r^3},$$

with the resulting field due to a single point charge q :

$$\mathbf{E} = \frac{q\mathbf{e}_r}{4\pi\epsilon_0 r^2} \quad (\text{rationalized mksa units}),$$

where \mathbf{e}_r is a unit vector pointing in the direction of increasing \mathbf{r} . The field due to a number of discrete charges is the vector sum

$$\mathbf{E} = \frac{1}{4\pi\epsilon_0} \sum_i \frac{q_i(\mathbf{e}_r)_i}{r_i^2},$$

while that due to a continuous distribution of charges is

$$\mathbf{E} = \frac{1}{4\pi\epsilon_0} \int \frac{\rho\mathbf{e}_r dV}{r^2}.$$

The potential at some point in space due to a single point charge, referred to an origin of potential at infinity, is $\phi = q/4\pi\epsilon_0 r$, while the potentials respectively due to a number of discrete charges or to a continuous distribution of charges are

$$\phi = \frac{1}{4\pi\epsilon_0} \int \frac{\rho dV}{r} \quad \text{and} \quad \phi = \frac{1}{4\pi\epsilon_0} \sum_i \frac{q_i}{r_i^2},$$

again referred to an origin of potential at infinity. If the potential function ϕ has been determined, then the electric field may be determined from $\mathbf{E} = -\nabla\phi$ where $\nabla\phi$ is the gradient of ϕ . Alternatively, if the field \mathbf{E} has been determined, the potential ϕ may be obtained from $\phi = \int_{\infty}^R \mathbf{E} \cdot d\mathbf{s}$.

The basic law of electrostatics, the Coulomb law, may alternatively be expressed either as the **Gauss law** or as the **Poisson equation**. In the absence of local charges, the Poisson equation reduces to the special case of the Laplace equation.

The electrostatic field is a conservative field, which leads to the fact that it is possible to set up a potential function ϕ . This fact may be alternatively stated in terms of the closed line integral $\oint \mathbf{E} \cdot d\mathbf{s} = 0$, or in terms of the curl of \mathbf{E} : $\nabla \times \mathbf{E} = 0$.

ELECTROVALENT BOND. See **heteropolar bond**.

ELEMENT. (1) A quantity identified by two symbols designating a row and column in an array, such as a **matrix** element or an element of a **determinant**. (See also **integral**, **line**, etc.) (2) A collection of atoms of one type which cannot be decomposed into any simpler units by any chemical transformation. To date 102 different elements are known; these may be grouped into an ascending series according to the nuclear charge; some elements (those in the so-called radioactive series) spontaneously decompose into simpler elements; radioactive decomposition can be induced artificially where it does not occur in nature and for each element there is known a number of isotopes, i.e., atoms with the same nuclear charge but different nuclear masses which may vary within certain limits. There are also instances in which atoms have the same nuclear charge and nuclear mass, but differ only in nuclear energetics, and hence stability and behavior. (3) In network topology, an **edge**. (4) Any electrical device with terminals at which it may be directly connected to other electrical devices. (5) An integral part of a device (e.g., of an electron tube or a semiconductor) which contributes to its operation. (6) A parameter in an acoustical system which defines a distinct activity in its part of the system.

ELEMENTARY. The elementary operations on a **matrix** consist of the interchange of two rows (or columns), the multiplication of a row (or column) by a constant and the addition to any one row (or column) of any multiple of a different row (or column).

The elementary **functions** are the algebraic functions (that is, functions $y = f(x)$ defined by an algebraic equation in x and y) and the exponential functions (of the form $y = e^{f(x)}$) and their inverses (logarithmic functions). Since, for example, $2 \cos x = e^{ix} + e^{-ix}$, the trigonometric functions are included, as well as combinations of the above functions. The derivative of an elementary function is always an elementary function, but not every elementary function can be so obtained. Examples of non-elementary functions are the **gamma function**, **Bessel's functions**, etc.

ELEMENTARY SYSTEM. A system whose manifold of states constitutes a representation space for an irreducible representation of the **inhomogeneous Lorentz group**. Equivalently,

all the states of the system can be obtained from the Lorentz transforms of any *one* state by superposition. In other words, there exists no relativistically invariant distinction between the various states of the system. Elementary systems are of particular interest because they have the transformation properties of what is usually called a particle, e.g., a proton or α -particle.

ELEMENT, CIRCUIT. An **element** of a **graph** G which is contained in some **circuit** of G .

ELEMENT, NON-CIRCUIT. An **element** of a **graph** G which is not contained in a **circuit** is a non-circuit element of G . The removal of a non-circuit element from a **connected** graph G leaves G unconnected. The removal of a circuit element leaves the connectivity and the number of **vertices** invariant.

ELEMENT, ORIENTED. An oriented element of a **graph** is an **element** with an orientation assigned by ordering the **vertices** of the element. If the vertices β_1 and β_2 of element ϵ_1 are ordered as (β_1, β_2) , ϵ_1 is said to be oriented away from β_1 and toward β_2 .

ELEMENTS, CONJUGATE. See **conjugate elements of a group**.

ELEMENTS OF SYSTEM. See **indicial notation**.

ELIMINATION. A method of solving a system of equations in which one of the equations is solved for one of the unknowns in terms of the others, and the solution used to replace this unknown in all the other equations. Thus if the original system was one of n equations in n unknowns, one obtains a new system of which $n - 1$ of the equations contain only $n - 1$ of the unknowns.

ELLIPSE. A **conic section** obtained by a cutting plane parallel to no element of a right-circular conical surface. It is the **locus** of a point which moves so that the sum of its distances from two foci is a constant. Its eccentricity (see **conic section**) is less than unity. The standard equation may be taken as $x^2/a^2 + y^2/b^2 = 1$. The curve is a central conic for it is symmetric about both the X - and Y -axes. When placed in its standard position, the center of the ellipse is the coordinate origin, the major axis of length $2a$ is along

the X -axis, and the minor axis of length $2b$ is along the Y -axis. The distance from the center to either focus is $\sqrt{a^2 - b^2}$; the eccentricity e is given by $ae = \sqrt{a^2 - b^2}$; the length of the latus rectum is $2b^2/a$; the equations for the directrices are $x = \pm a/e$. The distance from any point on the ellipse to a focus is a focal radius and the sum of the two focal radii equals $2a$.

If the semi-major axis equals the semi-minor axis ($a = b$), the ellipse degenerates into a circle.

The polar equation of an ellipse is

$$r = \frac{a(1 - e^2)}{1 - e \cos \theta}$$

and its parametric equations are $x = a \cos \phi$, $y = b \sin \phi$.

ELLIPSE, GEODETIC. See **geodesic ellipse on a surface**.

ELLIPSOID. A **central quadric**, given in its standard form, with center at the coordinate origin, as

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1$$

where a, b, c are the semi-axes. Any plane section is an ellipse.

If two of the axes become equal, the surface is a spheroid, which can be generated as a surface of revolution. Consider an ellipse in the XZ -plane

$$\frac{x^2}{a^2} + \frac{z^2}{c^2} = 1$$

with $a > c$, so that its major axis is along the X -axis of the coordinate system and its minor axis along the Z -axis. There are then two possibilities: (1) rotate the ellipse about its major axis and the result is a prolate spheroid with $a > b = c$; (2) rotate about the minor axis and obtain an oblate spheroid, $a = b > c$.

In the final degenerate case, $a = b = c$, the surface is a **sphere**.

ELLIPSOIDAL COORDINATES. A system of coordinates λ, μ, ν based on confocal quadrics. If constants a, b, c are taken with $a > b > c$, the surfaces are: (1) **ellipsoids**, $\lambda = \text{const.}$, $c^2 > \lambda > -\infty$; (2) **hyperboloids** of one sheet, $\mu = \text{const.}$, $b^2 > \mu > c^2$; (3) **hyperboloids** of two sheets, $\nu = \text{const.}$, $a^2 > \nu > b^2$.

The relation between the rectangular Cartesian coordinates and the ellipsoidal coordinates of a point are

$$x^2 = \frac{(a^2 - \lambda)(a^2 - \mu)(a^2 - \nu)}{(b^2 - a^2)(c^2 - a^2)}$$

$$y^2 = \frac{(b^2 - \lambda)(b^2 - \mu)(b^2 - \nu)}{(a^2 - b^2)(c^2 - b^2)}$$

$$z^2 = \frac{(c^2 - \lambda)(c^2 - \mu)(c^2 - \nu)}{(a^2 - c^2)(b^2 - c^2)}$$

Since x, y, z occur as squares in these relations they give eight points symmetrically located in the Cartesian system. Some convention must then be adopted for the signs of the ellipsoidal coordinates in order to locate a point uniquely.

Most of the curvilinear systems used in mathematical physics (including rectangular and spherical polar coordinates) are degenerate cases of the ellipsoidal system.

ELLIPSOID, MOMENTAL (ELLIPSOID OF POINSON). For a rotating body with no resultant external torque acting on it

$$\boldsymbol{\omega} \cdot \mathbf{H} = 2T$$

where \mathbf{H} is the vector angular momentum, $\boldsymbol{\omega}$ is the resultant vector angular velocity and T is the total kinetic energy. When expressed in component form, this becomes the equation of an ellipsoid in angular velocity space.

$$I_{xx}\omega_x^2 + I_{yy}\omega_y^2 + I_{zz}\omega_z^2 = 2T.$$

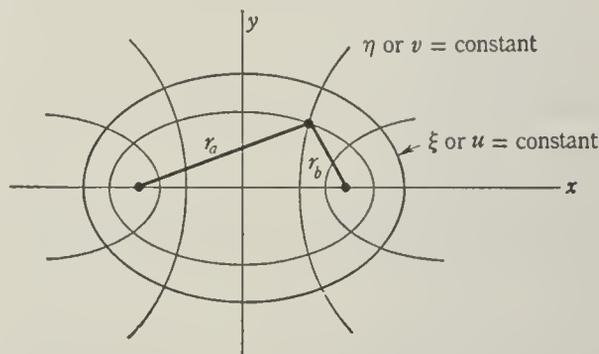

I_{xx}, I_{yy} and I_{zz} are the moments of inertia with respect to the principal axes fixed in the body. $\omega_x, \omega_y, \omega_z$ are the components of angular velocity with respect to the principal axes fixed in the body. The length of the radius vector from the origin to the surface of the ellipsoid represents a value of the angular speed consistent with the total kinetic energy and angular momentum. (See inertia, moments and products of; rigid body, kinetic energy of.)

ELLIPSOID, POLARIZABILITY. See polarizability.

ELLIPTICAL COORDINATES. A plane, two dimensional, coordinate system in which the coordinate curves are the mutually orthogonal sets of confocal ellipses and hyperbolas. The transformation equations are, with the foci at $x = \pm a, y = 0$:

$$x = a \cosh u \cos v,$$

$$y = a \sinh u \sin v.$$

Alternatively, the two coordinates $\xi = \cosh u$ and $\eta = \cosh v$ may be used, in which case the following hold:

$$\xi = \frac{r_A + r_B}{2a}, \quad \eta = \frac{r_A - r_B}{2a}.$$

These coordinates are useful in some two-center problems of physics.

ELLIPTICALLY LOADED WING. A wing for which the distribution of circulation across the span is given by

$$\Gamma = \Gamma_0 [1 - (y/s)^2]^{1/2}, \quad (1)$$

where s is the semi-span and y is measured from the mid-span position.

With this type of loading the induced angle of downwash, due to the trailing vortices, is constant across the span. The coefficient of trailing-vortex drag has the minimum value $\frac{C_L^2}{\pi A}$, for given values of the lift coefficient C_L and aspect ratio A .

(See also **lifting-line theory**.)

ELLIPTICALLY POLARIZED WAVE. See polarization cycle.

ELLIPTIC CYLINDRICAL COORDINATES. A degenerate case of ellipsoidal coordinates where the coordinate surfaces are: (1) elliptic cylindrical with semi-axes $a = c \cosh u, b = c \sinh u, u = \text{const.}$; (2) hyperbolic cylindrical with $a = c \cos v, b = c \sin v, v = \text{const.}$; (3) planes parallel to the XY -plane, $z = \text{const.}$ A point in this system has rectangular Cartesian coordinates

$$x = c \cosh u \cos v$$

$$y = c \sinh u \sin v$$

$$z = z$$

and $0 \leq u \leq \infty$; $0 \leq v \leq 2\pi$; $-\infty < z < \infty$.

ELLIPTIC FUNCTION. A single-valued, doubly-periodic, meromorphic function of a complex variable. The functions which are inverses of **elliptic integrals** are elliptic functions. Elliptic functions satisfy many of the non-linear differential equations arising in mathematical physics.

ELLIPTIC INTEGRAL. Any integral of the type

$$\int f(x, \sqrt{R}) dx,$$

where f is a rational function of its two arguments and R is a third or fourth degree polynomial in x , with no repeated roots. It may be reduced, by suitable change of variable, to a sum of elementary integrals and one or more of the following types:

$$u_1 = \int_0^x \frac{dt}{\sqrt{(1-t^2)(1-k^2t^2)}}$$

$$= \int_0^\phi \frac{dw}{\sqrt{1-k^2 \sin^2 w}}$$

$$u^2 = \int_0^x \sqrt{\frac{1-k^2t^2}{1-t^2}} dt = \int_0^\phi \sqrt{1-k^2 \sin^2 w} dw$$

$$u_3 = \int_0^x \frac{dt}{(t^2-a)\sqrt{(1-t^2)(1-k^2t^2)}}$$

$$= \int_0^\phi \frac{dw}{(\sin^2 w - a)\sqrt{1-k^2 \sin^2 w}}.$$

These are incomplete elliptic integrals of the first, second, third kind, respectively. When expressed in terms of $t = \sin w$, they are Legendre's normal forms. The constant k ($0 < k^2 < 1$) is the modulus and a is an arbitrary constant. If $\phi = \pi/2$, the integrals are called complete.

Series evaluation of the elliptic integrals may be made and numerical tables for them are available. They are called elliptic because they were first studied in order to determine the circumference of the ellipse. Their properties are best studied in terms of their inverse functions.

ELLIPTIC PARABOLOID. See paraboloid.

ELLIPTIC PARTIAL DIFFERENTIAL EQUATION. Consider the general linear partial differential equation of second order with two independent variables,

$$A \frac{\partial^2 u}{\partial x^2} + 2B \frac{\partial^2 u}{\partial x \partial y} + C \frac{\partial^2 u}{\partial y^2} + D \frac{\partial u}{\partial x} + E \frac{\partial u}{\partial y} + F = 0$$

where the coefficients A, B, C, D, E, F are continuous functions of x, y . This equation, which includes the majority of the differential equations of physics, is said to be of *elliptic*, *hyperbolic* or *parabolic* type at a point x, y according as the discriminant $B^2 - AC$ is negative, positive, or zero. By a real transformation of variables it can be brought, respectively, into one of the following three forms,

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \dots \quad \text{elliptic}$$

$$\frac{\partial^2 u}{\partial x \partial y} + \dots \quad \text{hyperbolic}$$

$$\frac{\partial^2 u}{\partial x^2} + \dots \quad \text{parabolic}$$

where in each case the dots denote terms of lower order than the second in the derivatives of u . These concepts can easily be generalized for equations of higher order.

For an elliptic partial differential equation, it is customary, if the solution is to be well defined, to impose conditions along the boundary, such as the value of the dependent variable (Dirichlet condition), or its normal derivative (Neumann condition). In the simplest case, namely, the Laplace equation,

$$\nabla^2 \phi = 0,$$

the solution may be approximated by finite difference methods by representing the Laplace operator (also written $D_x^2 + D_y^2$) by $h^{-2}(\delta_x^2 + \delta_y^2)$ which gives rise to the coefficient scheme

$$\begin{array}{ccc} & & 1 \\ & \bullet & \\ & & \\ 1 & & -4 & & 1 \\ & & & & \\ & & & & 1 \end{array}$$

which is always implicit (see **matrix inversion**). (See also Lothar Collatz, *Numerische Behandlung von Differentialgleichungen*, 2nd edition, Springer, 1955; Kaiser S. Kunz, *Numerical Analysis*, McGraw-Hill Book Company, 1957.)

ELLIPTIC POINT (ON A SURFACE). A point at which the product of the principal curvatures of the surface (see **curvature of surface**, **radius of**) is positive.

ELONGATION OR EXTENSION. The increase in length of a line joining two points, especially the increase of the gauge length of a tension specimen.

ELONGATION QUADRIC. See **strain ellipsoid**.

EMAGRAM. A thermodynamic diagram, designed by A. Refsdal, with temperature as abscissa and the logarithm of pressure, increasing downward, as ordinate. Since work or energy in a cyclic process is expressible as

$$R \oint T \frac{dp}{p}$$

where T is temperature, p pressure, and R the gas constant, it is proportional to the area enclosed on the emagram by the curve representing the process. (See **skew T — log p diagram**.)

EMDEN EQUATION (EMDEN FUNCTION). Various models of the stars have been developed for various conditions. A number of polytropic models have been proposed, subject to the condition that pressure and density would be determined in accord with the adiabatic gas law

$$P = k\rho^\gamma.$$

One of the fundamental equations which a gaseous sphere in adiabatic equilibrium must satisfy is known as the Emden equation

$$\frac{1}{x^2} \frac{d}{dx} \left(x^2 \frac{dy}{dx} \right) + y^n = 0$$

in which n is defined by

$$\gamma = 1 + \frac{1}{n}.$$

Tables of Emden functions have been published by the British Association of Science for various values of the polytropic index n .

EMERGENT STEM CORRECTION. See **exposed stem correction**.

EMISSION COEFFICIENT. The emission coefficient ϵ_ν measures the energy emitted per second in the frequency range $d\nu$ by a volume element dV into the solid angle $d\omega$. The total energy per second emitted by a volume element is therefore

$$E = dV \int_0^\infty \int_\omega \epsilon_\nu d\nu d\omega.$$

ϵ_ν depends on the physical properties of the emitting substance, on the frequency ν , and, sometimes, on the direction of the flow of radiation.

The total energy per second emitted by a volume element may also be expressed in terms of wavelengths, as is the usage in certain other forms of emission functions, by the relationship

$$E = dV \int_0^\infty \int_\omega \epsilon_\lambda d\lambda d\omega$$

where ϵ_λ measures the energy emitted per second in the wavelength range $d\lambda$ by the volume element dV into the solid angle $d\omega$.

EMISSION SPECTRUM. See **spectrum**, **emission**.

EMISSIVE POWER. In radiation, energy emitted per unit time and area from a surface over the waveband spectrum. When the energy is computed at a given wavelength, it is called the **monochromatic emissive power**. I_λ , where

$$I_\lambda = \frac{dq}{d\lambda}.$$

(See **black body radiation**.)

EMISSIVITY. (More precisely, hemispheric emissivity.) The ratio of the radiant energy q emitted by a surface to that, q_b , emitted by a **black body** at the same temperature T ,

$$\epsilon = \frac{q}{q_b}.$$

The emissivity at one particular wavelength is called **monochromatic (hemispheric) emissivity**. The monochromatic emissivity of a surface is a function of the wavelength λ , the angle of emission ϕ , and the temperature T . (See also **spectral emissivity**; **total emissivity**.)

EMITTANCE. The radiant emittance of a source is the power radiated per unit area of the surface. This may be either the radiant emittance per unit range in wavelength, the spectral radiant emittance, or its integral over all wavelengths, the total radiant emittance. If the radiant emittance is evaluated by the **standard luminosity function**, it is called luminous emittance. For a perfectly diffusing surface, the luminous emittance is equal to π times the **luminance intensity**.

EMU SYSTEM OF UNITS. See **electromagnetic units**.

ENCASTRÉ BEAM. See **beam, fixed-ended**.

END MOMENT. See **moment, end**.

ENDOMORPHISM. See **homomorphism**.

ENDOTHERMIC REACTIONS. See **thermal coefficients**.

END-POINT METHOD. A method of approximation for treating the integral equations with displacement kernel, which appear in problems of **neutron transport theory** characterized by plane or spherical geometry. In this method, the solution near each boundary is treated as though no other boundary existed, in which case the integral equation is amenable to the Wiener-Hopf technique of solution. A complete solution is then obtained by combining the one-boundary solutions in such a way that their asymptotic values coincide.

ENDURANCE LIMIT. See **fatigue**.

ENERGY. Energy is often defined as the ability to do work. Thus, a capacitance of magnitude C , carrying a charge Q , possesses electrical energy in the amount $Q^2/2C$, and can do this much work in the process of being discharged. In this instance, the energy is considered to reside in the electric field between the plates of the capacitor. In other cases, e.g., that of kinetic energy (see **energy, kinetic**), the energy is considered to reside in the body itself. The mechanical or electrical energy of a system is always measured as the maximum amount of work that the system can do in coming to static equilibrium.

In thermodynamics, energy is a general term embracing heat, work (both being "energy in transition") and internal energy. Some authors tend to restrict the term energy to be synonymous with internal energy. In that

terminology, heat and work are distinct from energy and are not regarded as "forms of energy." The authors who use the term energy for internal energy tend to use the term "internal energy" in a more restricted sense too. In that terminology, internal energy means that part which describes the internal energy (in the wider sense) of a pure, homogeneous stable substance at rest in a constant (or very weak) gravitational, electric and magnetic field and free from surface tension.

In special relativity, energy and mass are equivalent, being connected by the Einstein equation $E = mc^2$ where c is the speed of light. Hence, when relativistic mechanics must be applied, e.g., when speeds comparable to c are involved, the energy of a system includes the rest energy m_0c^2 of all the bodies in the system. Here m_0 is the mass of a body at rest with respect to the other bodies of the system and to the observer.

Energy is particularly important because it is a conserved quantity, which can be neither created nor destroyed. It may, however, be exchanged among various bodies or may be converted from one form to another, or interconverted with mass as in the Einstein equation above. (See also **work; conservation of energy**.)

ENERGY, ACTIVATION. See **activation energy**.

ENERGY, BINDING. See **binding energy**.

ENERGY, CLASSICAL ELECTRON. See **electron energy (classical)**.

ENERGY, COHESION. The energy which would be required to break up a solid or liquid into its constituent atoms or molecules. The cohesion energy is often expressed as the energy per mole of a body of such extent that the surface energy is negligibly small.

ENERGY CONSERVATION. See **conservation of energy**.

ENERGY CONSERVATION IN CLOSED SYSTEMS. In closed systems and in the absence of an external field, the energy U supplied from the outside during the time interval dt is equal to the sum of the heat dQ and the mechanical work dW performed at the boundaries of the system. If the pressure is normal to the surface, the mechanical work is simply

$-pdV$ and the expression of the energy conservation becomes (see also **energy conservation in thermodynamics**)

$$dU = dQ - pdV. \quad (1)$$

From a purely phenomenological point of view (1) may be considered as the definition of the heat received by the system. The extension of the mechanical principle of conservation of energy to include the flow of heat is due mainly to Carnot, Joule, Helmholtz and Clausius.

ENERGY CONSERVATION IN CONTINUOUS SYSTEMS. In order to express the energy conservation in continuous systems, it is useful to introduce the energy density per unit volume

$$u_v = \frac{\delta U}{\delta V}. \quad (1)$$

In agreement with the general formulation of the principle of energy conservation (see **energy conservation in thermodynamics**) we shall have

$$\frac{\partial u_v}{\partial t} = -\operatorname{div} \Phi[U] \quad (2)$$

where $\Phi[U]$ is the energy flow. This flow contains in general different contributions, among which are

(1) the convection flow corresponding to a center of mass motion ω

$$u_v \omega \quad (3)$$

(2) a heat flow

$$\mathbf{Q} \quad (4)$$

(3) a flow of energy corresponding to the pressure tensor p_{ij} in the fluid, its i component being

$$\sum_j p_{ij} \omega_j \quad (5)$$

(4) a flow of potential energy (for example the **Poynting** flow of electromagnetic energy)

(5) a flow of energy related to diffusion.

The total energy U may be split into an internal energy, a potential energy and a macroscopic kinetic energy. Each contribution taken separately does no more satisfy an equation of the simple form (2), because of the possible transformation of one form of energy to another.

ENERGY CONSERVATION IN THERMODYNAMICS. The principle of conservation of energy plays in thermodynamics a fundamental role. It is therefore also called the first law of thermodynamics. (See **thermodynamics, first law of**.) In its most general form it postulates the existence of a function of state, called the internal energy of the system U , such that its change per unit time is equal to some flow, called the energy flow from the surroundings.

This statement can be expressed symbolically by the formula (see **conservation of mass in open systems**)

$$dU = d_e U \quad \text{or} \quad d_i U = 0 \quad (1)$$

$d_e U$ is the energy received during the time dt from the outside and $d_i U$ is the energy "creation" inside the system.

The explicit form of the energy flow depends on the nature of the system considered. (See **energy conservation in closed systems; energy conservation in continuous systems**.)

ENERGY, COULOMB. See **Coulomb energy**.

ENERGY DENSITY (ELECTROMAGNETIC). The energy required to set up electric and magnetic fields can be thought of as residing in the fields. The energy density is then the field energy per unit volume.

The energy required to set up an electric field, E , in space, or in an isotropic medium, is given, if rationalized units are used, by $\int \frac{1}{2} \epsilon E^2 d\tau$, where $d\tau$ is a volume element. The expression $\frac{1}{2} \epsilon E^2$ is the electric energy density.

Similarly, the energy required to set up a magnetic field, H , is $\int \frac{1}{2} \mu H^2 d\tau$, and the expression $\frac{1}{2} \mu H^2$ is the magnetic energy density. In an electromagnetic wave the instantaneous value of the energy density is $\frac{1}{2} \epsilon E^2 + \frac{1}{2} \mu H^2$ where E and H are the instantaneous magnitudes of the electric and magnetic fields.

For anisotropic media the terms ϵE^2 and μH^2 used above should be replaced by $\mathbf{E} \cdot \mathbf{D}$ and $\mathbf{H} \cdot \mathbf{B}$ respectively. If non-rationalized units are employed, the factor $\frac{1}{2}$ is replaced by $\frac{1}{8\pi}$.

ENERGY DENSITY SPECTRUM. (Sometimes called energy spectrum.) The square of the amplitude of the (complex) **Fourier transform** of an aperiodic function. Thus, if

$f(t)$ is the given function, its Fourier transform is

$$F(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} f(t)e^{-i\omega t} dt,$$

and the energy density spectrum is $|F(\omega)|^2$. It is assumed that the total energy

$$\int_{-\infty}^{\infty} |f|^2 dt$$

is finite. (See **power spectrum**.)

ENERGY, DISTORTION. See **distortion energy**.

ENERGY, DISTRIBUTION IN. See **distribution in energy**.

ENERGY EIGENFUNCTION. An **eigenfunction** of the **Hamiltonian operator**. The associated eigenvalue is often called the *energy eigenvalue*.

ENERGY EIGENSTATE. See **energy eigenfunction**.

ENERGY EQUATION FOR BOUNDARY LAYER. The energy equation for steady flow of an incompressible fluid in a two-dimensional boundary layer is

$$\frac{1}{2U^3} \frac{d}{dx} (U^3 \delta^{**}) = \frac{1}{\rho U^2} \int_0^{\delta} \tau \frac{\partial}{\partial y} \left(\frac{u}{U} \right) dy, \quad (1)$$

where δ^{**} is the energy thickness, τ is the shear stress, u is the local velocity at a distance y from the wall and U is the velocity outside the boundary layer, i.e., for $y > \delta$.

Equation (1) applies both to laminar and to turbulent boundary layers. The right-hand side represents, non-dimensionally, the rate at which energy is taken from the mean flow by the shear stresses, while the left-hand side represents the rate of increase of kinetic energy defect of the mean flow.

In the case of a laminar boundary layer,

$$\tau = \mu \frac{du}{dy},$$

so that Equation (1) may be written

$$\frac{1}{2} \frac{d}{dx} (U^3 \delta^{**}) = \frac{\mu}{\rho} \int_0^{\delta} \left(\frac{\partial u}{\partial y} \right)^2 dy. \quad (2)$$

ENERGY EQUATION FOR STEADY ADIABATIC FLOW. For any adiabatic gas flow,

i.e., with no heat transfer across the boundaries of a stream tube,

$$h + \frac{1}{2}v^2 = \text{constant}, \quad (1)$$

where v is velocity and h is specific enthalpy. For a perfect gas, Equation (1) becomes

$$C_p T + \frac{1}{2}v^2 = C_p T_o, \quad (2)$$

where T is the temperature, C_p is the specific heat at constant pressure, and suffix o refers to "stagnation" conditions (with $v = 0$).

Equation (2) may also be written in the alternative forms

$$\left(\frac{\gamma}{\gamma - 1} \right) \frac{p}{\rho} + \frac{1}{2}v^2 = \left(\frac{\gamma}{\gamma - 1} \right) \frac{p_o}{\rho_o} \quad (3)$$

or

$$\frac{a^2}{\gamma - 1} + \frac{1}{2}v^2 = \frac{a_o^2}{\gamma - 1}, \quad (4)$$

where a is the velocity of sound.

It should be noted that Equations (1) to (4) are valid even when viscous effects are important, e.g., in flow through a shock wave.

ENERGY, EQUIPARTITION OF. See **equipartition of energy**.

ENERGY, EXCITATION. See **excitation energy**.

ENERGY, FREE. See **free energy**.

ENERGY GAP. The energy gap ϵ_g is the minimum energy required to excite an electron from the normally filled **valence band** to the normally empty **conduction band**. For thermal equilibrium at temperature T the following relation enables ϵ_g to be determined:

$$np = 2.33 \times 10^{31} \left(\frac{m_n m_p}{m^2} \right)^{3/2} T^3 \exp(-\epsilon_g/kT)$$

where n and p are the number of electrons and the number of holes per cm^3 respectively, m_n and m_p are the effective masses of electrons and holes, m is the free electron mass, and k is Boltzmann's constant. The value of ϵ_g for exciting an electron from a valence band to a conduction band optically is generally higher than that for thermal excitation.

ENERGY INTEGRAL. The first integration of the **Newton equation of motion** $m\dot{\mathbf{r}} = \mathbf{F}$, in which \mathbf{r} is the position vector of the particle of mass m and \mathbf{F} is the resultant (vector) force acting in it, yields an integral of the form

$$\frac{1}{2}mv^2 - \int \mathbf{F} \cdot d\mathbf{r} = C$$

where v is the velocity at any instant and C is a constant of integration. This is usually called the energy integral, since $\frac{1}{2}mv^2$ is the kinetic energy. If \mathbf{F} is a conservative force

$-\int \mathbf{F} \cdot d\mathbf{r}$ depends only on the position of the particle and is therefore called the potential energy. The constant C becomes the total energy and the existence of the energy integral implies the conservation of mechanical energy.

ENERGY, INTERNAL. See internal energy.

ENERGY, IONIZATION. See ionization energy.

ENERGY, KINETIC. The scalar quantity or measure of the energy of motion is called kinetic energy. It is given by $\frac{1}{2}mv^2$ for a particle of mass m traveling with speed v , and by $\frac{1}{2}I_o\omega^2$ for a rigid body of moment of inertia I_o rotating about a fixed axis O with angular velocity ω . The kinetic energy for general motion of a rigid body is

$$\frac{1}{2}mv_c^2 + \frac{1}{2}I_{cx}\omega_x^2 + \frac{1}{2}I_{cy}\omega_y^2 + \frac{1}{2}I_{cz}\omega_z^2$$

where m is the total mass and x, y, z , are principal axes through the center of mass denoted by subscript c .

ENERGY, KINETIC, OF A MASS POINT. In classical mechanics it is $\frac{1}{2}m_o v^2$, but in relativistic mechanics it is

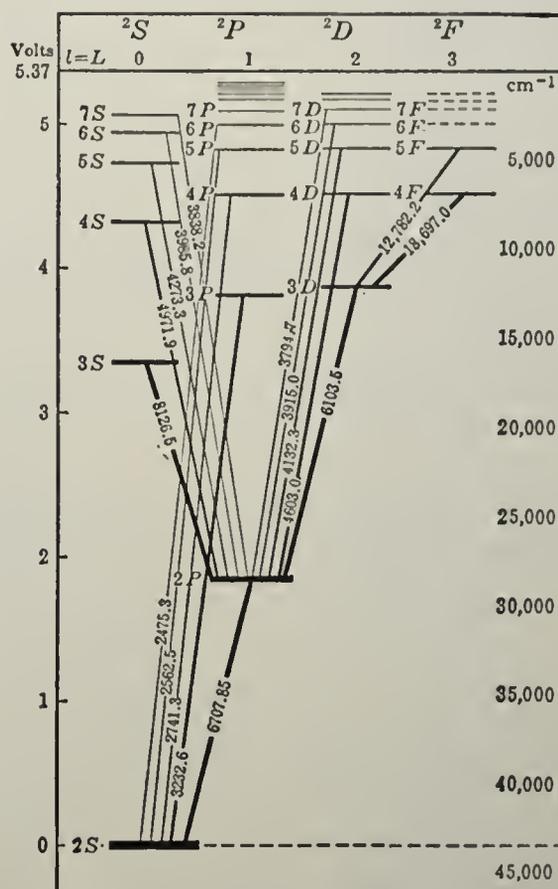

$$\frac{m_o c^2}{\sqrt{1 - v^2/c^2}} = m_o c^2 + \frac{1}{2}m_o v^2 + \dots \text{ for small } v/c;$$

where m_o is the rest mass, v is the speed of the particle, and c is the speed of light.

ENERGY LEVEL. A stationary state of energy of any physical system. The existence of many stable, or quasi-stable states, in which the energy of the system stays constant for some reasonable length of time, is an essential characteristic of quantum-mechanical systems, and is the basis of large areas of modern physics.

ENERGY LEVEL DIAGRAM. The graphical presentation of the energy levels of an atom, molecule, nucleus, etc., with respect to an arbitrary zero level, as a rule the ground state, or, for atoms, the ionized state. Atomic

and molecular energy level diagrams are in general designed to give a picture of the energetic order of the different types of energy state terms (S, P, D , etc.) and of the terms of different multiplicity. Usually important transitions are indicated by lines connecting the energy levels involved. See for example the energy level diagram of the lithium atom (figure). (The numbers on the lines indicating the transitions are the corresponding wavelengths.)

Energy level diagram of the lithium atom (after Grotian). (From G. Herzberg, *Molecular Spectra and Molecular Structure I Spectra of Diatomic Molecules*, 2nd ed., D. Van Nostrand Company, Inc., Princeton, 1950).

ENERGY LEVELS, ATOMIC, STATISTICAL WEIGHT OF. See statistical weight of atomic energy levels.

ENERGY LEVELS, MOLECULAR. See molecular energy levels; electronic energy levels of a molecule; rotational energy levels of a molecule; vibrational energy levels of a molecule.

ENERGY LEVELS, MOLECULAR, STATISTICAL WEIGHT OF. See statistical weight of molecular energy levels.

ENERGY LEVELS OF HARMONIC OSCILLATOR. See harmonic oscillator, energy levels of.

ENERGY LEVELS OF RIGID DIATOMIC ROTATOR. See rigid diatomic rotator, energy levels of.

ENERGY, MECHANICAL. For a conservative dynamical system the mechanical energy is the invariant of the motion which is equal to the sum of the kinetic energy (see **energy, kinetic**) and the potential energy (see **energy, potential**). This invariant or constant results from a first integration of the equations of motion and the first integral is usually known as the **energy integral**. Strictly speaking the mechanical energy does not exist for a non-conservative system. However, the concept is so useful that it is customary to treat a dissipative system as a system whose energy (defined for the equivalent non-dissipative system) decreases with the time. This makes possible an important connection with non-mechanical forms of macroscopic energy, for example, heat.

ENERGY MOMENTUM TENSOR. See Lagrangian.

ENERGY, MUTUAL. See interaction energy.

ENERGY, NEGATIVE KINETIC. (1) In quantum mechanics there may be a finite probability of finding a particle in the classically forbidden region where the total energy of the particle is less than its potential energy. In such a region, the kinetic energy, given as the difference between the total energy and the potential energy, would be negative. If an attempt is made to observe a particle in this classically forbidden region, one gives to the particle an indeterminate amount of energy (see **uncertainty principle**), with the result that negative kinetic energy is not observable. Particles pass through such classically forbidden regions of negative kinetic energy in the *tunnel effect*.

(2) The term is also used to describe the energy states of particles in those energy levels that were first predicted by the **Dirac electron theory**.

ENERGY OF A CHARGED SYSTEM. If the charges q_i are varied on a set of conductors at potentials V_i , the resulting change of energy of the system is given by

$$dU = \sum_i V_i dq_i.$$

Expressed in terms of coefficients of potential (see **potential, coefficients of**)

$$dU = \sum_i \sum_j p_{ij} q_j dq_i$$

which yields upon integration

$$\begin{aligned} U &= \frac{1}{2} \sum_i \sum_j p_{ij} q_i q_j = \frac{1}{2} \sum_i V_i q_i \\ &= \frac{1}{2} \sum_i \sum_j c_{ij} V_i V_j \end{aligned}$$

where the c_{ij} are the coefficients of induction. (See **induction, coefficients of**.)

ENERGY OF ACTIVATION. See activation energy.

ENERGY OF A SYSTEM OF CURRENT CIRCUITS. The magnetic fluxes through a set of circuits carrying steady currents I_j can be written

$$\dot{\phi}_i = \sum_j M_{ij} I_j$$

where the $M_{ij} = M_{ji}$ are the **mutual inductances**, and $M_{ii} \equiv L_i$ is the **self-inductance** of the i th circuit. If the circuits are of constant length, i.e., they may be non-rigid, but have no sliding contacts, the induced emf's are

$$\begin{aligned} \varepsilon_i &= -d\phi_i/dt \\ &= -\sum_j M_{ij} dI_j/dt - \sum_j I_j dM_{ij}/dt. \end{aligned}$$

Establishing the currents requires doing work at the rate

$$\frac{dW}{dt} = -\sum I_i \varepsilon_i$$

hence

$$\begin{aligned} dW &= -\sum I_i \varepsilon_i dt \\ &= \sum \sum M_{ij} I_i dI_j + \sum \sum I_i I_j dM_{ij}. \end{aligned}$$

If the circuits are held stationary so that no mechanical work is done, the work becomes stored energy of the system, and

$$\begin{aligned} dU &= \sum \sum M_{ij} I_i dI_j \\ U &= \frac{1}{2} \sum \sum M_{ij} I_i I_j. \end{aligned}$$

ENERGY OF n-PARTICLE SYSTEM (THE VIRIAL). If in a system of n particles confined to a finite region of space whose position vectors with respect to a given origin are \mathbf{r}_i the resultant force on the i th particle is \mathbf{F}_i , the virial of the system is defined to be

$$-\frac{1}{2} \overline{\sum_{i=1}^n \mathbf{r}_i \cdot \mathbf{F}_i}$$

The bar over the sum refers to a time average over a time interval long compared with the time taken by a particle to traverse the region in which the particles are confined. It is understood that not only are the magnitudes of the position vectors \mathbf{r}_i bounded, but that the same is true of the velocities of the particles. According to the virial theorem the virial of the system is equal to the average kinetic energy of the system.

ENERGY, POTENTIAL. The potential energy of a system is energy of configuration or position measured with respect to a reference configuration. For a static conservative system, the potential energy is the work needed to bring the system from the reference configuration to the configuration it is in. The potential energy is a minimum for stable equilibrium. (See **conservative force field**.)

ENERGY PRODUCT. The product of the magnitudes of \mathbf{B} and \mathbf{H} at any point on the demagnetization curve. The maximum value of this product is the best single criterion for a material to be used in permanent magnets. (See **hysteresis**.)

ENERGY RELATIONS IN UNIFORM FORCE FIELD. A uniform force field is a special case of central force field (see **force, central**). In such a field the force is constant in direction and magnitude. Examples: the gravitational field near the surface of the earth, and the electrostatic field between the two parallel plates of a condenser.

ENERGY, RELATIVE. The energy of particles in the **center of mass** (coordinate) system.

ENERGY STATE. See **state, energy and energy eigenfunction**.

ENERGY STATE, NEGATIVE. (1) Any bound state, in which the sum of the kinetic energy and the potential energy, the latter reckoned relative to zero at infinity, is less than zero. The existence of such states is essential for the stability of any system that is not surrounded by a region of positive potential energy, such as the Coulomb barrier.

(2) A consequence of the **Dirac electron**

theory is that there exist electron states of negative total energy (including both rest mass energy and kinetic energy). Electrons in such states of negative energy are unobservable, only electrons of positive total energy being observable. The allowed positive and negative states are restricted (only $E > m_0c^2$ and $E < m_0c^2$ are allowed in a field-free region). If a γ -ray photon of energy greater than $2m_0c^2$ (where m_0 is the rest mass energy of the electron) is absorbed by an electron of negative energy, it will be lifted into a positive energy state and will become observable. The positron is identified with the hole that is left behind.

The negative energy states are ordinarily completely filled with electrons, with no room for further electrons, a consequence of the **Pauli exclusion principle**. However, when a hole is created, an electron of positive energy near by may "fall" into it (pair annihilation) with the emission of γ -rays.

A similar picture may be developed for any pair composed of a particle and its anti-particle, the latter being the result of the lifting of the particle from a state of negative energy to one of positive energy.

ENERGY STATE TERMS. Terms designating the discrete energy states of a particle in a system. Thus the energy states of an atom are called S, P, D, F, \dots terms, respectively, corresponding to the values 0, 1, 2, 3, \dots of L , the resultant angular momentum **quantum number** of the atom. The energy states of a molecule are called $\Sigma, \Pi, \Delta, \Phi \dots$ terms, respectively, corresponding to the values 0, 1, 2, 3, \dots of Λ , the electronic orbital angular momentum (about internuclear axis) quantum number.

The letters indicating the value of L are usually preceded by a superscript denoting the **multiplicity** and followed by a subscript denoting the total angular momentum quantum number J . In addition, the principal quantum number is often written as a coefficient. Energy state terms and their transitions are shown in **energy level diagrams**.

ENERGY THICKNESS OF BOUNDARY LAYER. The energy thickness δ^{**} for a boundary layer is defined by

$$\delta^{**} = \int_0^{\delta} \frac{u}{U} \left[1 - \left(\frac{u}{U} \right)^2 \right] dy,$$

where u is the velocity at a distance y from the wall and U is the velocity outside the boundary layer, i.e., for $y > \delta$.

The defect of flux of kinetic energy, per unit width of boundary layer, is $\frac{1}{2}\rho U^3\delta^{**}$. (See also **energy equation for boundary layer**.)

ENGINE. (1) A mechanical device which produces some desired effect. (2) In a more restricted sense, a mechanical device which produces power, as distinct from a machine which produces some desired effect (e.g., the compression of a gas by a compressor; the maintenance of a body at a temperature lower than that of the surroundings by a refrigerator, etc.) other than the production of power. In that sense the term engine is synonymous with *prime mover*.

ENGINE CAPACITY. See **swept volume**.

ENGINEERING SYSTEM OF UNITS. (Also known as gravitational system of units.) A system of units based on the following three fundamental units: force, length, time. There exist several gravitational systems of units. The metric gravitational system is based on the kilogram (kg) as unit of force. In order to avoid confusion this unit has now been renamed kilopond (kp). The unit of length is the meter (m), and the unit of time is the second. The English gravitational system (also called the f lbf s system) is based on the pound (lb or lbf) for force, the foot (ft) for length and the second (sec) for time. The table below lists the principal derived units in the above systems.

GRAVITATIONAL
SYSTEM

Derived unit	Metric	English
Mass	1 $\frac{\text{kp sec}^2}{\text{m}}$ (no name)	1 slug = 1 $\frac{\text{lbf sec}^2}{\text{ft}}$
Work, energy	1 kp m (no name)	1 lbf ft = 1 foot pound
Pressure	1 $\frac{\text{kp}}{\text{m}^2}$ or 1 at = $10^4 \frac{\text{kp}}{\text{m}^2}$	1 $\frac{\text{lbf}}{\text{ft}^2}$ or 1 $\frac{\text{lbf}}{\text{in}^2} = 144 \frac{\text{lbf}}{\text{ft}^2}$
Power	1 $\frac{\text{kp m}}{\text{sec}}$ or 1 PS = $75 \frac{\text{kp m}}{\text{sec}}$	1 $\frac{\text{lbf ft}}{\text{sec}}$ or 1 HP = $550 \frac{\text{lbf ft}}{\text{sec}}$

(See also **acoustical units; electrical units; mechanical units; thermal units**.)

ENLARGEMENT ENERGY. See **delocalization energy**.

ENLARGEMENT, METHODS OF. Methods of **matrix inversion** by which the inverse of a matrix of order m is expressible in terms of that of a submatrix of order $m - 1$.

ENSEMBLE. A collection of similar systems considered in statistical mechanics. Ensembles were introduced by Gibbs, and their importance lies in the fact that the average behavior of a system in an ensemble can often be used to predict the behavior of an actual physical system. Usually all systems in an ensemble are supposed to have the same number of constituent particles. Such ensembles are called *petit ensembles*. Examples of petit ensembles which are used extensively are the **micro-** and **macrocanonical** ensembles. In order to study systems in which chemical reactions can take place, Gibbs introduced the so-called *grand ensembles* where the different systems do not have all the same number of particles. The most often used grand ensemble is the **grand canonical ensemble**.

In the Fowler-Darwin formulation of statistical mechanics, an ensemble is a single macrocanonical (macroscopic) collection of identical microcanonical systems. Average values are taken over the microcanonical possible states of the single macrocanonical ensemble of microcanonical systems, rather than over a set of replicas of a macrocanonical system.

ENSEMBLE, CANONICAL. See **canonical ensemble**.

ENSEMBLE, COOPERATIVE. An ensemble in which the interactions between the systems composing the ensemble are not negligible. The state of a given system is largely determined by the states of the neighboring systems.

ENSEMBLE DENSITY. A quantity ρ defined in such a way that $\rho d\Omega$ is the fraction of systems in an **ensemble** which have values of the momenta and position coordinates of all the particles in the system corresponding to a point in **gamma-space** within the **extension in phase** $d\Omega$. (For **grand ensembles** one must suitably alter this definition.)

ENSEMBLE, IDEAL. An ensemble in which the interactions between the systems composing the assembly can be neglected, such as a perfect gas or an ideal solution.

ENSEMBLE, MICROCANONICAL. See microcanonical ensemble.

ENSKOG-MAXWELL EQUATIONS OF CHANGE. The evaluation of any molecular property ϕ depending on velocity, position or time, can be obtained from the Boltzmann equation on multiplication by ϕ , and integration over the whole velocity space.

One obtains thus the Enskog-Maxwell equations of change

$$\frac{\partial(n\bar{\phi})}{\partial t} = -\frac{\partial}{\partial \mathbf{r}} \cdot (n\bar{\phi}\mathbf{v}) + n \left(\frac{\partial \bar{\phi}}{\partial t} + \mathbf{v} \frac{\partial \bar{\phi}}{\partial \mathbf{v}} + \frac{\mathbf{X}}{m} \frac{\partial \bar{\phi}}{\partial \mathbf{v}} \right) + 2\pi \sum_j \iiint \phi(f'_i f'_j - f_i f_j) \mathbf{g}_{ij} b db dv_i dv_j \quad (1)$$

$\bar{\phi}$ is the average value of ϕ ; n is the concentration in molecules per cc, \mathbf{v} , the molecular velocity, \mathbf{X} , the external force, f_i, f_j, f'_i and f'_j are the molecular distribution functions of the molecules involved in the direct and inverse collisions respectively. \mathbf{g}_{ij} is the relative velocity of the collision partners.

Equation (1) expresses the fact that the local variation of the property ϕ can result: (a) from the streaming of the molecules into and out of the volume element under consideration; (b) from the dependence of ϕ for each molecule on time, on its position and on its velocity, and (c) from the variation of ϕ through collisions between molecules.

(1) takes a much simpler form when the molecular property considered is a **summational invariant**, such as mass, momentum or energy. The last term of (1) is then equal to 0, and one obtains the **equation of continuity**, the **equation of motion**, and the **equation of energy conservation**, respectively. (See **Navier-Stokes equations, general treatment for mixtures.**)

ENSKOG SERIES FOR THE SOLUTIONS OF THE BOLTZMANN EQUATION. Enskog's solution of the Boltzmann equation is based on the introduction of a perturbation parameter ϵ which increases or decreases the total number, but does not change the rela-

tive number of collisions of various types. Enskog proposes an equation of the types:

$$\frac{\partial f_i}{\partial t} + \mathbf{v}_i \frac{\partial f_i}{\partial \mathbf{r}} + \mathbf{A}_i \frac{\partial f_i}{\partial \mathbf{v}_i} = \frac{1}{\epsilon} \sum_j J(f_i, f_j) \quad (1)$$

f_i is the distribution function of the molecule of velocity \mathbf{v}_i . \mathbf{A}_i is the acceleration caused by the external forces. $J(f_i, f_j)$ are the collision integrals (see **Boltzmann transport equation**).

The solution for small ϵ corresponds then to very frequent collisions, which tend to establish the local equilibrium.

The distribution function f_i is written as a power series in ϵ :

$$f_i = f_i^{(0)} + \epsilon f_i^{(1)} + \epsilon^2 f_i^{(2)} + \dots \quad (2)$$

When this expansion is introduced in Equation (1), one obtains, by equating the coefficients of equal powers of ϵ , a set of integro-differential equations:

$$0 = \sum_j J(f_i^{(0)}, f_j^{(0)}) \quad (3)$$

$$\frac{\partial f_i^{(0)}}{\partial t} + \mathbf{v}_i \frac{\partial f_i^{(0)}}{\partial \mathbf{r}} + \mathbf{A}_i \frac{\partial f_i^{(0)}}{\partial \mathbf{v}_i} = \sum_j [J(f_i^{(0)}, f_j^{(1)}) + J(f_i^{(1)}, f_j^{(0)})] \quad (4)$$

These equations can be solved, and the distribution function is obtained as a series of successive approximations:

$f^{(0)}$ is the local equilibrium distribution, leading to the Euler equation of change.

$f^{(1)}$ leads to the **Navier-Stokes equations**.

$f^{(2)}$ yields the **Burnett equations**, etc.

The convergence of this series has often been questioned, but the excellent agreement of the transport coefficients calculated in the first approximation with the experimental values and with the coefficients obtained by other methods for the solution of the Boltzmann equation (see **thirteen moments approximation**) indicate that the first Enskog approximation is fairly accurate for dilute gases under small relative gradients of the macroscopic quantities (temperature, concentration, pressure).

ENSKOG THEORY FOR THE TRANSPORT PHENOMENA IN DENSE GASES. Enskog has extended the classical theory for the trans-

port properties of diluted gases to the case of dense gas consisting of *hard spheres*. In this hypothesis, binary collision only must be retained in the collision integral of the **Boltzmann equation**; but these collision integrals are modified because of the **collisional transfer** which is important at high densities, and because of the finite volume of the molecules.

An equation of state for hard sphere gases was used to estimate the effect of the latter factor. When the experimental conditions are such that the intermolecular repulsive forces are predominant, the agreement between the experimental values and the values predicted by Enskog's theory, coupled with the above-mentioned equation of state, is surprisingly good, taking into account the rough approximation made.

ENTHALPY. Thermodynamic potential defined as

$$H = U + pV$$

where U is the internal energy of the system. In older text-books, the term total heat, to be discouraged, was used for enthalpy.

The principle of conservation of energy for closed systems expressed in terms of the enthalpy is

$$dH = dQ + Vdp.$$

(See also **thermodynamics, characteristic functions of**.)

ENTHALPY DROP. The difference between the final and initial specific enthalpy of the working fluid in a turbine or turbocompressor. Since the process of expansion in a turbine, or the process of compression in a turbocompressor is very nearly adiabatic (but not necessarily reversible), the application of the first law of thermodynamics to the respective open system gives

$$W = (h_1 - h_2)\dot{m}.$$

The work in a turbine or turbocompressor stage per unit mass flow \dot{m} is equal to the enthalpy drop. (Hence the importance of the concept in engineering thermodynamics.)

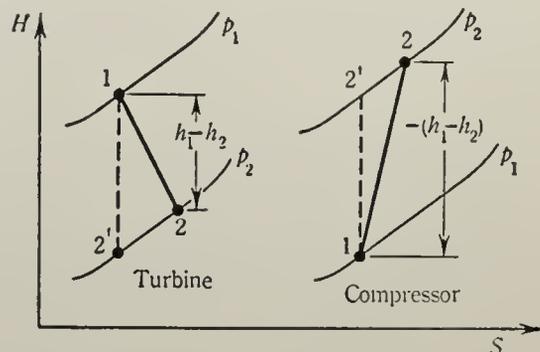

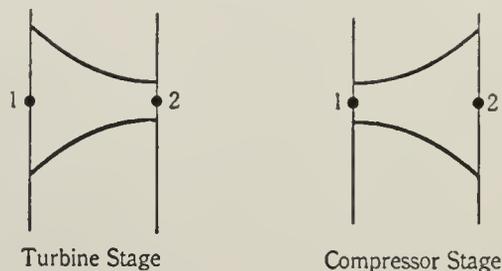

In the ideal case, the process of expansion or compression is also **isentropic**: in a real process, as shown in the figure, the entropy must increase; it cannot decrease according to the second law of **thermodynamics**. The ideal enthalpy drop is known as the *isentropic*

enthalpy drop. (In older text-books it is called adiabatic enthalpy drop.) Hence:

$$\text{enthalpy drop} = h_1 - h_2.$$

$$\text{isentropic enthalpy drop} = h_1 - h'_2.$$

The isentropic enthalpy drop serves as a standard of comparison for the operation of turbines, turbine stages, rotary compressors

and compressor stages. This is achieved by defining an expansion efficiency

$$\eta_e = \frac{h_1 - h_2}{h_1 - h'_2} \quad (\eta_e < 1)$$

and a compression efficiency

$$\eta_c = \frac{h'_2 - h_1}{h_2 - h_1} \quad (\eta_c < 1).$$

Values of η_e or η_c approaching unity signify low losses and good design.

The enthalpy drop is sometimes still called heat drop because in older texts the term "total heat" was used for "enthalpy"; however, such terminology is to be discouraged.

ENTHALPY OF ACTIVATION. See **absolute reaction rate theory**.

ENTHALPY THEOREM. The formulation of the first law of thermodynamics for open systems. (See **thermodynamics, first law of**.)

ENTIRE FUNCTION. An entire function of a complex variable for example, $\sin z$, e^z , is a function which has no singularities in the finite plane; that is, it is represented everywhere by its Taylor series about any point.

ENTRAINMENT. A process whereby fluid adjacent to a moving stream is caused to move with the stream, either on account of the viscous drag in the shearing layer which bounds the stream in laminar flow, or on account of the turbulent mixing at the edge of the stream. Turbulent entrainment is particularly important at the boundaries of a jet.

Entrainment also occurs on the boundary of a mass of buoyant fluid as it rises through otherwise stationary surroundings provided the fluids are miscible. The volume of the buoyant mass is thereby increased but the whole mass is decelerated.

ENTRANCE PUPIL. The Gaussian image of the aperture of an optical system in object space.

ENTROPIES, STATISTICAL METHOD OF. See statistical method of entropies.

ENTROPY. In thermodynamics, a property of a system which remains constant during a reversible adiabatic process, and which is defined by the equation

$$dS = dQ/T$$

where dS is an infinitesimal change in the entropy of a system, dQ is the infinitesimal quantity of heat that enters the system, and T is the Kelvin temperature of the system.

In statistical mechanics, entropy is a quantity proportional to the logarithm of the probability of the state considered, which is defined by the equation

$$S = k \log_e P + \text{constant}$$

where S is the entropy, k is the Boltzmann constant, and P is the statistical probability. It can be shown that the two definitions are equivalent.

For use of the term entropy in information theory, see information content, average.

(See also thermodynamics, second law of; thermodynamics, characteristic functions of; Carathéodory treatment of the second law; second law in one-component closed systems.)

ENTROPY CHART. A thermodynamic diagram in which entropy is used as one of the

coordinates, mostly restricted to systems with two independent variables. Entropy charts are often drawn exactly to scale and fulfill the function of an equation of state. They are widely used for practical calculations. The most widespread entropy chart is the **Mollier chart** drawn in the coordinates h,s (enthalpy-entropy). Mollier charts are very useful in calculations involving steam engines. Another useful entropy chart is that drawn in the coordinates T,s (absolute temperature-entropy).

ENTROPY, COMMUNAL. The contribution to the entropy of a gas due to the fact that the molecules occupy a common volume. Its value is nk , where n is the number of molecules present and k is the Boltzmann constant.

ENTROPY CONSTANT. An additive constant entering into the equation for the entropy which is determined by the requirement that entropy vanishes at the absolute zero of temperature. (See also thermodynamics, third law of.)

ENTROPY INCREASE, PRINCIPLE OF. It is a corollary of the second law of thermodynamics that in an isolated system a decrease in the total entropy is impossible—the total entropy of the system increasing when the process within it is irreversible, and remaining constant when the process is reversible.

An alternative and entirely equivalent formulation asserts that the change in entropy dS in any infinitesimal process in a closed system can be split into two parts

$$dS = d_e S + d_i S.$$

The part $d_e S$ is due to an exchange of heat with the surroundings and is given by

$$d_e S = \frac{dQ}{T}.$$

The part $d_i S$ is generated inside the system by the process, and can never be negative; it is positive for irreversible processes and zero for reversible processes. In a homogeneous system, the quantity

$$\dot{\theta} = \frac{d_i S}{dV dt}$$

is called the (local rate of) entropy production.

ENTROPY OF ACTIVATION. See absolute reaction rate theory; activated complex.

ENTROPY OF MONATOMIC GAS. Its value is given by one of the following three equations:

(Boltzmann statistics)

$$S = kN\left(\frac{5}{2} - \nu\right),$$

(Bose-Einstein statistics)

$$S = -\nu kN + \frac{5}{2}k \left(\frac{2\pi m}{\beta h^2}\right)^{\frac{3}{2}} V \sum_{n=1}^{\infty} \frac{e^{n\nu}}{n^{\frac{5}{2}}},$$

(Fermi-Dirac statistics)

$$S = -\nu kN - \frac{5}{2}k \left(\frac{2\pi m}{\beta h^2}\right)^{\frac{3}{2}} V \sum_{n=1}^{\infty} \frac{(-e^\nu)^n}{n^{\frac{5}{2}}},$$

where S is the entropy, k is Boltzmann's constant, m is the mass of the gas atoms, N is the total number of atoms in the system, V is the volume occupied by the gas, $\beta = 1/kT$ (T is absolute temperature), h is Planck's constant, and $\nu = \beta g$ (g is the partial **thermal potential**) which is related to N by the following equations:

(Boltzmann statistics)

$$N = \left(\frac{2\pi m}{\beta h^2}\right)^{\frac{3}{2}} V e^\nu,$$

(Bose-Einstein statistics)

$$N = \left(\frac{2\pi m}{\beta h^2}\right)^{\frac{3}{2}} V \sum_{n=1}^{\infty} \frac{e^{n\nu}}{n^{\frac{3}{2}}},$$

(Fermi-Dirac statistics)

$$N = - \left(\frac{2\pi m}{\beta h^2}\right)^{\frac{3}{2}} V \sum_{n=1}^{\infty} \frac{(-e^\nu)^n}{n^{\frac{3}{2}}}.$$

Expressed in terms of the pressure p and the temperature T one has in the case of Boltzmann statistics the **Sackur-Tetrode equation**,

$$S = k \left(\frac{5}{2} \ln T - \ln p + \frac{3}{2} \ln \frac{2\pi m}{h^2} + \frac{5}{2} \ln k + \frac{5}{2} \right),$$

and similar expressions for Bose-Einstein and Fermi-Dirac gases.

ENTROPY, STANDARD. The total **entropy** of a substance in a state defined as standard. Thus, the standard states of a solid or a liquid are regarded as those of the pure solid or the pure liquid, respectively, and at a

stated temperature. The standard state of a gas is at 1 atmosphere pressure and specified temperature, and its standard entropy is the change of entropy accompanying its expansion to zero pressure, or its compression from zero pressure to 1 atmosphere. The standard entropy of an ion is defined in a solution of unit activity, by assuming that the standard entropy of the hydrogen ion is zero.

ENTROPY, STATISTICAL DEFINITION. See **entropy** and **entropy of monatomic gas**.

ENTROPY VECTOR. The **four-vector** obtained by multiplying the proper entropy density by the local **four-velocity** in the relativistic theory of classical thermodynamics.

ENTROPY, VIRTUAL. See **virtual entropy**.

ENTRY LENGTH FOR PIPE OR CHANNEL. The usual expressions for velocity distribution and skin friction in pipe or channel flow refer to conditions at a large distance from the entry. Near the entry the **boundary layer** forms on the wall of the pipe or channel, and there is a central core of fluid which is unaffected by viscosity. As the boundary layer grows the central core is accelerated and the pressure falls. The central core ceases to exist when the boundary-layer thickness becomes equal to the radius of the pipe or the half-width of the channel. Still further downstream the velocity distribution becomes approximately parabolic (for laminar flow), the exact parabolic distribution being attained only asymptotically.

In a pipe of circular section the velocity distribution becomes approximately parabolic at a distance x from the entry given by $\frac{x}{dR} \approx 0.05$, where d is the diameter and R is the Reynolds number based on diameter and mean velocity. In a two-dimensional channel the corresponding condition is $\frac{x}{bR} \approx 0.05$, where b is the channel width and R is the Reynolds number based on this width and the mean velocity.

When the Reynolds number is so large that the flow eventually becomes turbulent, the flow near the entry depends on the initial disturbances. When the entry is almost undisturbed, transition to turbulent flow occurs when the Reynolds number based on distance from the entry is of order 10^5 to 10^6 . Still further downstream the velocity distribution

assumes its final form. For more disturbed entry conditions, the positions both for transition to turbulent flow and for attainment of the fully developed velocity distribution are further upstream.

ENUMERABLE. Synonym of **countable**, denumerable.

ENUMERABLE SET. See **cardinal**.

ENVELOPE. A curve that is tangent to each of a given family of curves. The envelope of the family of curves $f(x,y,t) = 0$, where t is the variable parameter of the family, is given by the pair of equations

$$f(x,y,t) = 0; \quad \frac{\partial f}{\partial t} = f_t(x,y,t) = 0.$$

These parametric equations of the envelope may be used to eliminate the parameter. This definition may be at once generalized to higher dimensions; e.g., the envelope of a family of surfaces. (See **surface**, **characteristic of**.)

ENVELOPE OF FAMILY OF SURFACES. See **surface**, **characteristic of**.

ENVELOPE OF TWO-PARAMETER FAMILY OF SURFACES. See **characteristic points for a two-parameter family of surfaces**.

ENVIRONMENTAL LAPSE RATE. The rate of decrease of temperature with elevation, $-\partial T/\partial z$, or occasionally $\partial T/\partial p$, where p is pressure. The concept may be applied to other atmospheric variables (e.g., lapse rate of density) if these are specified. The environmental lapse rate is determined by the distribution of temperature in the vertical at a given time and place and should be carefully distinguished from the **process lapse rate**, which applies to an individual air parcel. (See **supcradiabatic lapse rate**.)

EOLOTROPIC. An alternative spelling of **acolutropic** and synonymous with **anisotropic**, meaning not **isotropic**.

EPSILON-SYSTEM (IN n -DIMENSIONS). The system $\epsilon_{i_1 i_2 \dots i_n}$ or $\epsilon^{i_1 i_2 \dots i_n}$ defined by

$$\epsilon_{i_1 i_2 \dots i_n} = \sqrt{g} e_{i_1 i_2 \dots i_n}$$

$$\epsilon^{i_1 i_2 \dots i_n} = \frac{1}{\sqrt{g}} e^{i_1 i_2 \dots i_n}$$

where g is the determinant of the components of the covariant **metric tensor** for an n -dimensional coordinate system and $e_{i_1 i_2 \dots i_n}$ and $e^{i_1 i_2 \dots i_n}$ are **e-systems**.

EQUATION. For particular equations, **differential**, **integral**, **Laplace**, **Abcl**, etc., see under the respective names.

EQUATION OF CHANGE. See **Enskog-Maxwell equation of change**.

EQUATION OF CONTINUITY. The flux of fluid across any closed surface always composed of the same fluid particles is zero, or the rate of accumulation of mass within a closed surface fixed in space is equal to the flux across the surface. The corresponding forms of the equation are

$$\frac{D\rho}{Dt} + \rho \operatorname{div} \mathbf{v} = 0$$

$$\frac{\partial \rho}{\partial t} + \operatorname{div} \rho \mathbf{v} = 0.$$

For an incompressible fluid $D\rho/Dt = 0$ and the equation is

$$\operatorname{Div} \mathbf{v} = \frac{\partial u_i}{\partial x_i} = \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0.$$

If the flow is in parallel planes or axisymmetric then the equation contains only two terms and there exists a **stream function**. (See also **equations of fluid motion**.)

EQUATION OF ENERGY BALANCE. See **Navier-Stokes equations**; **Enskog-Maxwell equation of change**.

EQUATION OF MOTION OF GAS. See **Navier-Stokes equations**; **Enskog-Maxwell equation of change**.

EQUATION OF PIEZOTROPY. (Also called **physical equation**.) An equation relating the thermodynamic variables in processes of a **piezotropic fluid**. In its general form it expresses the density ρ as a function of the pressure p .

$$\rho = f(p).$$

The derivative $d\rho/dp$ is called the **coefficient of piezotropy**. The most familiar such equation is that for polytropic changes of state in an ideal gas:

$$p\rho^{-\lambda} = \text{constant},$$

where λ is the modulus of the polytropic process.

In many meteorological problems the equation of piezotropy may be obtained by combination of the **equation of state** and the first law of **thermodynamics** for an adiabatic ($\lambda = 1.4$), isobaric ($\lambda = 0$), or isothermal ($\lambda = 1$) process. The equation of piezotropy, when taken together with the **equations of fluid motion** and the **equation of continuity**, forms a complete system of five equations in the unknowns p , ρ , and the three velocity components.

The equation of piezotropy refers to processes undergone by individual parcels and not to the spatial distribution of the state variable; it is to be distinguished from the equation of **barotropy**.

EQUATION OF STATE. (Also called characteristic equation.) A relation, empirical or derived, between thermodynamic properties of a substance or system.

The equation of state must be single-valued in terms of its variables. This is a direct consequence of the concept of a **state**.

There exist systems, namely systems which undergo processes involving hysteresis, (plastic deformation, ferromagnetism, etc.) for which no equation of state can be indicated. Although it is believed that the laws of thermodynamics apply to such systems, the rigorous results of classical thermodynamics cannot be applied to such systems because the science of thermodynamics is developed on the assumption of the existence of the single-valued function.

In the realm of classical thermodynamics, equations of state are assumed given. They can be derived from first principles only by the methods of statistical mechanics and quantum mechanics. These rely on the adoption of suitable molecular models for substances, and so far no universal, generally applicable model has been discovered even for narrow classes of substances such as gases.

It is an experimental fact that every thermodynamic system possesses a definite number n of independent properties which determine its state. Consequently, an equation of state is a relation between n properties (mutually independent) chosen (otherwise arbitrarily) as the independent properties ($x_1, x_2 \dots x_n$) of the system and one more property, the dependent

property y . Hence the equation of state is a function of the form

$$F(y, x_1, x_2, \dots x_n) = 0. \quad (a)$$

The simplest thermodynamic systems possess two independent properties, consequently the simplest equation of state is written in terms of three variables. When it is written in terms of pressure p , volume V , and absolute temperature T , it is called the p - V - T relation for the system or the thermal equation of state. When one of the caloric-thermodynamic properties (better called caloric properties, because p, V, T are thermodynamic properties also), such as **enthalpy**, **entropy**, **Gibbs function**, or work function (**Helmholtz function**) are given, the equation is called a thermodynamic equation, or better, a **caloric equation of state**, although the latter is not a commonly accepted designation.

Even in the case of a simple system, one equation of state, e.g., the equation $f(p, V, T) = 0$, does not necessarily determine the form of all the other equations of state. This is connected with the fact that the derivation of the other equations of state may involve the integration of partial derivatives which leads to the appearance of whole functions in the integration "constant." An equation from which other equations of state can be derived by differentiation only, is called a **fundamental equation** (of state). In the case of a pure substance in a specified phase, the p, V, T relation does not constitute a fundamental equation with respect to the properties U, H, S, G, A , or their derived properties C_p, C_v, γ , etc. Consequently, it is possible to have two or more substances whose p, V, T relations are identical but whose specific heats, for example, are different.

In the case of continuous systems, for which the state changes from point to point, for example, a flow field of a viscous fluid, it is assumed that at every point, the equation of state is the same as for a homogeneous system and does not involve the gradients of the thermodynamic properties. Hence, such systems can only be studied with the aid of thermodynamics if local departures from equilibrium are small (near-equilibrium processes), i.e., if the gradients of the thermodynamic properties are not too great.

An equation of state must necessarily involve a finite (even if very large) number of

independent variables. The particular variables which are chosen as independent is immaterial, on condition that they are mutually independent, and that their number is appropriate to the physical nature of the system.

For the equations of state of various types of systems, see the corresponding entries in this book. Thus, the **Curie equation** is the equation of state of a paramagnetic solid. The equation of state, in p, V, T , for a **perfect gas** is given under that heading. The p, V, T equations of state for imperfect (real) gases are given under the headings **imperfect gases**; **virial equation of state**; **Beattie and Bridgman equation**; **Berthelot equation**; **Clausius equation**; **Dieterici equation**; **Keyes equation**, **van der Waals equation**, etc.

It should also be noted that equations of state for systems which consist of several components, rather than a single substance, can be written by introducing the variables n_1, n_2, \dots, n_c , which are the mole numbers of the components present.

Finally, it should be recognized that the data represented by equations of state of substances can be obtained in the form of diagrams or tables, e.g., **steam charts** and **steam tables**.

EQUATION OF STATE, ADIABATIC. See **adiabatic equation of state**.

EQUATION OF STATE FOR CRYSTALS. See **Mie-Grüneisen equation of state**.

EQUATIONS, HOLONOMIC. See **conservative force**.

EQUATIONS, NON-HOLONOMIC. See **conservative force**.

EQUATIONS OF COMPATIBILITY OF STRAIN (FOR INFINITESIMAL STRAIN). Differential equations which are satisfied by the infinitesimal strain components and which express the necessary and sufficient condition that there exists a displacement field consistent with them. In a rectangular Cartesian coordinate system x they may be written, using the **indicial notation** and **summation convention**,

$$\frac{\partial^2 e_{ij}}{\partial x_k \partial x_l} + \frac{\partial^2 e_{kl}}{\partial x_i \partial x_j} - \frac{\partial^2 e_{ik}}{\partial x_j \partial x_l} - \frac{\partial^2 e_{jl}}{\partial x_i \partial x_k} = 0,$$

where e_{ij} denotes the infinitesimal strain components in the system x . Only six of these

equations are independent. Also called *Saint-Venant compatibility equations*.

EQUATIONS OF FLUID MOTION. For a viscous fluid these are the **Navier-Stokes equations**. For an incompressible fluid $\text{div } \mathbf{v} = 0$; for a homogeneous, or well-stirred, fluid $\frac{1}{\rho} \text{grad } p = \text{grad } \int \frac{dp}{\rho} = \text{grad } \frac{p}{\rho}$ if the fluid is also incompressible; if the body forces are conservative, $F = -\text{grad } \Omega$; (for gravity $\Omega = -gz$, where z is height) and writing $\text{curl } \mathbf{v} = \boldsymbol{\omega}$ the equations reduce to

$$\frac{\partial \mathbf{v}}{\partial t} - \mathbf{v} \times \boldsymbol{\omega} = -\text{grad} \left(\Omega + \frac{p}{\rho} + \frac{1}{2} \mathbf{v}^2 \right) - \nu \text{curl } \boldsymbol{\omega}. \quad (1)$$

If the motion is irrotational $\boldsymbol{\omega} = 0$ and $\mathbf{v} = \text{grad } \phi$, ϕ being the velocity potential, and then

$$\text{grad} \left(\frac{\partial \phi}{\partial t} + \Omega + \frac{p}{\rho} + \frac{1}{2} \mathbf{v}^2 \right) = 0.$$

This may be integrated to give

$$\frac{\partial \phi}{\partial t} + \Omega + \frac{p}{\rho} + \frac{1}{2} \mathbf{v}^2 = \mathcal{F}(t).$$

The left hand side may be put equal to a constant if $\mathcal{F}(t)$ may be regarded as absorbed into $\frac{\partial \phi}{\partial t}$ and this is then the general form of **Bernoulli's equation** for irrotational flow.

Equation (1) may also be integrated for the steady motion $\left(\frac{\partial \mathbf{v}}{\partial t} = 0 \right)$ of inviscid fluids for then

$$\begin{aligned} \mathbf{v} \cdot \text{grad} \left(\Omega + \frac{p}{\rho} + \frac{1}{2} \mathbf{v}^2 \right) \\ = \boldsymbol{\omega} \cdot \text{grad} \left(\Omega + \frac{p}{\rho} + \frac{1}{2} \mathbf{v}^2 \right) \\ = 0 \end{aligned}$$

showing that

$$\Omega + \frac{p}{\rho} + \frac{1}{2} \mathbf{v}^2$$

= constant along a streamline or vortex line. The expression is therefore constant in the surface composed of all the vortex lines through a streamline. Such a surface is called a *Bernoulli surface*.

Conservative body forces may be eliminated when the fluid is incompressible and of uniform

density by subtracting out the hydrostatic pressure p_0 given by

$$\frac{p_0}{\rho} + \Omega = 0.$$

Writing $p' = p - p_0$ the equation is

$$\frac{D\mathbf{v}}{Dt} = -\text{grad} \frac{p'}{\rho} + \nu(\text{div grad})\mathbf{v}$$

or

$$\frac{Du_i}{Dt} = -\frac{1}{\rho} \frac{\partial p'}{\partial x_i} + \nu \frac{\partial^2 u_i}{\partial x_j \partial x_j}$$

according to the notation used.

EQUATIONS OF GAUSS AND CODAZZI.

Equations which must be satisfied by the fundamental magnitudes of the first and second orders, $a_{\alpha\beta}$ and $b_{\alpha\beta}$, for a surface. The *Codazzi equations of the surface*, or *Mainardi-Codazzi relations* are

$$b_{\alpha\beta,\gamma} - b_{\alpha\gamma,\beta} = 0.$$

This tensor equation represents two independent relations

$$b_{11,2} - b_{12,1} = 0 \text{ and } b_{22,1} - b_{21,2} = 0.$$

The *Gauss equation of the surface*, or the *Gauss characteristic equation*, is

$$R_{\sigma\alpha\beta\gamma} = b_{\alpha\gamma}b_{\sigma\beta} - b_{\sigma\gamma}b_{\alpha\beta},$$

where $R_{\sigma\alpha\beta\gamma}$ is the **Riemann-Cristoffel tensor** for the surface and is defined in terms of the **fundamental magnitudes of the first order**. The tensor equation represents a single equation

$$R_{1212} = b_{11}b_{22} - b_{12}^2.$$

EQUATIONS OF MOTION. A set of equations, generally in differential form, which when solved yield information concerning the motion of a particle or system of particles. Initial or boundary conditions on position and/or velocity and a knowledge of the forces acting on the system at any instant is necessary. There are several equivalent forms in which the equations of motion may be expressed. (See **Newton laws of motion**; **Lagrange equations of motion**; **canonical equations of motion**; and **Euler equations of motion** (for rotational motion); **kinematics**; **equations of motion, parametric**.)

EQUATIONS OF MOTION, PARAMETRIC.

In certain cases of motion in two and three

dimensions, the solutions of the differential equations of motion yield the displacements of the components along the coordinate axes as a function of time with the general form of these parametric equations:

$$x = f_1(t)$$

$$y = f_2(t)$$

$$z = f_3(t).$$

These are called parametric equations of the path with the time t as the parameter. To determine the path of the motion in the particular two or three dimensional space, it is necessary to eliminate the time and obtain a function of the form $\Phi(x,y,z) = 0$.

The motion of a projectile and the composition of simple harmonic motions in a plane are examples. (See **kinematics**.)

EQUATIONS, RHEONOMIC. See **conservative force**.

EQUATIONS, SCLERONOMIC. See **conservative force**.

EQUATOR. (1) An imaginary line cut on the surface of the earth by a plane perpendicular to the axis of rotation, and passing through the center of the earth. (2) An imaginary line cut by this plane on the **celestial sphere**. This line is often called the "celestial equator" or "equinoctial" to differentiate it from the terrestrial equator.

EQUICONTINUOUS. A set of functions $f_n(x)$ is said to be equicontinuous over their common domain of definition if, for every $\epsilon > 0$ there exists a $\delta > 0$ such that, for all x in the domain of definition,

$$|f(x_1) - f(x)| < \epsilon \text{ if } |x_1 - x| < \delta.$$

(Compare **Aseoli's theorem**.)

EQUIDISTANT ALLEYS. In the Luneberg geometry of binocular vision, equidistant alleys are pairs of curves that are the loci of points apparently equidistant from the median. Blumenfeld's experiment showing that equidistant alleys are not parallel alleys shows that binocular visual space is non-Euclidean.

EQUI-ENERGY SPECTRUM. A spectrum in which the spectral concentration of energy evaluated on a wavelength basis is constant throughout the visible region.

EQUILIBRANT. A force or force system which is equivalent to the negative of an existing force system. The existing force system plus its equilibrant is equivalent to zero force and zero couple.

EQUILIBRIA, CHEMICAL. See **chemical equilibria, calculation of.**

EQUILIBRIUM. (1) A state of a system characterized by the fact that no spontaneous processes occur in it. (a) When chemical processes are involved, the system may be in a state of *retarded equilibrium* (for example, a stoichiometric mixture of hydrogen and oxygen at atmospheric pressure and temperature). In such a system, a spontaneous process can occur by the removal of constraints (in the example, by the application of a catalyst (or catalyzer) or by a local increase in temperature. (b) When mechanical entities are involved, all forces are counterbalanced by equal and opposite forces. (See various mechanical systems in following entries.) In a state of equilibrium, at least some of the quantities describing the system are independent of time. (See also **equilibrium, dynamic.**)

(2) In statistical mechanics an **ensemble** is in equilibrium when it is in the state of most probable distribution. Fluctuations about this most probable state upset the statistical equilibrium but not the macroscopic equilibrium.

Some special or qualified types of equilibria are *apparent equilibrium*, a condition in which some factor prevents the system from reaching true equilibrium, and *metastable equilibrium*, an equilibrium which is not the *most stable* under the given conditions. Two other terms sometimes used are *stable equilibrium*, in which the potential energy of the system is a minimum, and *unstable equilibrium*, in which the potential is not a minimum, or is a maximum. (See **equilibrium, dynamic; equilibrium, metastable; equilibrium, neutral.**)

EQUILIBRIUM COMPLIANCE. See **compliance, equilibrium.**

EQUILIBRIUM CONSTANT. See **chemical equilibria, calculation of.**

EQUILIBRIUM, DYNAMIC. The application of D'Alembert's principle, or the introduction of inertia forces, reduces dynamics to statics in a formal sense. $\mathbf{F} = m\mathbf{a}$ becomes $\mathbf{F} - m\mathbf{a} = 0$. Equations of motion then may be called equations of dynamic equilibrium.

EQUILIBRIUM, FROZEN. See **frozen equilibrium.**

EQUILIBRIUM, METASTABLE. A definite equilibrium state which is not the most stable equilibrium under the given conditions. A metastable system will often undergo a spontaneous change upon addition of the stable phase, or frequently under the action of vibratory forces.

EQUILIBRIUM MODULUS. See **modulus, equilibrium.**

EQUILIBRIUM, NEUTRAL. A system is said to be in neutral equilibrium when it is not **unstable** and when some displacement from the equilibrium configuration produces no tendency to return to the original equilibrium position or to depart farther from it. Therefore, such a system, while in a **steady state**, cannot be said to exhibit either stability or instability.

This term is often used in connection with the **parcel method** of stability analysis; if the perturbation is a wave, "neutral equilibrium" and "stability" are often used interchangeably. (See **neutral stability.**)

EQUILIBRIUM OF A PARTICLE. A particle is said to be in equilibrium if the vector sum of all the forces acting on the particle is equal to zero. This condition can be expressed in component form by the equations $\Sigma F_x = 0$, $\Sigma F_y = 0$, $\Sigma F_z = 0$. Since a single particle does not possess the property of extension by definition, every force acting on the particle must act through the same point. Hence, the condition for equilibrium of a particle is identical with the first condition for equilibrium of rigid body as given under **equilibrium of forces.**

EQUILIBRIUM OF A RIGID BODY WITH RESPECT TO ROTATION. A rigid body, initially at rest, is in rotational equilibrium if the algebraic sums of the **torques** or moments about each of three mutually-perpendicular axes through the center of mass are zero. This is identical with the second condition for **equilibrium of forces on a rigid body.**

EQUILIBRIUM OF A RIGID BODY WITH RESPECT TO TRANSLATION. A rigid body is said to be in equilibrium with respect to translation if the vector sum of all the forces acting on the body is equal to zero. This

condition is identical with the first condition for **equilibrium of forces on a rigid body**, and also with the single condition for equilibrium of a particle.

EQUILIBRIUM OF A SYSTEM OF CONNECTED PARTICLES. If a system of connected particles (e.g., joined by strings or rods, etc.) is acted on by external forces, the equilibrium of the whole can be studied by examining the equilibrium of each particle separately under the influence of *all* the forces which act on it. This is called the principle of separate equilibrium. It is useful in the study of flexible jointed cables. Each particle must be in equilibrium separately for the system to be in equilibrium. $\Sigma \mathbf{F} = 0$ and $\Sigma \mathbf{M} = 0$ for the system is necessary but not sufficient.

EQUILIBRIUM OF FORCES ON A RIGID BODY. A state of balance between or among forces. The much used term equilibrium is here confined to its dynamical sense; such subjects as thermal equilibrium, radioactive equilibrium, etc., are treated in appropriate places elsewhere. Unless otherwise specified, the term refers to that set of conditions to which a system of forces must be adjusted in order that a free body acted upon by them will experience no acceleration. This is termed "static equilibrium," to distinguish it from the "kinetic or dynamic equilibrium" with which **d'Alembert's principle** is concerned.

Two conditions are necessary for the equilibrium of a set of forces: (1) The vector sum of the forces must be zero; then if they are resolved into rectangular components, the algebraic sums of the *X*, the *Y*, and the *Z* components must separately reduce to zero, or symbolically, $\Sigma F_x = 0$, $\Sigma F_y = 0$, and $\Sigma F_z = 0$. (2) The algebraic sum of the torques or moments of the forces about each of any three mutually perpendicular axes must be zero; the body then has no tendency to accelerate in any direction or about any axis.

EQUILIBRIUM, PRINCIPLE OF SEPARATE. The principle whereby the equilibrium of several particles can be studied by examining the equilibrium of a single particle in the group with respect to all the forces acting on it. (See **statics**.)

EQUILIBRIUM, STABLE. An equilibrium state of a system of one or more particles such

that the **potential energy** of the system is a minimum. (Contrast **equilibrium, unstable**.)

EQUILIBRIUM THEORY IN CHEMICAL KINETICS. The standard theories of chemical kinetics are equilibrium theories in which a **Maxwell-Boltzmann distribution** of reactants is postulated. This is true both for the **collision theory** and for the **absolute rate theory**. Because of the existence of an **activation energy** for most chemical reactions, "energetic molecules" play a dominant role in the reaction rate. The condition for the applicability of the equilibrium theory is then that the process

Average molecules \rightleftharpoons Energetic molecules
is much faster than the process:

Energetic molecules \rightarrow Products of chemical reactions.

EQUILIBRIUM, THERMAL. A system is said to be in thermal equilibrium if the temperature is uniform throughout the system and is the same as that of the surroundings.

EQUILIBRIUM, THERMODYNAMIC. A system is said to be in thermodynamic equilibrium if it is simultaneously in mechanical, thermal and chemical equilibrium. For a chemical system this means that the thermodynamic variables temperature, pressure and thermodynamic potentials are constant throughout the system and are the same as those of the surroundings.

EQUILIBRIUM, UNSTABLE. If the **resultant** of the forces acting on a rigid body is zero, the body is in equilibrium. The equilibrium is unstable if the system does not tend to return to the equilibrium position after a static displacement, but tends instead to depart farther from it. A pencil balanced on its point is an illustration of unstable **equilibrium**.

EQUIPARTITION OF ENERGY. In a system which can be treated by classical physics and which consists of a large number of particles, the average kinetic energy per particle is found to be proportional to the absolute temperature and to the number of **degrees of freedom** of one particle, the coefficient of proportionality being $\frac{1}{2}k$, where *k* is Boltzmann's constant. The average kinetic energy is thus independent of the mass of the particles.

The principle of equipartition of energy can

be generalized under certain circumstances to include degrees of freedom corresponding to terms in the potential energy. It breaks down when degrees of freedom begin to be frozen in. (See **freezing in of degrees of freedom**.)

EQUIPHASE SURFACE. In a three-dimensional wave, $A(x,y,z)e^{j[\omega t - \Phi(x,y,z)]}$, the surfaces $\Phi(x,y,z) = \text{constant}$ are called *equiphase surfaces*.

EQUIPOTENTIAL REGION. A field-free region. If the **potential** is uniform in a region,

$$\nabla\phi = 0,$$

hence there is no electric field. Conversely if

$$\mathbf{E} = -\nabla\phi = 0,$$

ϕ is independent of position.

EQUIPOTENTIAL SURFACE. A surface on which the **potential** is independent of position. At each point of the surface, the **gradient** $\nabla\phi$ crosses perpendicularly, i.e., equipotential surfaces are **normal** to the lines of force.

EQUIVALENCE. A (binary) relation R for the elements a, b, c of a set S is an equivalence, if it is *reflexive*, *symmetric*, and *transitive*. (For the meaning of these terms, and for the fundamental importance in mathematics of the concept of equivalence, see **relation**.)

EQUIVALENCE THEOREM. The field in a source-free region bounded by a surface could be produced by a distribution of electric and magnetic currents (**current-sheets**) on that surface that would be equivalent, for points inside the surface, to the actual external sources. (See **induction theorem**.)

EQUIVALENT-BAROTROPIC MODEL. A model atmosphere characterized by (1) frictionless and adiabatic flow, (2) hydrostatic and **quasi-geostrophic** equilibrium, and in which (3) the vertical shear of the horizontal wind is assumed to be proportional to the horizontal wind itself. It is, accordingly, an atmosphere in which the wind does not change direction with height and consequently one in which the contours and isotherms (on isobaric surfaces, for example) are everywhere parallel. In such an atmosphere, the vertically averaged motions are presumably equivalent to those at some intermediate level, the *equivalent-barotropic level*. In terms of the motion at this level, assumed to be an isobaric sur-

face, the behavior of the equivalent-barotropic model may be described by a single equation (the *vorticity equation*) in a single unknown (the height of the isobaric surface). (See **barotropic vorticity equation**.)

EQUIVALENT DEVIATE. See **deviate**, **deviation**.

EQUIVALENT ELECTRONS. Equivalent electrons in an atom or molecule are electrons in states with the same quantum numbers, apart from spin, and eigenfunctions having the same symmetry with respect to a reflection at the center (*even* or *odd* for atoms, g or u for molecules with a center of symmetry). The **Pauli principle** restricts the number of equivalent electrons to a maximum of $2(2l + 1)$ (l is the azimuthal quantum number).

EQUIVALENT FORCE SYSTEMS. Two force systems are said to be equivalent when they have the same resultant. Summation of forces in any direction and summation of moment about any axis are equal. Both systems can be reduced to the same wrench. (For definition of wrench, see **couple**, **theorems about**.)

EQUIVALENT POTENTIAL TEMPERATURE. The **potential temperature** corresponding to the *adiabatic equivalent temperature*.

$$\theta_E = T_{ac} \left(\frac{1000}{p} \right)^{0.286},$$

where θ_E is the equivalent potential temperature, T_{ac} the adiabatic equivalent temperature, and p the pressure in millibars. This temperature is conservative with respect to **dry-** and **pseudo-adiabatic processes**.

EQUIVALENT REPRESENTATIONS OF GROUPS. Two representations $g \rightarrow T_g$ and $g \rightarrow T'_g$ of a group G are said to be equivalent if there exists a non-singular operator M (i.e., one for which M^{-1} exists) such that $T'_g = MT_gM^{-1}$ for all g . Two equivalent representations can be considered as the realizations of the same representation in terms of two different bases in the vector space.

EQUIVALENT SYSTEMS IN THERMODYNAMICS OF IRREVERSIBLE PROCESSES. See **transformation theory of thermodynamics of irreversible processes**.

EQUIVALENT TEMPERATURE. (1) *Isobaric equivalent temperature:* The temperature that an air parcel would have if all water vapor were condensed out at constant pressure, the **latent heat** released being used to heat the air.

$$T_{ie} = T \left(1 + \frac{Lw}{c_p T} \right),$$

where T_{ie} is the isobaric equivalent temperature, T the temperature, w the mixing ratio, L the latent heat, and c_p the specific heat of air at constant pressure. (2) *Adiabatic equivalent temperature (or pseudo-equivalent temperature):* The temperature that an air parcel would have after undergoing the following (physically unrealizable) process: **dry-adiabatic expansion** until saturated; **pseudo-adiabatic expansion** until all moisture is precipitated out; dry-adiabatic compression to the initial pressure. This is the equivalent temperature as read from a **thermodynamic chart** and is always greater than the *isobaric equivalent temperature*.

$$T_{ae} = T \exp \frac{Lw}{c_p T},$$

where T_{ae} is the adiabatic equivalent temperature. (3) A term used in British engineering for that temperature of a uniform enclosure in which, in still air, a sizeable **black body** at 75°F would lose heat at the same rate as in the environment.

EQUIVALENT THICKNESS. The thickness, expressed in terms of the mass per unit area, of a foil which will just prevent the passage of α -particles of known range in air. The equivalent thickness in mg/cm² is equal to the product of the range (in cm) and the density (in mg/cm³). (See **stopping power**.)

EQUIVALENT WIDTH OF A SPECTRAL LINE. A practical measure for the intensity of an observed absorption line which is independent of the instrumental resolving power. The equivalent width of a spectral line is defined as

$$W_\nu = \int \frac{I_o - I_\nu}{I_o} d\nu$$

or

$$W_\lambda = W_\nu \lambda^2,$$

where I_o is the intensity of the continuous background at the wavelength λ of the absorp-

tion line and I_ν the measured intensity at wavenumber ν . The equivalent width of a spectral line is given by the width (in wavenumber or wavelength units) of a rectangle of height I_o and an area equal to the total area under the line profile. (Cf. **line width**.)

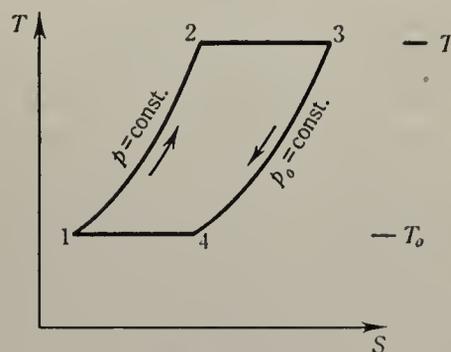

ERGODIC AND QUASI-ERGODIC HYPOTHESES.

Hypotheses which were introduced to justify the use of statistical mechanics in describing mechanical systems. The ergodic hypothesis introduced by Boltzmann (and by Maxwell who called it the principle of continuity of path) assumed that any system will after a sufficiently long time return to its original state. In this form it is certainly incorrect, but the quasi-ergodic hypothesis, introduced by P. and T. Ehrenfest, which states that any system will after a sufficiently long time return arbitrarily closely to its original state, is probably correct for all systems of physical interest.

ERGODICITY. A property of dynamic stochastic systems which, in general terms, may be expressed by saying that a system is ergodic if it tends in probability to a limiting form which is independent of the initial conditions.

ERGODIC THEOREM. See **ergodic and quasi-ergodic hypotheses**.

ERICSSON CYCLE. A cycle consisting of: 1-2 heating at constant pressure p ; 2-3 isothermal expansion (T); 3-4 cooling at constant pressure p_o ; 4-1 isothermal compression (T_o).

T,S diagram of Ericsson cycle.

The Ericsson cycle is approached by a closed cycle gas turbine when compression and expansion occur in a large number of stages with interstage cooling or heating, respectively.

The efficiency of this cycle is equal to that of a Carnot cycle

$$\eta = 1 - \frac{T_o}{T}$$

(See **gas turbines**.)

ERROR. In general, any deviation of a computed quantity from the theoretically correct value. In a restricted sense, that deviation due to unavoidable random disturbances, or to the use of finite approximations to what is defined by an infinite series, and hence to be contrasted with **blunder**. Errors of measurement arise from the use of instruments of less than infinite precision, and from random, uncontrollable disturbances. Truncation errors are due to the use of a term as an approximation for the limit of an infinite sequence, or, in general, to the use of any approximation in place of the theoretically correct quantity (cf. **remainder**, **roundoff**). If $f(x)$ is to be computed but only the approximation x^* to x is known, then $f(x) - f(x^*)$ is the *propagated error*. (See **error**, **propagation of**.) Bounds for the propagated error can be had by applying mean value theorems when f has suitable continuity properties. Generated errors are those which arise in the computation itself because of rounding. They depend upon the details of the routine.

If f is the true and f^* the computed value, sometimes $f - f^*$ is called the **correction**, $f^* - f$ the **error**. The term correction, however, is used in a different way in this book, to designate a quantity to be added to f^* for reducing the error, hence an approximation to the error. The word error occurs in several specialized senses in different sciences. We may distinguish two main fields: errors of measurement (or, more generally, errors of observation) and sampling errors, apart from such things as copying errors, interpretation errors and so forth. Errors of observation are themselves capable of classification, e.g., into *instrumental errors*, due to imperfections in instruments, and *personal errors*, attributable to the observer. *Sampling errors* are variations due to incompleteness of the sample coverage; they are not "mistakes" or imperfections in measurement. In control systems, the error is the difference, expressed as a function of time, between the input or command and the output or controlled variable. In most of the literature the error is defined as "input

minus output" but some authors use the definition "output minus input" derived from the instrument field, in which a meter with positive error is one that reads high, that is, one for which the reading (or output) is greater than the desired value (or input).

ERROR FUNCTION. The definite **integral**, also called the Gauss error function,

$$\operatorname{erf}(t) = \frac{2}{\sqrt{\pi}} \int_0^t e^{-y^2} dy.$$

When the results of a series of measurements are described about an average by a Gaussian curve, $\operatorname{erf}(ha)$ is the probability that the error of a single measurement lies between $\pm a$, where h is the precision index.

The function is mainly employed in the theory of observational errors. In statistics the related **normal distribution** is almost universal.

ERROR, PROPAGATION OF. When a quantity is calculated as a function of one or more measured quantities, instead of being measured directly, it is often necessary to estimate the uncertainty in the calculated quantity which results from the estimated errors of the measured quantities. In other words, if z is a function of x_1, x_2, \dots, x_p , say $f(x_1, x_2, \dots, x_p)$ and it is desired to find the **distribution** of z given that of the x 's, this is usually done by finding large sample approximations to the **variance** of z in terms of the **variances** and **covariances** of the x 's.

ERRORS, DETECTION OF. See **detection of tabulation errors**.

ESCALATOR METHOD. A method of **enlargement** for **matrix inversion**, and for computing **eigenvalues** and **eigenvectors** of **matrices**.

ESCAPE PROBABILITY, FIRST FLIGHT. The complement of the first flight collision probability (see **collision probability**, **first flight**), thus, $1 - P_o$.

ESCAPE PROBABILITY, RESONANCE. See **resonance escape probability**.

ESCAPE SPEED (VELOCITY). The minimum speed at which an inert body must be shot from the earth to avoid recapture by the earth's gravitational field is called the escape speed or escape velocity.

A projectile accelerated from the earth's surface at a speed below that of escape travels away from the earth in an elliptical path gradually losing speed until at the point farthest from the earth (apogee), it turns earthward and begins to travel back to the earth, under the influence of its gravitational field; but still following the elliptical path. If the velocity of the projectile were sufficient (orbital velocity) it would establish a permanent orbit beyond the sensible atmosphere of the earth, becoming a satellite. When the projectile velocity is sufficient for escape from the earth's gravity field, its path becomes a parabola (or hyperbola) hence the term parabolic velocity. The escape velocity from the earth is given by the following relationship:

$$V_e = R_e \sqrt{\frac{2g_e}{R_e + h}}$$

where R_e is radius of the earth, g_e is the gravitational acceleration of earth at the surface, and h is the altitude at take-off.

ESSENTIAL SINGULARITY. See **singularity**.

ESTIMATED POSITION. See **dead reckoning**.

ESTIMATES, CONSISTENT. See **consistent estimates**.

ESTIMATION, THEORY OF. Given a **sample** from a **population** whose specification involves one or more **parameters**, it is necessary to form estimates of the parameters. Usually, many different estimates of a given parameter can be derived, and the theory of estimation is concerned with the properties of these different estimates. Together with the estimate itself, it is useful to provide some idea of its precision and this is commonly done by specifying an interval which is intended to contain the true value of the parameter (see **confidence limits, fiducial inference**).

A basic result in the theory of estimation states that, under general conditions, a **consistent** estimator has a sampling variance in large samples which is not less than a certain lower bound. Statistics whose variance attains this lower bound are said to be *efficient*.

ESU. See **electromagnetic units**.

e-SYSTEM (IN n -DIMENSIONS). The system $e^{i_1 i_2 \cdots i_n}$ or $e_{i_1 i_2 \cdots i_n}$, the components of which take the values 1 or -1 accordingly as $i_1 i_2 \cdots i_n$ is an even or odd permutation of $1, 2, \cdots, n$ and 0 otherwise.

ETA (H OR η). In reactor theory, and nuclear physics, the quantity η is the average number of fission neutrons emitted as a result of the capture of one thermal neutron by a fissionable nucleus.

ETTINGSHAUSEN COEFFICIENT. See **galvanometric and thermometric effects**.

ETTINGSHAUSEN EFFECT. See **galvanometric and thermometric effects**.

EUCKEN CORRECTION. According to the kinetic theory of dilute gases, the thermal conductivity coefficient λ , the viscosity coefficient η and the heat capacity per gram at constant volume \hat{c}_v for a monoatomic gas should be related by the equation:

$$\lambda = 2.5\eta\hat{c}_v. \quad (1)$$

This equation is in excellent agreement with the experimentally observed values in the rare gases.

For diatomic and polyatomic molecules, Equation (1) does not hold: whereas the transfer of internal energy hardly affects the viscosity coefficient, it increases both the heat capacity and the heat flux (and therefore the thermal conductivity coefficient). The two increases are not proportional.

Eucken has calculated the thermal conductivity of a polyatomic gas, assuming that the collisions maintain the internal degrees of freedom at their equilibrium energy value at the local temperature. Then, for a perfect gas;

$$\lambda = \eta\hat{c}_v \cdot a = \frac{1}{4} \left(g \frac{c_p}{c_v} - 5 \right) \eta\hat{c}_v. \quad (2)$$

a in this equation is called the Eucken correction or Eucken factor.

Other models have been proposed to calculate the energy transfer when the collisional exchange of energy between the translational and internal degrees of freedom is slow. Molecules with a higher energy content are formed in the warm parts of the apparatus, and diffuse towards the colder regions where they are deactivated with a liberation of energy. The molecules with a lower energy content diffuse

in the opposite direction. The Eucken factor calculated for such models differs by about 20% from that deduced from (2). This explains why, in spite of its rough theoretical basis, the Eucken equation has been fairly successful for the prediction of λ of the polyatomic molecules.

EUCLIDEAN ALGORITHM. The algorithm for finding the **highest common factor** of two numbers. It consists of forming a sequence of numbers of which the first two are the given numbers (the larger one first), the third is the remainder when the first is divided by the second, the fourth is the remainder when the second is divided by the third and so forth until zero is reached. The last non-zero number in the sequence is the desired highest common factor.

EUCLIDEAN SPACE. An n -dimensional Euclidean space is described abstractly by the following three properties, which determine that it is a linear, metric, n -dimensional space.

1(a). For every pair of points p, q which may also be called vectors, i.e., with base point at the origin, there exists a unique point $p + q$ such that $p + q = q + p$ and $p + (q + r) = (p + q) + r$ for every point r .

1(b). For every point p and every real number m there exists a unique point mp such that for all points q, r and numbers n

$$m(p + q) = mp + mq; \quad (m + n)p = mp + np;$$

$$(mn)p = m(np); \quad 1.p = p.$$

1(c). There exists a point 0 such that $p + 0 = 0, 0p = 0$ for every point p .

2. For every pair of points p, q there exists a unique **scalar product** (p, q) which is a real number such that, for all points r and numbers m , we have: $(mp, q) = m(p, q); (p + q, r) = (p, r) + (q, r); (q, p) = (p, q); (p, p) > 0$ if $p \neq 0$.

3. There exist in the space n linearly independent points p_1, p_2, \dots, p_n but no set of $(n + 1)$ linearly independent points.

As a concrete realization of a Euclidean n -space we may consider as points p the sets of n real numbers (p_1, p_2, \dots, p_n) with scalar product of p and q defined as

$$p_1q_1 + p_2q_2 + \dots + p_nq_n.$$

EULER ANGLE. One of three parameters describing the orientation of a rigid body relative to a **Cartesian coordinate system** (x, y, z) fixed in space. Suppose another coordinate

system (x', y', z') is fixed in the body. Then the two systems may be made coincident by three successive rotations, applied in the appropriate order, and the three angles of rotation are the **Euler angles**. The order of performing the rotations and the symbols for the angles have been given in different ways by various authors so that some confusion exists in the literature of mechanics, where these parameters are most frequently used, as to the definition of the angles.

EULER CONSTANT. See **Euler-Mascheroni constant**.

EULER EQUATION. The condition that the integral

$$\int_{x_1}^{x_2} I(x, y, y') dx$$

have a stationary value is

$$\frac{\partial I}{\partial y} - \frac{d}{dx} \frac{\partial I}{\partial y'} = 0$$

the latter being known as the Euler equation or the Euler-Lagrange equation in the calculus of variations. (See **variations, calculus of**.)

EULER EQUATIONS OF MOTION. For a rigid body with one point fixed and coordinates fixed in the body and coinciding with the principal axes, the equations of motion of the body can be written as

$$I_{xx}\dot{\omega}_x + (I_{zz} - I_{yy})\omega_y\omega_z = M_x$$

$$I_{yy}\dot{\omega}_y + (I_{xx} - I_{zz})\omega_z\omega_x = M_y$$

$$I_{zz}\dot{\omega}_z + (I_{yy} - I_{xx})\omega_x\omega_y = M_z$$

where I_{xx}, I_{yy} and I_{zz} are the moments of inertia about the principal axes, L_x, L_y and L_z are the components of moment about the principal axes, ω_x, ω_y and ω_z are the components of the angular velocity about the principal axes and the dot indicates the time derivative. (See **moments of inertia; rotational motion**.)

EULER FORMULA (COLUMNS). A formula which gives the maximum axial load that a long, slender ideal column can carry without buckling. An ideal column is one which is perfectly straight, homogeneous and free from initial stress. This maximum load, sometimes called the critical load, causes the column to be in a state of unstable equilib-

rium, that is, any increase in the loads or the introduction of the slightest lateral force will cause the column to fail by buckling. The Euler formula for columns is given below.

$$P = \frac{K\pi^2 EI}{l^2}$$

in which P is maximum or critical load, E is modulus of elasticity, I is moment of inertia of cross-sectional area, l is unsupported length of column, K is a constant whose value depends upon the conditions of end support of the column. For both ends free to turn $K = 1$; for both ends fixed, $K = 4$; for one end free to turn and the other end fixed $K = 2$ approximately, and for one end fixed and the other end free to move laterally $K = 1/4$. (See column.)

EULER FORMULA (TURBINE). See velocity diagram.

EULERIAN ANGLES. See Euler angles.

EULERIAN METHOD OF ANALYSIS. A method in which the fluid within an arbitrary surface fixed in space is considered. By considering the local rates of change of density and momentum the equations of continuity and fluid motion are deduced. All properties of the fluid are expressed as functions of three coordinates of position, in a fixed frame of reference, and time.

EULERIAN WIND. In the classification of Jeffreys, a wind motion only in response to the pressure force. It is defined mathematically by

$$\frac{dV}{dt} = -\alpha \nabla_H p,$$

where V is the horizontal velocity, α the specific volume, ∇_H the horizontal vector differential operator and p the pressure.

The **cyclostrophic wind** is a special case of the Eulerian wind, which is limited in its meteorological applicability to those situations in which the **Coriolis effect** is negligible.

EULER-LAGRANGE EQUATIONS. See Lagrange equations.

EULER-MACLAURIN FORMULA. The formal expansion

$$\int_{x_0}^{x_m} f(x) dx = h(f_0/2 + f_1 + f_2 + \dots + f_{m-1} + f_m/2) - \sum_2^{\infty} B_\nu h^\nu (f_m^{(\nu-1)} - f_0^{(\nu-1)})/\nu!,$$

where

$$f_i = f(x_i) = f(x_0 + ih)$$

and the B_ν are the **Bernoulli numbers**.

EULER-MASCHERONI CONSTANT. A number, also often called simply Euler's constant, which occurs, for example, in one definition of the **gamma function**. It can be defined by several equivalent infinite integrals, one example being

$$C = \int_0^{\infty} e^{-t} \ln t dt.$$

but most often its definition is given by the equation,

$$C = \lim_{n \rightarrow \infty} \left(1 + \frac{1}{2} + \frac{1}{3} + \dots + \frac{1}{n} - \ln n \right).$$

Its numerical value is 0.577215665... but the quantity $\gamma = 1.781072 \dots$, defined by $\ln \gamma = C$ is sometimes defined as the Euler Mascheroni constant.

EULER METHOD (FOR SOLVING AN ORDINARY DIFFERENTIAL EQUATION).

$$y' = f(x, y)$$

takes

$$y_{\nu+1} = y_\nu + hf_\nu,$$

$$f_\nu = f(x_\nu, y_\nu).$$

The "improved Euler method" obtains sequentially

$$y_{\nu+1/2} = y_\nu + hf_\nu/2,$$

$$y_{\nu+1} = y_\nu + hf_{\nu+1/2}$$

and can be considered an elementary form of the **Runge-Kutta method**. The "improved Euler-Cauchy method" forms

$$y_{\nu+1}^* = y_\nu + hf_\nu, \quad f_{\nu+1}^* = f(x_{\nu+1}, y_{\nu+1}^*),$$

$$y_{\nu+1} = y_\nu + h(f_\nu + f_{\nu+1}^*)/2.$$

(See Lothar Collatz, *Numerische Behandlung von Differentialgleichungen*, 2nd edition, Springer, 1955.)

EULER RECIPROCITY RELATION. If Z is a single-valued function of the variables x and y , the total or exact differential dZ may be written

$$dZ = Xdx + Ydy,$$

where X and Y are also functions of x and y . Then it can be shown that

$$\left(\frac{\partial X}{\partial y}\right)_x = \left(\frac{\partial Y}{\partial x}\right)_y.$$

This is known as the Euler criterion, or reciprocity relation. It is useful for deriving thermodynamic relationships, e.g., the **Maxwell relations**.

EULER-RODRIGUES PARAMETER. One of four parameters used to describe the orientation of a rigid body. They are functions of three **direction cosines** and they form the components of a **quaternion**.

EULER SUMMATION FORMULA. The **Euler-Maclaurin formula** when used for summing a series.

EULER THEOREM FOR HOMOGENEOUS FUNCTIONS. The function $f(x,y,z)$ is called homogeneous of the m^{th} degree in variables x,y,z,\dots if one has identically

$$f(kx,ky,kz,\dots) = k^m f(x,y,z). \quad (1)$$

By differentiating in respect to k and putting $k = 1$, one obtains the second identity

$$\frac{\partial f}{\partial x} x + \frac{\partial f}{\partial y} y + \dots \equiv m f(x,y,z). \quad (2)$$

This is Euler's theorem. Conversely it can be shown that any function which satisfies (2) is homogeneous of the m^{th} degree in x,y,z,\dots .

In thermodynamics one is concerned mainly with the two simplest cases $m = 1$ and $m = 0$. For example, the volume $V(p,T,n_1 \dots n_c)$ is an **extensive variable** of the mole numbers $n_1 \dots n_c$. Therefore applying (2) with $m = 1$, there results

$$\sum_{i=1}^c \left(\frac{\partial V}{\partial n_i}\right)_{T,p} n_i = V(T,p,n_1 \dots n_c). \quad (3)$$

On the contrary a partial molar volume v_j (see **partial molar quantities**) is an **intensive variable**. Therefore ($m = 0$)

$$\sum_{i=1}^c n_i \left(\frac{\partial v_j}{\partial n_i}\right)_{T,p} = 0.$$

(See also **Gibbs-Duhem relations**.)

EULER THEOREM ON NORMAL CURVATURE. The normal curvature κ_n at a point on a surface in a direction which makes angles θ and $\frac{1}{2}\pi - \theta$ with the principal directions at the point, corresponding to which the principal curvatures of the surface are κ_a and κ_b respectively, is given by

$$\kappa_n = \kappa_a \cos^2 \theta + \kappa_b \sin^2 \theta.$$

Dupin's theorem follows immediately; the sum of the normal curvatures at a point in two perpendicular directions is constant and equal to the sum of the principal curvatures at the point.

EULER TRANSFORMATION. (Of an infinite series whose partial sums are

$$S_n = a_0 + a_1 x + \dots + a_n x^n.)$$

This transformation utilizes the identity

$$(1-x)S_n = a_0 - a_n x^{n+1} + x \sum_0^{n-1} \Delta a_i x^i.$$

It is a method for the **summation of series**.

EULER TURBINE FORMULA. See **velocity diagram**.

EUTECTIC POINT. See **crystallization curve**.

EV. Symbol for one electron volt, a unit of energy equal to 1.602×10^{-12} erg, being the energy gained by a single electronic charge passing *in vacuo* through a potential difference equal to one volt.

EVAPORATION. See **boiling**.

EVEN AND ODD VARIABLES IN THERMODYNAMICS OF IRREVERSIBLE PROCESSES. See **reciprocity relations**.

EVEN FUNCTION. A function such that $f(x) = f(-x)$, typical examples being x^2 and $\cos x$. (See **odd function**.)

EVENT. A physical occurrence involving the interaction between two or more physical entities. For example, the collision between two bodies; or the emission of a photon by an excited atom as a result of its interaction with the radiation field. Events are described as

occurring at specified positions and times in a given coordinate system, or frame of reference. The special theory of relativity treats such problems as the descriptions of the same event, or the simultaneity of two events, as viewed by observers in two equivalent inertial frames of reference.

EVEN TERM OF AN ATOM. A term for which Σl_i , summed over all the electrons of an atom, is even. The eigenfunctions of even terms remain unchanged for a reflection of all particles at the center.

EVERETT INTERPOLATION FORMULA.

In the notation of **difference operators**

$$E^u = (1 - u) + \left(\begin{matrix} 2 - u \\ 3 \end{matrix} \right) \delta^2 + \left(\begin{matrix} 3 - u \\ 5 \end{matrix} \right) \delta^4 \\ + \dots + \left[u + \left(\begin{matrix} 1 + u \\ 3 \end{matrix} \right) \delta^2 \right. \\ \left. + \left(\begin{matrix} 2 + u \\ 5 \end{matrix} \right) \delta^4 + \dots \right] E.$$

It thus requires differences of even orders only, but they must be taken both at x_0 and at $x_1 = x_0 + h$.

EVJEN METHOD. A method for the evaluation of **lattice sums** in which charges of opposite signs are taken together in neutral groups, so that the contribution of each group is small and the sum converges rapidly.

EVOLUTE. The evolute of a given curve is the locus of its centers of **curvature**. (Discussed in entry on **involute**.)

EVOLUTE OF A SURFACE. See **involute of a surface**. Also called *surface of centers of the surface*.

EXACT. An exact differential equation of the form $f(x, dx, y, dy, \dots) = 0$ is one whose left side is an exact **differential**. For an equation of the form $M(x, y)dx + N(x, y)dy = 0$ to be exact, it is necessary and sufficient that

$$\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}.$$

EXALTATION. The positive difference between the observed and the calculated values of the **molar refractivity** of a substance. (See **optical exaltation**.)

EXCESS FUNCTIONS. The difference between the **thermodynamic functions of mixing** for an actual system and the value corresponding to a perfect solution at the same temperature, pressure and composition is called the thermodynamic excess function (denoted by superscript E). Thus the excess Gibbs free energy (see **thermodynamics, characteristic functions of**) is (per mole)

$$g^E = g^M - RT(x_1 \ln x_1 + x_2 \ln x_2). \quad (1)$$

In terms of activity coefficients (1) becomes (see **reference systems**)

$$g^E = RT x_1 \ln \gamma_1 + RT x_2 \ln \gamma_2. \quad (2)$$

Similar definitions hold for the other thermodynamic quantities.

Very often the excess functions have a simple parabolic form. (They must vanish at $\alpha_1 = 0$ and $\alpha_2 = 0$.)

EXCHANGE. (1) A quantum mechanical concept based on the idea of identical particles. For example, suppose that two electrons are in **states** that allow them to come close together. Then, because they are indistinguishable particles, one could not tell the difference if they exchanged states. Thus the wave function of the system must be such that an exchange of the electrons leaves the magnitude of the wave function unchanged, except possibly for sign, i.e., the **wave function** must be either symmetric or antisymmetric to an exchange of the two particles. Particles whose total wave function (including both space and spin coordinates) is symmetric under an exchange operator obey the **Bose-Einstein statistics**. Particles whose total wave function is antisymmetric obey the **Fermi-Dirac statistics**.

(2) Exchange is also used more specifically as the exchange of one particle between two others, as in the exchange of the single electron between the two identical protons in the hydrogen molecular ion, or the exchange of a meson between two nucleons.

EXCHANGE COEFFICIENTS. (Also called *austausch coefficients*, *eddy coefficients*, *interchange coefficients*.) Coefficients of **eddy flux** (e.g., of momentum, heat, water vapor, etc.) in turbulent flow, defined in analogy to those of the kinetic theory of gases (see **eddy**). The *exchange-coefficient hypothesis* states that the mean eddy flux per unit area of a conservative

quantity (suitably expressed) is proportional to the **gradient** of the mean value of this quantity, that is,

$$\text{mean flux per unit area} = -A \frac{d\bar{E}}{dn},$$

where A is the exchange coefficient, \bar{E} the mean value of the quantity, and n the direction normal to the surface. In strict analogy to molecular properties A would be constant, for turbulent flow A turns out to depend on time and location.

EXCHANGE DEGENERACY. An exchange process which does not entail a change in value or configuration. For example, by the Heitler-London theory, the essential reason for the strong attraction (or repulsion), of the two H-atoms in the H_2 molecule is the exchange degeneracy, i.e., the fact that for very large internuclear distance, by exchange of the two electrons of the two atoms a configuration results that is indistinguishable from the original configuration. Therefore, as they approach, an interaction between them arises which may be treated mathematically as electron exchange.

EXCHANGE ENERGY. A specifically quantum-mechanical effect (see **quantum mechanics**) which has no classical analogue. It is due to the interaction between two systems that arises, or could arise, from the continuous exchange of a particle between them. Exchange energy is the origin of **covalent bonding**, of **ferromagnetism** and **antiferromagnetism**, probably of **nuclear forces** (where exchange energy could arise by exchange of π -mesons between nucleons, giving rise to an effective potential which involves an operator which exchanges the spins, isotopic spins and/or positions of the particles) and of numerous other physical phenomena.

Specifically in the case of a covalent bond, the major part of the energy is due to the "electron exchange" between the atoms. The wave function representing two *isolated* atoms may be represented by

$$\psi = \psi_A(1)\psi_B(2)$$

where electron 1 is supposed in interaction with nucleus A and electron 2 interacts with nucleus B. The alternate configuration $\psi_A(2)\psi_B(1)$ is another good description of the system at large internuclear distances. Both

wave functions lead to the same energy (**exchange degeneracy**).

At shorter distances, neither of these approximations alone is an adequate description of the system, since both electrons interact with both nuclei. The total wave function must be constructed as either a symmetrical, or an antisymmetrical linear combination of $\psi_A(1)\psi_B(2)$ and $\psi_A(2)\psi_B(1)$. (In what follows the spin contribution to the equation of the wave function is neglected.)

In a first approximation, the total energy is split up into three contributions: the first is the energy of *interaction of each electron with its proton*, that is the energy (see **Coulomb integral**) of two isolated H atoms; the second is a **Coulomb energy**

$$\int \psi_A(1)\psi_B(2)W\psi_A(1)\psi_B(2)d\tau_1d\tau_2,$$

representing the average electrostatic interaction of each electron cloud with the other, with the nucleus of the other electron, and the electrostatic repulsion of the two nuclei, where W is the perturbation potential; the third contribution is the *exchange integral*:

$$\int \psi_A(1)\psi_B(2)W\psi_A(2)\psi_B(1).$$

At intermediate distance, the contribution of this integral to the total energy (exchange energy) is much larger than that of the Coulomb integral. It is attractive for the symmetrical wave function, and repulsive for the antisymmetrical wave function.

The electron exchange leads thus to a splitting of the energy levels. The exchange energy depends essentially on the *overlaps* of the wave functions $\psi_A(1)$, $\psi_B(1)$ and $\psi_A(2)$, $\psi_B(2)$; it decreases rapidly (exponentially) as the internuclear distance increases. (See **overlap integral**.)

The name "exchange energy" is somewhat misleading since there is no real frequency of exchange of the electrons from one nucleus to the other. In fact the exchange energy results from a greater mobility of the electrons in the fields of the two nuclei, whence there results a lowering of the zero point energy. (See **delocalization energy**.)

EXCHANGE FORCES. If, in the interaction between two nucleons, their charges or spins, or both, are interchanged, the forces which

give rise to the interaction are called exchange forces. They may be pictured as arising through the exchange or virtual mesons between the nucleons. Phenomenologically, however, they are represented in terms of an ordinary potential function $V(r)$, where r is the separation between the nucleons, multiplied by a permutation operator P which exchanges charges, spin, or both. If the wave function of the two particles is totally antisymmetric (in space, spin, and isotopic spin), then the combined exchange of spin and charge is equivalent to the exchange of position, except for a change of sign. A space exchange potential may therefore be written $V(r)P_r$, where $P_r = -P_\sigma P_\tau$, and P_σ, P_τ exchange spin and isotopic spin respectively. The operator P_r has eigenvalues $+1$ or -1 according as the relative orbital angular momentum L of the pair of nucleons is even or odd. This potential is therefore equivalent to $(-1)^L V(r)$, giving rise to attractive or repulsive forces according to the parity of L . The space exchange force is known as a *Majorana force*; forces which exchange spin or charge separately are called *Bartlett* and *Heisenberg* forces, respectively. Nuclear forces are known to have exchange properties of this general kind.

EXCHANGE INTEGRAL. See **exchange energy**.

EXCITATION. (1) Addition of energy to a system, whereby it is transferred from its ground state to a state of higher energy, called an excited state. (2) The field excitation of dynamo machines, meaning the current or voltage of the field circuit. (3) In electron-tube circuits, the input signal of any stage is commonly called the excitation. Thus in a radio receiver, the signal picked up by the antenna supplies the excitation for the first stage, the output of the first supplies the excitation for the next, and so on.

EXCITATION CURVE. In nuclear physics, a graphical relationship between the energy of the incident particles or photons, and the relative yield of a specified nuclear reaction.

EXCITATION ENERGY (EXCITATION POTENTIAL). The energy necessary to bring an atom, molecule, atomic nucleus, etc., from the ground state into an excited state.

EXCITATION FUNCTION, ATOMIC. The **cross section** for the excitation of an atom to a particular excited state expressed as a function of the energy of the incident electrons.

EXCITATION FUNCTION, NUCLEAR. The **cross section** for a particular nuclear reaction expressed as a function of the energy of the incident particle or photon. The term excitation function is sometimes used also as a synonym for **excitation curve**.

EXCITATION LEVELS. See **excited state**.

EXCITATION POTENTIAL. See **excitation energy**.

EXCITATION PURITY. A quantity denoted by p_e and defined by the following relations

$$p_e = \frac{y - y_w}{y_d - y_w} \quad \text{or} \quad p_e = \frac{x - x_w}{x_d - x_w}$$

x and y are the **chromaticity coordinates** of the light considered, x_d and y_d those of the spectral light which has the same hue as the light considered; x_w and y_w are the chromaticity coordinates of the adopted achromatic light. Whether the formula in x or that in y is to be taken depends on which gives the numerator the greater numerical value. For colors for which no spectral light of the same hue can be found, the chromaticity coordinates to be taken for x_d and y_d are those of the corresponding point on the line joining the ends of the spectrum locus (the line of pure purples).

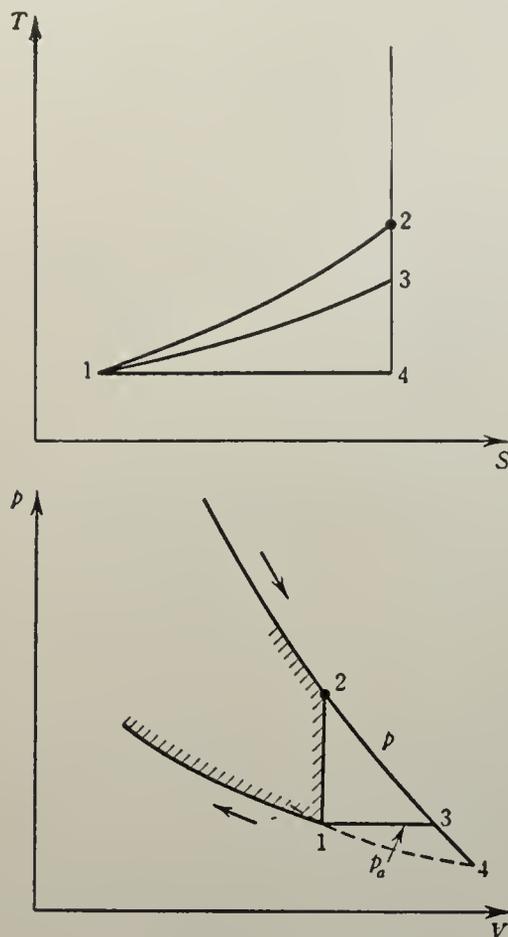

EXCITED STATE. A stationary state having an energy higher than that of the ground state.

EXCITON. A combination of an electron and a hole in a semiconductor or insulator in an excited state. The hole behaves as a positive charge, and it is supposed that the electron is attracted to it to form a state akin to that of a hydrogen atom. The probability of the electron falling into the hole is limited by the difficulty of losing the excess energy, so that the exciton may have a relatively long life. The existence of these states may be inferred from the absorption of light associated with their excitation. (Cf. **positronium**.) Alternatively, an exciton may be thought of as an excited state of an atom or ion, the excitation wandering from one cell of the lattice to another.

EXCLUSION PRINCIPLE. See Pauli exclusion principle.

EXHAUST GAS TURBINE. A gas turbine driven with the exhaust gases from a reciprocating internal combustion engine. Historically, exhaust gas turbines were the first successful gas turbines: they were easier to build than separate efficient gas turbines owing to the comparatively low temperature of the combustion gases.

The exhaust gas turbine utilizes the energy available in the working fluid of an internal combustion engine at release, state 2 in the figure. Ideally, the expansion through the tur-

T,S diagram and p,V diagram for exhaust gas turbine.

bine is isentropic along 23, and the ideal work W_t of the turbine is

$$W_t = \dot{m}(h_2 - h_3),$$

where \dot{m} is the mass rate of flow, and $h_2 - h_3$ is the isentropic enthalpy drop. The reciprocating engine is incapable of utilizing this enthalpy drop because losses due to piston friction along 23 would exceed the work obtainable, as the engine stroke would become excessively large, and the piston force, propor-

tional to the pressure difference $p - p_a$ would be small over most of the additional stroke.

In principle, more work could be obtained if expansion from state 2 could be continued below the atmospheric pressure p_a , to state 4, such that $T_4 = T_1$. However, such a scheme is not practicable owing to the additional complications in the design of the plant which it would entail.

An exhaust steam turbine (Bauer-Wach turbine) operates on the same principle.

EXHAUST LOSS. Loss of work associated with the fact that the working fluid from a reciprocating steam or internal combustion engine is capable of performing further work after exhaust. (See **exhaust-gas turbine**.)

EXHAUST-STEAM TURBINE. See **exhaust-gas turbine**.

EXHAUST (JET) VELOCITY. See **exhaust velocity**.

EXHAUST VELOCITY. The velocity at which a propelling fluid is discharged from a jet-type engine. The exit or exhaust velocity of a thermal engine depends on several parameters which can be subdivided into thermochemical parameters and motor parameters. Thermochemical parameters are: energy content of the fuel, mixing ratio of the propellants, expansion pressure ratio, and degree of combustion. Motor parameters are: thrust, mass of weight flow of propellant, nozzle divergence, difference between nozzle exit pressure, and ambient pressure. Although some of the thermochemical parameters, such as expansion ratio and degree of combustion, are strongly influenced by the motor design, they must be known, or at least be assumed for thermochemical performance calculations. The second group of parameters contains quantities which serve to measure the exhaust velocity (thrust, weight flow), or which depend on the motor design (divergence angle), or on operational conditions, such as the exit-ambient pressure difference. In a given motor, the nozzle dimensions are fixed, hence, for a given chamber pressure, the exit pressure is determined. Therefore, a variation of the pressure difference is due to change of ambient pressure as it occurs during powered ascent.

The exhaust velocity defined by the first group of parameters describes the propellant performance, independent of motor design and

operational conditions, and indicates the impulse, that is, the thrust for a given mass flow and length of time, which can be expected from the propellant in question. Therefore, this velocity is termed "impulse exhaust velocity." If divided by the gravitational constant, it yields the specific impulse, a parameter which depends only on thermochemical data and the expansion ratio.

The second group of parameters defines an exhaust velocity which describes the motor performance. It is determined by the thrust, obtained at a given propellant consumption, and varies with changing ambient pressure. For instance, the over-all thrust increases as the difference of exit minus ambient pressure increases (pressure thrust). Instead of accounting separately for the pressure thrust (as distinguished from the momentum thrust, produced by the discharge of matter), one can add this effect to the momentum thrust (defined as the product of mass flow and exhaust velocity). If, in an ascending rocket the over-all thrust increases and the propellant mass flow remains constant, the exhaust velocity necessarily increases. This illustrates that exhaust velocity is not the physical or thermochemical exhaust velocity but an equivalent velocity which converts instantaneous operational conditions into equivalents of a standard condition (namely exit pressure equal to ambient pressure, i.e., no pressure thrust). For this reason exhaust velocity is better termed *equivalent exhaust velocity*. If this velocity is divided by the gravitational constant, one obtains the specific thrust.

EXHAUST VELOCITY, EFFECTIVE. In jet propulsion terminology, the thrust divided by the mass of propellant flowing per second of time. It appears in the equations:

$$c = \frac{F}{w/g}$$

or

$$c = \frac{F}{\dot{m}} = gI_{sp} = \frac{Fg}{\dot{w}} = c^*C_f = \eta_v c_{th}$$

$$= V_e + \frac{A_e}{\dot{m}}(p_e - p_0)$$

where c is the effective exhaust velocity, F is the thrust, w is the weight of propellant, g is the acceleration of gravity, \dot{m} is the mass flow through motor, I_{sp} is the specific impulse, \dot{w} is

the weight flow of propellant through the motor, c^* is the characteristic velocity, C_f is the thrust coefficient, η_v is the motor velocity correction factor, and $c_{th} = \lambda V_e$, where λ is the nozzle correction factor, and V_e is the exhaust velocity. A_e is the exit area, p_e is the exhaust pressure, and p_0 is the ambient pressure.

The theoretical effective exhaust velocity is given by the equation:

$$c_{th} = \lambda V_e + (p_{eth} - p_0) \frac{A_e}{\dot{m}_{th}}$$

Theoretical and actual values differ because of the losses due to friction and heat transfer. Logical theoretical values of c might range between 3300-9000 feet/second. A typical actual value is on the order of 6300 feet/second. The effective exhaust velocity is an experimentally determined value, but it is not the exhaust velocity actually attained by the motor. In the flow of gas through a rocket nozzle, variations occur in the thermodynamic parameters because of friction, of the continued combustion of the propellant, and of the secondary effects of compressible fluid flow, such as shock waves. For these reasons the effective exhaust velocity is used primarily in solving actual problems.

EXHAUST VELOCITY, THEORETICAL.

Theoretically, the full amount of the lower heat of **combustion** could be utilized in an engine to provide an expansion of the gas down to the datum temperature; this yields a theoretical exhaust velocity. For actual operation, however, this would not be practical, even if the resulting low exit pressure could be attained without overexpansion, since it requires an extremely large area ratio of the nozzle. This ratio could be obtained either by using a short nozzle with a large angle of divergence, or a very long nozzle with a moderate angle of divergence. In the first case, considerable losses result from a decrease in the magnitude of the useful velocity component which lies parallel to the motor axis, in favor of the component normal to the axis. The latter component is of no use for the propulsion. In the second case a very long nozzle would increase the motor weight excessively and thus reduce the overall rocket performance more than the additional heat utilization would increase it. There exists an optimum

compromise between nozzle geometry and heat energy utilization.

EXIT APERTURE. The exit aperture, or image numerical aperture, of an axially symmetrical optical system is $n' \sin \theta'$ where n' is the refractive index in image space and θ' is the angle subtended, at the Gaussian image point, by the radius of the **exit pupil**. (See **numerical aperture**.)

EXIT PUPIL (OR IMAGE-SIDE PUPIL). The Gaussian image of the aperture of an optical system in image space.

EXOTHERMIC REACTIONS. See **thermal coefficients**.

EXOTHERMIC REACTION (EXOERGIC). (1) For exothermic reactions of molecules or between atoms, see **thermal coefficients**.

(2) A nuclear reaction in which, roughly speaking, the maximum kinetic energy of the products exceeds that of the reactants; i.e., one in which there is a net production of energy. More precisely, one for which the Q -value is positive. (See **reaction energy**.)

EXPANSION. (1) For mathematical expansions, see **Taylor series**, **Laplace expansion**, **binomial theorem**, etc. (2) The process of increasing the volume of a system either reversibly, as in a cylinder provided with a piston, or irreversibly, as in the **Joule-Thomson** throttling experiment through a porous plug.

Sometimes the term expansion is applied to describe any process involving a reversible or irreversible decrease in pressure. In most instances both meanings are identical. They are different when either pressure or volume is constant, but it is customary to use the phrases constant-pressure expansion (meaning an increase in volume) and constant-volume expansion (meaning a decrease in pressure).

EXPANSION, COEFFICIENT OF. See **coefficient of thermal expansion**.

EXPANSION AREA RATIO. The ratio of the cross-sectional area at the exit of a rocket motor, or the exit section of a nozzle, to the cross-sectional area of the throat of the motor or nozzle. This quantity is sometimes denoted by the shorter expression, **expansion ratio**, but in that case it should be distinguished from the other meaning of the latter term.

EXPANSION EFFICIENCY. See **enthalpy drop**.

EXPANSION, PARTIAL FRACTION. See **partial fraction expansion**.

EXPANSION RATIO. (1) The ratio of the pressure at a point just outside the rear lip of an exhaust nozzle to the pressure in the combustion chamber. This ratio is important because of its relationship to the **exhaust velocity** of the rocket. (2) The ratio of the area of the exit section of a nozzle to its throat. However, the more common term for this ratio is **expansion area ratio**.

EXPANSION WAVE. (Also called *rarefaction wave*.) A simple wave or progressive disturbance in the isentropic flow of a compressible fluid, such that the pressure and density of a fluid particle decrease on crossing the wave in the direction of its motion.

EXPECTATION. If $F(x)$ is the **distribution function** of a variate x , the expected value of a quantity t depending on x is

$$\int_{-\infty}^{\infty} t dF(x).$$

It is in fact the average or mean value of t over the distribution of x . Analogous expressions apply to multivariate situations.

EXPECTATION VALUE. In quantum mechanics, the expectation value or mean value of a quantity A in a normalized state ψ , for which $(\psi, \psi) = 1$, is given by a scalar product $(\psi, A\psi)$. If ψ is an **eigenstate** of A , then the expectation value is equal to the corresponding **eigenvalue**.

EXPLOSION ENGINE. See **spark ignition engine**.

EXPLOSION WAVES. Gravity waves produced in the atmosphere by large explosions, of which the classical examples are the eruption of Krakatoa in 1883 and the fall of the great Siberian Meteorite in 1908. Each produced barometric oscillations detected at distances of thousands of miles. They are tidal waves and are dispersed, although the velocity of each component wavelength is equal to the velocity of sound at some altitude in the atmosphere. They differ from solar and lunar diurnal and semi-diurnal oscillations in the atmosphere, whose nodes are lines of longi-

tude or latitude in that their amplitude is greatest in the troposphere, the others having their maximum amplitude at several times the height of the tropopause.

EXPONENT. Also called index, it is the power to which an expression is raised. The concept of exponent plays an important role in obtaining the solution of a second-order linear **differential equation** in the neighborhood of a regular **singular point**. For if we assume a formal solution

$$w = (z - c)^\alpha [1 + a_1(z - c) + a_2(z - c)^2 + \dots],$$

and seek to determine the coefficients a_i by substituting into the differential equation and comparing coefficients, we get an equation (called the **indicial equation**), determining two values of α , which are called the exponents of the equation at the point c . The concept can be generalized directly for equations of higher order.

"EXP-6" POTENTIAL. See **interatomic potential**.

EXPONENTIAL DISTRIBUTION. A distribution of the form

$$dF = \frac{1}{\sigma} \exp \left\{ -\frac{|x - m|}{\sigma} \right\} dx, \quad m \leq x \leq \infty.$$

The distribution

$$dF = \frac{1}{2\sigma} \exp \left\{ -\frac{|x - m|}{\sigma} \right\} dx, \quad -\infty \leq x \leq \infty$$

is sometimes called the double exponential distribution.

EXPOSED THREAD CORRECTION.

When temperatures are measured with the aid of a liquid-in-glass (e.g., mercury) thermometer, it is necessary for the whole of the thermometric fluid to be at the measured temperature. Normally this is impossible, because the thread must emerge and be visible to the eye. Consequently, in accurate measurements it is usual to apply a correction, known as the exposed or emergent stem correction. The correction is proportional to the average temperature of the stem outside the bath; the latter can be measured with the aid of a special thermometer (known as a Mahlke (thread) thermometer) provided with a very large bulb.

The reading of the main thermometer should be corrected by an amount

$$a(t - t_0)c.$$

Here a is the length of the exposed thread; t is the temperature reading; t_0 is the mean temperature of the exposed thread (measured by the auxiliary thermometer); and c is a coefficient which depends on the properties of the glass and the thermometer fluid.

With temperatures of the order of 300°C, the exposed thread correction may amount to as much as 10°C. The correction can be reduced or nearly eliminated by completely submerging the thermometer, but that is possible only very rarely.

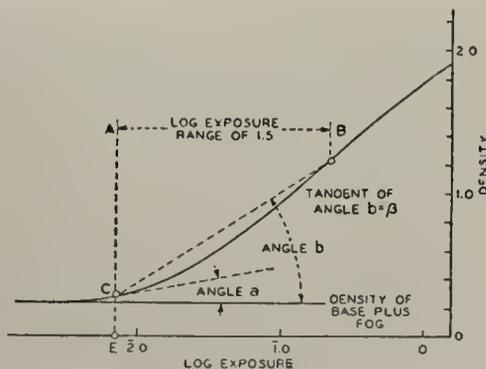

EXPOSURE. A measure of photographic stimulus defined as

$$\int I(t) dt,$$

where $I(t)$ is the **illumination** at time t .

EXPOSURE-DENSITY RELATIONSHIP.

The response of a sensitive material, as shown by the relationship between density and exposure, is usually represented by a curve in which density is plotted against the *logarithm* of the exposure. This curve is known as (1) the *D log E curve*; (2) the *H & D curve*, after Hurter & Driffield, two English investigators who were the first to plot such curves; and (3) as the *characteristic curve* since it indicates the principal characteristics of a sensitive material insofar as the relationship between exposure, development and density is concerned.

D log E curve. (From Neblette, *Photography, Its Materials and Processes*, 5th ed., D. Van Nostrand Company, Inc., Princeton, 1952).

EXPOSURE, PHOTOGRAPHIC. The product of **illuminance** I and time t of exposure. This definition assumes that the reciprocity

law holds. Sometimes the exposure is taken as It^p , where p is a constant of the particular photographic emulsion and has a magnitude approximately equal to unity.

EXTENDED SINE RELATIONSHIP. If n, n' are indices of refraction, y, y' are distances from the optical axis, θ, θ' are the angles light rays make with the optical axis in object, image space respectively and ϕ is the power of the optical system, then

$$ny \sin \theta + n'y' \sin \theta' = yy'\phi$$

is the extended sine relationship. When the approximation

$$yy'\phi \cong 0$$

is valid this is equivalent to Abbe's sine condition.

EXTENSION IN PHASE. Term introduced by Gibbs for volume elements in gamma-space.

EXTENSION, SIMPLE. See simple shear; simple extension.

EXTENSIVE VARIABLES. Properties such as mass m and volume V are defined for the system as a whole, and called in thermodynamics extensive variables or extensive properties. They always may be expressed as integrals over the whole system; i.e.,

$$m = \iiint_V \rho dx dy dz$$

where ρ is the density. (See also **thermodynamic system**.)

EXTENT OF REACTION (OR DEGREE OF ADVANCEMENT OF CHEMICAL REACTION.) (See conservation of mass in closed systems.) Consider a closed system, i.e., a system which does not exchange mass with the external world. If a reaction, either chemical or physico-chemical (e.g., a change of phase), takes place inside this system, the mass balance equation for the individual species taking part in the reaction can be written:

$$\begin{aligned} m_1 - m_1^0 &= \xi \nu_1 M_1 \\ m_2 - m_2^0 &= \xi \nu_2 M_2 \\ &\dots \dots \dots \\ m_n - m_n^0 &= \xi \nu_n M_n \end{aligned}$$

where m_1^0, m_2^0, m_n^0 are the initial masses of components 1, 2 \dots n and $\nu_1, \nu_2, \dots, \nu_n$ are the **stoichiometric coefficients**. ξ is called the extent of the reaction (Th. De Donder). The extension of this concept to several simultaneous reactions is immediate: to each distinct reaction ρ corresponds a distinct value ξ_ρ . The rate V_ρ of reaction ρ is the time derivative of ξ_ρ

$$V_\rho = \frac{d\xi_\rho}{dt}$$

EXTERNAL FORCE. See force, external or active.

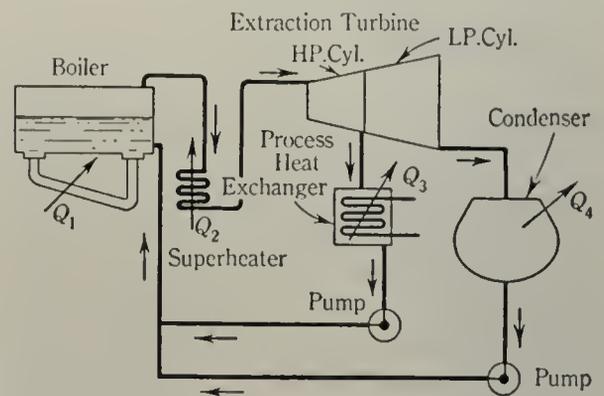

EXTERNAL HEAT OF EVAPORATION. See latent heat.

EXTERNAL OPTICAL DENSITY. External optical density or reflection density is the logarithm to base ten of the reciprocal of the (total) reflection factor.

EXTINCTION. The decrease in intensity of radiation traversing a medium due to both absorption and scattering.

EXTINCTION COEFFICIENT (ABSORPTION COEFFICIENT.) The internal absorption factor of an infinitesimally thin layer of a medium divided by the thickness of the layer.

EXTRACTION TURBINE. In order to increase the overall economy of a plant which requires process heat, it is advantageous to use a back-pressure turbine. The use of a back-pressure turbine becomes inconvenient when

Extraction turbine and related equipment.

the heat and power requirements are not well matched. Furthermore, if the temperature difference between the maximum temperature available and that required for process heating is small, the power produced will be small

and may not warrant the capital cost. In such cases it is possible to use an extraction turbine (or *pan-out turbine*) in which some steam is extracted from a turbine between stages at an appropriate temperature. The remainder of the steam is expanded to the lowest temperature available. This scheme enables variations in power and heat requirements to be easily accommodated.

EXTRANEIOUS. An extraneous root of a method of solving an **algebraic equation** E_1 is a root of an equation E_2 introduced by the method and having some of its roots in common with E_1 , which is not also a root of E_1 where the equation E_2 , introduced by the method, has some of its roots in common with E_1 . For example, let E_1 be the equation $\sqrt{x^2} = 3$ and E_2 the equation $x^2 = 9$ obtained by squaring both sides of E_1 .

EXTRAPOLATED END-POINT. In the theory of **neutron transport**, the flux distribution far from sources, boundaries, interfaces, appears as identical with the solution to an appropriate diffusion equation, adjusted to vanish at a point (z_0) outside the boundary-surface of the medium. This point is known as the extrapolated end-point.

EXTRAPOLATION. This process may be contrasted with **interpolation** when the function is required at a point outside the range of the x_i . The same methods are applied.

EXTREMAL. See **variations, calculus of.**

EXTREME PATH. See **Fermat principle.**

EYKMAN FORMULA. An empirical relationship for the molar refraction of a liquid, of the form:

$$R = \frac{M(n^2 - 1)}{\rho(n + 0.4)} = \frac{V(n^2 - 1)}{n + 0.4}$$

in which R is the **molar refraction** for a given optical frequency, n is the **index of refraction** for that frequency, M is the molecular weight, V is the **molecular volume**, and ρ is the density.

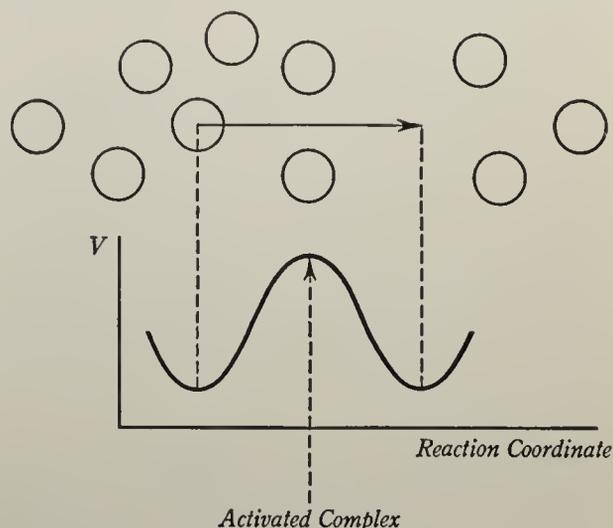

EYRING ACOUSTICAL ENERGY EQUATION. See **Franklin equation.**

EYRING THEORY OF REACTION RATES. See **absolute reaction rate theory.**

EYRING THEORY OF TRANSPORT PROCESSES. The **absolute reaction rate theory** has been applied by Eyring and others to transport processes in dense gases and liquids. The fundamental equation is

$$k = \left(\frac{kT}{h}\right) \exp\left(-\frac{\Delta G^\ddagger}{kT}\right). \quad (1)$$

It is assumed that in all these transport processes (viscosity, diffusion, thermal conductivity) the basic kinetic process is the motion of a molecule to a vacant site near it. In order to squeeze through the "bottleneck" formed by its nearest neighbors, the wandering molecule must pass through a region of high energy (see figure). One may apply the concepts of

activated complex, activation free energy, etc., exactly as in the theory of chemical rate processes (see **absolute reaction rate theory**) to obtain explicit expressions for the transport coefficients. The main weakness of the theory is the use of the equilibrium assumption for rates with relatively small activation energies (see **equilibrium theory.**) It is also not certain that one may consider the motion of simple molecules without taking account the perturbation of their neighbors.

F

FACTOR. See factor group, integrating factor, etc.

FACTOR ANALYSIS. Suppose we have a multivariate complex of variables x_1, x_2, \dots, x_k . We may be prepared to assume an underlying set of variables z_1, z_2, \dots, z_p , with $p < k$ such that each x is a linear function of the z 's together with a part specific to itself,

$$x_i = a_{i1}z_1 + a_{i2}z_2 + \dots + a_{ip}z_p + s_i.$$

Factor analysis is the name given to the techniques for estimating the various parameters in a model of this kind. Many such techniques exist, the most satisfactory from a theoretical point of view being usually laborious in computation. Electronic computers have proved very useful here.

The z 's are known as common factors, the s 's as specific factors. If one of the z 's contributes to all the x 's, it is called a *general factor*, while one that contributes to some but not to others is called a *group factor*. The a 's are called the *factor loadings* or *saturations*; a common factor with both positive and negative loadings is called *bipolar*. The proportion of the variance of a particular x accounted for by the common factors is called the *communality* of that x .

FACTOR-GROUP. If the subgroup N of a group G is normal (see **conjugate elements**) we can define a multiplication for its cosets as follows: If q, r are elements of G , and Q and R are cosets of N with q in Q and r in R , then the product QR is defined (uniquely since N is normal) as that coset which contains the element qr . Such a group is denoted by G/N and is called a factor-group; its number of elements is equal to the index (see **coset**) of N in G .

FACTORIAL. If n is a positive integer, factorial n means the product $1 \cdot 2 \cdot 3 \cdots n$. It may be denoted by the symbols \underline{n} or $n!$, but the latter form is generally preferred. For the general complex number z , we define $z! = \int_0^\infty u^z e^{-u} du$. Thus $z! = \Gamma(z + 1)$, where Γ denotes the **gamma function**.

FACTORIAL COEFFICIENTS. Stirling numbers, so called from their definition.

FACTORIAL EXPERIMENT. An experiment whose treatments are made up of combinations of the variants of several factors. The factor variants may be qualitative—e.g., crop varieties—or quantitative—e.g., amounts of fertilizer applied—but in either case are referred to as levels. Referring to the observations for convenience as yields, any **contrast** between the mean yields for different levels of one factor, averaged over all levels of the other factors in the experiment, is said to belong to the *main effect* of the factor. The mean yields for all combinations of the levels of two different factors, averaged over all levels of the other factors, can be set out in a two-way table; a contrast between the entries in this table which is orthogonal to all the main effect contrasts is said to belong to the first order interaction between the two factors. Interactions of higher order are similarly defined.

The underlying notion behind the analysis into main effects and interactions is that of additivity of the effects of the different factors. If the effects are perfectly additive, all interactions are zero; the presence of first or higher order interactions discloses the presence of less or more complicated departures from additivity. In many fields of application, interactions involving 3 or more factors are often small enough to be neglected.

One of the most useful types of factorial experiment is that in which each factor has the same number of levels. An experiment with s factors each at p levels is called an s^p experiment, and each replicate will contain s^p treatments. In practice, p is often 2 or 3, but if several factors are to be investigated s^p may be large and heterogeneity of the experimental material may lead to loss of accuracy. To avoid this, each replicate may be laid down in a number of blocks in such a way that the contrasts between blocks coincide with treatment contrasts that are of little interest, such as the higher order interactions. This device is known as *confounding*.

If the true values of the high order interactions are zero, their estimates will provide estimates of experimental error. An experiment with many factors can then be carried out in a single replication, a suitable estimate of error still being available. Extending this notion, it is possible to carry out an experiment using only a suitably chosen fraction $1/g$ of all the possible treatment combinations. In this case it is found that the contrasts that can be estimated are sums of groups of g main effect and interaction contrasts; each member of such a group is called an *alias* of all the others. If it can be arranged that all the aliases of the contrasts that are of interest are high order interactions, the interpretation of the results remains reasonably unambiguous. Experiments with single or fractional replication enable a large number of factors to be investigated in a single experiment without the amount of experimental material reaching unmanageable proportions.

FACTOR OF SAFETY. See **safety factor**.

FACTOR THEOREM OF ALGEBRA. If $(x - r)$ is a factor of a polynomial $P(x)$, then $x = r$ is a *zero* of the polynomial function $P(x)$, and a *root* of the polynomial equation $P(x) = 0$. Conversely, if $x = r$ is a zero of the polynomial or a root of the equation, then $(x - r)$ is a factor of $P(x)$. (See also **algebraic equations**.)

FAHRENHEIT TEMPERATURE SCALE. See **temperature**.

FAILURE. The inability of a **structure** or a structural member to perform its proper function causes a condition known as failure. This condition may be the result of sudden fracture as in the case of brittle materials or the excessive **deformation** of ductile materials. Another cause of failure is a lack of equilibrium between the external **loads** and resisting forces such as exists in structures which fail by sliding or overturning.

FAILURE, THEORIES OF. A term most often applied to yielding rather than more complete failure. Historically, in part because of a confusion between yielding and fracture, the criteria of failure include maximum normal stress, maximum extensional strain, maximum elastic energy, maximum shear strain or distortional energy, maximum shear stress, all possible combinations of the

invariants of stress for isotropic materials, and many others. Yielding of metals is only slightly effected by hydrostatic pressure and thus depends upon shear stress. For isotropic metals, the data seems to lie between the maximum shear stress hypothesis of Tresca and the J_2 criterion of Maxwell-Huber-Henky-Mises-Nadai.

FAIR GAME. In **games theory**, a game in which the participants have the same expectation of gain. This is not necessarily the same thing as having the same probability of success, since their stakes may be different.

FALSE POSITION, METHOD OF. See *Regula falsi*.

FALTUNG. Synonym of **convolution**.

FAMILY. A synonym of **aggregate**, **set**, etc., but usually used of a set (called an n -parameter family), which is determined by the values of n real (or complex) parameters. Thus the set of all circles in the plane is a 3-parameter family.

FAMILY OF SURFACES. See **surfaces**, **family of**.

FARAD. A unit of capacitance, abbreviation f or fd. The farad is the capacitance of a **capacitor** (condenser) which acquires a charge of one coulomb when a steady potential difference of one volt is maintained across its terminals. The microfarad (10^{-6} f) and the micromicrofarad (picofarad) (10^{-12} f) are used as units of capacitance much more often than is the farad.

FARADAY. The quantity of electric charge associated with one gram equivalent of an electrochemical reaction. It is equal to the product of the **Avogadro constant** and the charge on the **electron**. It has the value 9.651 abamperes per gram equivalent or 96.51 coulombs per gram equivalent.

FARADAY EFFECT. When a transparent isotropic medium is in a strong magnetic field there is a rotation of the plane of vibration of polarized light which is transmitted through the medium in the direction of the field. The direction of rotation depends on whether the velocity of the light is parallel or antiparallel to the magnetic field. The angle of rotation α is given by

$$\alpha = \omega H$$

where l is the length of the path traversed in a magnetic field of strength H and ω (sometimes C is known as the *Verdet constant*. The Faraday effect is one of the special cases mentioned under **rotation of the vibration plane**. (See Robertson, *Introduction to Optics*, 4th ed., D. Van Nostrand Co., Inc., Princeton, 1954.)

FARADAY LAW OF ELECTROMAGNETIC INDUCTION. When the magnetic flux, ϕ , linking a circuit, changes, an electromotive force given by

$$\varepsilon = - \frac{d\phi}{dt}$$

is induced in the circuit.

FAST EFFECT, INTERACTION. In reactor theory, that part of the **fast fission factor** stemming from fast fissions in one fuel rod caused by neutrons born in fission in a different rod.

FAST FISSION FACTOR. In reactor theory, this factor, denoted by ϵ , expresses the average number of fast neutrons slowing down past the fast fission threshold of U-238 or U-235, per neutron produced by fission in the system. A different definition, encountered occasionally, is the ratio of all neutrons produced per unit time by fission to the number of neutrons produced per unit time by thermal neutron induced fission.

FATIGUE. (1) The tendency for a metal to fracture under repeated stressing considerably below the ultimate tensile strength. In a common method of test, a polished specimen is rotated rapidly and subjected to alternate flexure. The *fatigue limit* or *endurance limit* of a metal or alloy is that stress below which failure will presumably not occur in an infinite number of cycles. When such a limit does not exist, the term is often applied to the stress causing fracture in a specified large number of cycles.

When alternating cycles cause appreciable alternating plastic deformations, fatigue occurs in a small number of cycles. This behavior is known as low-cycle fatigue. (See **shakedown**.)

FECHNER FRACTION. If the eye can just distinguish an object whose **brightness** differs by an amount dB from a large field of brightness B , the contrast sensitivity may be meas-

ured by dB/B , sometimes called the Fechner fraction.

FEEDBACK. General Concept. Feedback is said to be present in a system if at least one pair of physical quantities in the system, say $q_1(t)$, $q_2(t)$ are interrelated in such a way that q_1 affects q_2 and q_2 affects q_1 , the two relationships being independent. Thus if the relationships between the system quantities may be written

$$q_1(t) = f_1\left(\frac{d}{dt}\right) \cdot q_2(t) + \text{possible contributions from other quantities}$$

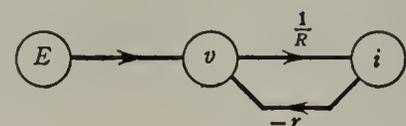

$$q_2(t) = f_2\left(\frac{d}{dt}\right) \cdot q_1(t) + \text{possible contributions from other quantities}$$

where $f_1(x)f_2(x) \neq 1$, then the feedback exists. Which direction of dependence is forward and which backward is largely a matter of arbitrary convention, though it is usual to associate the forward direction with a main causatory chain from the input to the output of the system: then any dependence by which a quantity earlier in the causatory chain is affected by a later one is a feedback. The essential point however, as stated above, is the existence of a two-way dependence of the above form. Surprisingly perhaps, the majority of systems are feedback systems. To illustrate this, consider a battery of e.m.f E and internal resistance r connected to a load resistance R . The current i is related to E by the single relation $i = E/(r + R)$ and therefore no feedback exists between i and E . If we introduce the voltage drop v across the load, however, we have the equations

$$v = E - ir$$

$$i = v/R$$

and we note that there exist two independent relations between v and i . Specifically, v controls i through the medium of the load resistance R , whereas i controls v through the medium of the battery internal resistance r . These equations may be pictorially depicted in a dependence or **signal flow diagram**:

Signal flow diagram.

The existence of the feedback existing between v and i is displayed here in the form of a closed loop threading the two quantities, called a *feedback loop*.

Although even such a simple system as this can be therefore considered as a feedback system, the more important class of feedback systems are those in which a feedback loop exists which includes an active element, i.e., a system element associated with a source of power, for instance, an electronic tube (with its source of anode voltage supply), a rotary machine amplifier (with its prime mover), a magnetic amplifier (with its a.c. power supply) or their equivalents in other fields of engineering. It is to such systems that feedback theory is mainly applied. It is also only such systems which are capable of sustained oscillations or instability, a property which distinguishes them from purely passive systems or systems including active elements which are not included in feedback loops.

This last statement is, however, only applicable to what might be called engineering systems. Feedback theory has been applied with some measure of success to other fields, notably economics and ecology. It is known that economic systems are liable to sustained oscillations (the so-called booms and slumps) as also are, for instance, the population densities of certain interacting animal species (e.g., lynxes and foxes). What, if anything, in these systems corresponds to an active element is difficult to assess.

The main reasons for introducing feedback into a system are as follows: (1) to modify the gain-frequency characteristic of a system; this includes, for instance, modifying the degree of stability of the system, modifying its cut-off frequency, making the gain more uniform over the working band of frequencies, etc.; (2) to minimize the effects of non-linearities of a system; (3) to minimize the effects of the variation of system parameters; (4) to minimize the output noise level of a system; (5) to modify, particularly in feedback amplifiers, the input and output impedances of the amplifier; (6) to limit the amplitude of one or more system quantities, e.g., torque in an electro-mechanical control system.

Single Loop Analysis. In a system containing a single feedback loop relating two quantities $q_1(t)$ and $q_2(t)$ we may write

$$q_1(t) = \theta_1(t) + \beta \left(\frac{d}{dt} \right) \cdot q_2(t)$$

$$q_2(t) = \mu \left(\frac{d}{dt} \right) \cdot q_1(t)$$

where $\theta_1(t)$ is an external input to the quantity $q_1(t)$. These equations, eliminating $q_1(t)$, may be written, dropping the brackets,

$$\frac{q_2}{\theta_1} = \frac{\mu}{1 - \mu\beta}$$

or, if we limit our attention to steady-state conditions at an angular frequency ω , writing $q_2(t) = Q_2 e^{i\omega t}$, $\theta_1(t) = \Theta_1 e^{i\omega t}$

$$\frac{Q_2}{\Theta_1} = \frac{\mu(i\omega)}{1 - \mu(i\omega)\beta(i\omega)} \equiv G(i\omega)$$

where $G(i\omega)$ is the output-to-input or gain frequency-function of the system, its modulus giving the amplitude ratio of q_2 and θ_1 , its phase, the phase advance of q_2 relative to θ_1 .

The chief effects of the feedback dependence β may be stated as follows:

(1) $G(i\omega)$ is multiplied at every frequency by the factor $\{1 - \mu(i\omega)\beta(i\omega)\}^{-1}$ i.e., the output-to-input amplitude ratio is multiplied by $|1 - \mu\beta|^{-1}$ and the output-to-input phase advance is reduced by $\text{ph}(1 - \mu\beta)$.

(2) Considering β to be a constant function but μ to vary (due, for instance, in an electronic amplifier to tube aging), logarithmic differentiation of the above expression for G gives

$$\begin{aligned} d \log G &= d \log \mu + \frac{\mu\beta}{1 - \mu\beta} d \log \mu \\ &= \frac{1}{1 - \mu\beta} d \log \mu \end{aligned}$$

or

$$\begin{aligned} d\{\log|G| + i \text{ph } G\} \\ &= \frac{1}{1 - \mu\beta} d\{\log|\mu| + i \text{ph } \mu\}. \end{aligned}$$

Thus, if and only if $\mu\beta$ is real and $\neq 1$,

$$\begin{aligned} d \log|G| &= \frac{1}{1 - \mu\beta} d \log|\mu| \\ d \text{ph } G &= \frac{1}{1 - \mu\beta} d \text{ph } \mu. \end{aligned}$$

That is, the variation in the gain (expressed in nepers or decibels), for a given variation in μ

expressed in the same units, is multiplied by $\frac{1}{1 - \mu\beta}$ and so is the variation in the phase of the gain function for a given phase change in μ .

It should be noted here that normally, over the pass-band of a feedback amplifier $|\mu\beta| \gg 1$ and $\text{ph } \mu\beta \doteq \pi$ i.e., $\mu\beta$ is sensibly large and negative real. Note further that as $|\mu\beta| \rightarrow \infty$, $G \rightarrow \frac{1}{\beta}$ and is thus unaffected by μ variation.

(3) The output noise level due to any source of noise injected into or developed in any part of the μ -sequence is multiplied by $|1 - \mu\beta|^{-1}$, assessed at noise frequency. The same is true of the effect of non-linearities in the μ -sequence, since these, by creating signal components at new frequencies (modulation products) may be considered as "noise" sources.

The simple concepts and properties above, however, are inadequate for the analysis of more complex, particularly multi-loop systems, if only for the reasons that in practice the addition of the β -sequence often modifies the μ -sequence, whereas μ has been assumed the same whether β is present or not, and that in practice it is very often difficult to disentangle the μ -sequence from the β -sequence. Some aspects of the more advanced theory are given under various separate headings, notably **stability**, **sensitivity**, **return difference**, **signal flow diagrams**, etc.

FEED-WATER HEATING. The process whereby the feed-water to the boiler is pre-heated by the use of steam bled from the power plant (turbine) between stages. This causes an increase in the efficiency of the plant. (See **carnotization**.)

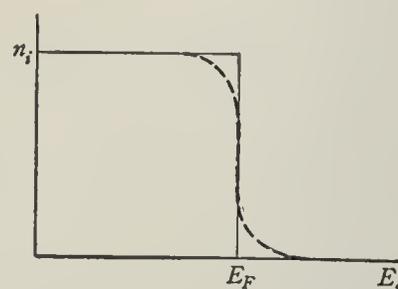

FERMAT'S PRINCIPLE. See **optical path**.

FERMI CONSTANT. A universal constant appearing in **β -disintegration theory**, expressing the strength of the interaction between the transforming nucleon and the electron-neutrino field. Its value is between 10^{-48} and 10^{-49} g cm⁵ sec⁻², and it is usually denoted by the symbol g or G . (See also **coupling constant**.)

FERMI-DIRAC DISTRIBUTION FUNCTION. In a **Fermi-Dirac gas** the number of particles, n_i , in a state of energy E_i , at the absolute temperature T is

$$n_i = \frac{1}{e^{(E_i - E_F)/kT} + 1}$$

where k is the **Boltzmann constant** and E_F is the **Fermi energy**. If $kT \ll E_F$ this function is nearly unity for $E_i < E_F$ and nearly zero

Fermi-Dirac distribution function for a gas at very low temperatures.

for $E_i > E_F$. The gas is then said to be degenerate, and only the particles in the range of energy levels of width kT about E_F are available for conduction, etc.

FERMI-DIRAC GAS. An assembly of independent particles obeying **Fermi-Dirac statistics (fermions)**. The essential property of such particles is that they obey the **Pauli exclusion principle** of quantum mechanics, which requires that no two particles may be in exactly the same state. If the gas is very dense, this requirement may mean that the particles must occupy a wide range of **energy levels**, much larger perhaps than can be supplied by thermal energy. It can be shown by statistical mechanics that in such a degenerate gas (of which the free electrons in a metal are the standard example) only a small proportion of the particles contribute to such properties as the susceptibility, specific heat, conductivity. (See also **quantum statistics**.)

FERMI-DIRAC LIQUID. A liquid whose constituent particles are **fermions**. The best known example is liquid He₃.

FERMI-DIRAC STATISTICS. In the case where the particles in a system of independent particles satisfy the Pauli exclusion principle, there will be either just one possible **macrostate** or none for a given set of numbers n_i of particles in the i -th single particle level, depending on whether or not all n_i are equal to zero or unity. In the first case the possible macrostate is the one corresponding to an anti-symmetric superposition of all possible **microstates**. This means that in Fermi-Dirac statistics all macrostates corresponding to a set of n_i , none of which is larger than unity, have the same weight, while any macrostate corre-

sponding to a set of n_i of which at least one is larger than unity has zero weight. (See also **quantum statistics**.)

FERMI ENERGY. According to the free electron theory of metals the electrons form a dense **Fermi-Dirac gas**, whose energy is very high even at very low temperatures. The Fermi energy is a measure of this, but the term seems to be used indiscriminately to refer either to (a) the energy E_F occurring as a parameter in the **Fermi-Dirac distribution function** and measuring the highest occupied level at very low temperatures, or to (b) the average energy of the electrons, which is $\frac{3}{5}E_F$. In most metals the Fermi energy is of the order of a few electron volts. The usage (b) is recommended, (a) being referred to as the **Fermi level** (it being, in fact, the **chemical potential** of the electrons).

FERMI HOLE. The depletion region surrounding an electron in the energy band theory of solids. As a result of electron correlations and **exchange** effects, there is a region surrounding each electron in which there is less than normal probability of finding other electrons.

FERMI LEVEL. The point on an **energy level diagram** corresponding to the top of the Fermi distribution; or the energy level (in a semi-conductor) for which the **Fermi-Dirac distribution function** has a value of $\frac{1}{2}$. It is thus the **thermal potential** of a Fermi-Dirac system of independent particles. Usually applied to a **degenerate gas**, where the Fermi level coincides with the top of the particle distribution.

FERMI LEVELS, QUASI. In a **semiconductor** a potential energy defined so as to give either the number of **holes**, or of electrons in the **conduction band**, when the material is not in thermal equilibrium, as if it were the **Fermi level**.

FERMION. A particle obeying **Fermi-Dirac statistics**.

FERMI OSCILLATOR. A system capable of only two **energy levels**.

FERMI PERTURBATION. See **Fermi resonance**.

FERMI RESONANCE. In a polyatomic molecule the accidental degeneracy of two

vibrational energy levels belonging to the same species, leading to **perturbation** (mutual "repulsion") of the "original" energy levels E_n^0 and E_i^0 . If ψ_n^0 and ψ_i^0 are the "original" eigenfunctions, the matrix element W_{ni} of the perturbation function is given by

$$W_{ni} = \int \psi_n^0 W \psi_i^0 d\tau$$

where W is essentially given by the anharmonic (cubic, quartic, ...) terms in the potential energy (see **vibrational energy levels of a molecule**).

If the separation $\delta = E_n^0 - E_i^0$ is small (close resonance), the energy E of the perturbed energy levels is given by

$$E = \bar{E}_{ni} \pm \frac{1}{2} \sqrt{4|W_{ni}|^2 + \delta^2}$$

where $\bar{E}_{ni} = \frac{1}{2}(E_i^0 + E_n^0)$. If δ is large compared to $2|W_{ni}|$ the energy of the perturbed levels is given by

$$E = \bar{E}_{ni} \pm \left[\frac{\delta}{2} + \frac{|W_{ni}|^2}{\delta} \right].$$

The eigenfunctions corresponding to the perturbed energy levels are given by

$$\psi_n = a\psi_n^0 - b\psi_i^0$$

$$\psi_i = b\psi_n^0 + a\psi_i^0$$

where

$$a = \left[\frac{\sqrt{4|W_{ni}|^2 + \delta^2} + \delta}{2\sqrt{4|W_{ni}|^2 + \delta^2}} \right]^{\frac{1}{2}}$$

$$b = \left[\frac{\sqrt{4|W_{ni}|^2 + \delta^2} - \delta}{2\sqrt{4|W_{ni}|^2 + \delta^2}} \right]^{\frac{1}{2}}.$$

Due to the interaction of rotation and vibration the Fermi resonance will as a rule also cause a change in the effective B values (see **rotational energy levels of a molecule**) of the interacting vibrational levels. If B_n^0 and B_i^0 are the B values for the unperturbed levels, the actual B values are given by

$$B_n = a^2 B_n^0 + b^2 B_i^0,$$

$$B_i = b^2 B_n^0 + a^2 B_i^0,$$

where a and b are the constants defined above. Since $a^2 + b^2 = 1$, it follows that

$$B_n + B_i = B_n^0 + B_i^0$$

that is the sum of the B values is unchanged by the perturbation.

FERMI TEMPERATURE. The degeneracy temperature of a **Fermi-Dirac** gas, defined by E_F/k , where E_F is the energy of the **Fermi level**, occurring as a parameter in the **Fermi-Dirac distribution function**. For the free electrons in a metal, this temperature is of the order of tens of thousands of degrees, so that the gas is highly degenerate.

FERMI THEORY OF BETA DECAY. The Fermi theory of β -decay was proposed in 1934 in analogy with quantum electrodynamics. It gives the probability P of the ejection, in unit time, of a β -particle whose energy lies between E and $E + dE$ as

$$PdE = f(Z, E)pE(E_{max} - E)^2dE$$

where p is the momentum of the electron. Here E is expressed in units of mc^2 and p in units of mc . $f(Z, E)$ is a slowly varying function of nuclear charge Z and energy.

FERMI THEORY OF COSMIC RAY ACCELERATION. A theory in which "collisions" are assumed to take place between charged cosmic ray particles and the magnetic fields associated with turbulent interstellar gas clouds. A charged particle will be reflected with increased energy if the gas cloud is moving toward it, and with decreased energy in an overtaking collision. Since more collisions per unit time will occur with gas clouds moving toward a particle than away from it, an average net gain of energy per collision results. Many such collisions can account for the high energies found in cosmic ray particles.

FERROELECTRIC EFFECT. The phenomenon whereby certain crystals may exhibit a spontaneous **dipole moment** (which is called ferroelectric by analogy with **ferromagnetic**—exhibiting a permanent magnetic moment). The effect in the most typical case, barium titanate, seems to be due to a **polarization catastrophe**, in which the local electric fields due to the polarization itself increase faster than the elastic restoring forces on the ions in the crystal, thereby leading to an asymmetrical shift in ionic positions, and hence to a permanent dipole moment. Ferroelectric crystals often show several **Curie points**, **domain structure hysteresis**, etc., much as do ferromagnetic crystals.

FERROMAGNETIC RESONANCE. The apparent **permeability** of a magnetic material

at **microwave frequencies** is affected (in the presence of a transverse, steady field) by the precession of electron orbits in the atoms. If the microwave frequency equals the precession frequency, **resonance** occurs and the apparent permeability reaches a sharp maximum. The resonance frequency depends upon the strength of the transverse field. Thus, a thin film of a ferromagnetic substance placed in a static magnetic field H is found to be capable of absorbing from an oscillating field whose magnetic vector is perpendicular to H at a frequency given by

$$\omega = \left(\frac{ge}{2mc} \right) (BH)^{1/2}$$

where B is the magnetic induction associated with H , e and m are the charge and mass of the electron, c is the velocity of light, and g is very near to 2, the **Landé factor** for free electrons.

FERROMAGNETISM, HEISENBERG THEORY. See Heisenberg theory of ferromagnetism.

FERROMAGNETISM, STATISTICAL TREATMENT. See cooperative phenomena.

FEYNMAN METHOD. In **neutron transport theory**, a method for the analysis of the integral equation form of the theory. We assume that for the system in question we can solve the one velocity integral equation (with isotropic scattering) for each velocity v . Thus, we generate a set of eigenfunctions $u_i(\mathbf{r};v)$ for any fixed v . The solution to the full integral equation is expanded in terms of these functions, thus reducing the full equation to a system of integral equations in v only. In certain cases the set u_i may be replaced by the set of solutions to the diffusion equation without severe loss of accuracy. (See **integral transport equation**.)

FEYNMAN DIAGRAM. See Feynman positron theory.

FEYNMAN POSITRON THEORY. In 1949 Feynman developed a theory the purpose of which was to simplify all calculations involving positrons and electrons interacting with external fields. The theory was then extended to include interactions between the particles, and the resulting theory was proved equivalent to the standard procedure of **quantized**

field theory. Feynman's theory gives a completely new physical viewpoint for the interacting process, permitting visualization and ease of understanding. We first illustrate it for the non-relativistic theory.

Consider the Schrödinger equation for a single particle, $i\hbar\partial_t|t\rangle = H|t\rangle$. The state vector at time $|t_2\rangle$ is related to the one at time $|t_1\rangle$ by the time-translation operator $U(t_2, t_1) = \exp(-iH(t_2 - t_1)/\hbar)$

$$|t_2\rangle = U(t_2, t_1)|t_1\rangle = \exp[-iH(t_2 - t_1)/\hbar]|t_1\rangle. \quad (1)$$

In the Schrödinger position representation $\psi(x, t) = \langle x|t\rangle$ is the Schrödinger wave function at time t , in terms of which (1) becomes

$$\begin{aligned} \langle \mathbf{x}_2|t_2\rangle &= \psi(\mathbf{x}_2, t_2) \\ &= \int \langle \mathbf{x}_2|U(t_2, t_1)|\mathbf{x}_1\rangle \langle \mathbf{x}_1|t_1\rangle d^3x_1 \\ &= \int d^3x_1 K(\mathbf{x}_2 t_2; \mathbf{x}_1 t_1) \psi(\mathbf{x}_1 t_1) \end{aligned} \quad (2)$$

where

$$\begin{aligned} K(\mathbf{x}_2 t_2; \mathbf{x}_1 t_1) &= \langle \mathbf{x}_2|U(t_2, t_1)|\mathbf{x}_1\rangle \\ &= \sum_E \langle \mathbf{x}_2|E\rangle \langle E|\exp[-iH(t_2 - t_1)/\hbar]|\mathbf{x}_1\rangle \\ &= \sum_E u_E(\mathbf{x}_2) \overline{u_E(\mathbf{x}_1)} \exp[-iE(t_2 - t_1)/\hbar] \end{aligned} \quad (3)$$

in the Green's function for Equation (1). In (3) the states $|E\rangle$ are the eigenfunctions of H , which is assumed to be time-independent. We have adopted the notation $u_E(\mathbf{x}) = \langle \mathbf{x}|E\rangle$. From the completeness of the set $\{|E\rangle\}$, i.e., from the fact that $\sum_E |E\rangle\langle E| = 1$, we note that (3) implies

$$K(\mathbf{x}_2 t; \mathbf{x}_1 t) = \langle \mathbf{x}_2|\mathbf{x}_1\rangle = \delta(\mathbf{x}_2 - \mathbf{x}_1) \quad (4)$$

as should be. From the fact that $U(t_2, t_1)$ vanishes for $t_2 < t_1$, $K(\mathbf{x}_2 t; \mathbf{x}_1 t)$, likewise vanishes for $t_2 < t_1$. The above Green's functions K is therefore that solution of

$$\begin{aligned} [i\hbar\partial_{t_2} - H(\mathbf{x}_2)]K(\mathbf{x}_2 t_2; \mathbf{x}_1 t_1) \\ = i\hbar\delta(\mathbf{x}_2 - \mathbf{x}_1)\delta(t_2 - t_1) \end{aligned} \quad (5)$$

which vanishes for $t_2 < t_1$. A perturbation theory can easily be developed in this formulation. Assume that $H = H_0 + V$ and that the problem is soluble for $H = H_0$, i.e., when $V = 0$. Let us denote by K_0 the Green's function

for $V = 0$, i.e., for the free particle. Then the solution of (5) which satisfies the boundary condition $K = 0$ for $t_2 < t_1$ is the solution of the integral equation

$$\begin{aligned} K(2, 1) &= K_0(2, 1) \\ &- \frac{i}{\hbar} \int K_0(2, 3)V(3)K(3, 1)d^4x_3 \end{aligned} \quad (6)$$

where $K(2, 1)$ stands for $K(\mathbf{x}_2 t_2, \mathbf{x}_1 t_1)$ and $d^4x = d^3x dt$. That (6) is a solution of (5) is readily verified by operating with $[i\hbar\partial_{t_2} - H_0(2)]$ on both sides of the equation; also since $K_0(2, 1)$ is zero if $t_2 < t_1$, $K(2, 1)$ likewise vanishes for $t_2 < t_1$. The **Neuman-Liouville** expansion of (6) yields

$$\begin{aligned} K(2, 1) &= K_0(2, 1) - \frac{i}{\hbar} \int d^4x_3 K_0(2, 3)V(3) \\ &\cdot K_0(3, 1) + \left(\frac{-i}{\hbar}\right)^2 \int d^4x_3 \int d^4x_4 K_0(2, 3) \\ &\cdot V(3)K_0(3, 4)V(4)K_0(4, 1) \end{aligned} \quad (7)$$

which can be interpreted as follows: the first term represents the particle traveling freely from 1 to 2. The second term represents the particle moving freely from 1 to 3 being scattered at 3 (due to $V(3)$) and again traveling as a free particle from 3 to 2. (The integration over 3 is evident.) The third term represents double scattering at 3, and at 4, etc.

A corresponding treatment of the **Dirac equation** can be given. For a free particle the latter reads

$$(i\gamma_\mu\partial^\mu - m)\psi(x) = 0 \quad (8)$$

(where we have set $\hbar = c = 1$). The Green's function K_0 connecting the wave function ψ at 2 to that at 1 is now a 4×4 matrix, which satisfies

$$\begin{aligned} (i\gamma_\mu\partial_2^\mu - m)K_0(2, 1) &= i\delta(2, 1) \\ [\delta(2, 1) &= \delta(\mathbf{x}_2 - \mathbf{x}_1)\delta(t_2 - t_1)]. \end{aligned} \quad (9)$$

A particular solution of this differential equation is given by

$$\begin{aligned} K_0 &= \sum_{E_n > 0} u_n(\mathbf{x}_2)\bar{u}_n(\mathbf{x}_1) \exp[-iE_n(t_2 - t_1)] \\ &+ \sum_{E_n < 0} u_n(\mathbf{x}_1)\bar{u}_n(\mathbf{x}_2) \exp[-iE_n(t_2 - t_1)], \end{aligned}$$

for $t_2 > t_1$

$$K_0 = 0, \quad \text{for } t_2 < t_1 \quad (10)$$

where u_n are energy eigenfunctions of the Dirac equation. The negative energy solutions must be included in order that for time $t_2 = t_1$, $K_0(2,1) = \delta(x_2 - x_1)$ [since only with the inclusion of the negative energy solutions is the set $u_n(x)$ complete].

This choice of K_0 corresponds to the one-electron theory rather than to the correct **hole theory**. This can be seen as follows: Consider an electron being scattered by a potential V which vanishes for $t < -T$ and for $t > T$. The result of a perturbation calculation [Equation (7)] is then that for $t > T$ the wave function of the electron will contain components corresponding to positive as well as negative energy solutions of the Dirac equation, implying a non-vanishing probability for finding the particle in a negative energy state which is clearly unphysical. The correct Green's function can be obtained by noting that according to the hole theory, the negative energy states are occupied, hence they are not available to the electron after scattering. This requires that for $t_2 > t_1$, K is a sum over positive energy states only; K must, however, still satisfy (9) in order that it be a Green's function. This can be done by subtracting from the solution K_0 given by (10) the following solution of the homogeneous equation: $\sum_{E_n < 0} u_n(x_2)\bar{u}_n(x_1) \exp[-iE_n(t_2 - t_1)]$. This yields the new Green's function K_+ with the properties that

$$K_+ = \sum_{E_n > 0} u_n(x_2)\bar{u}_n(x_1) \exp[-iE_n(t_2 - t_1)], \quad \text{for } t_2 > t_1$$

$$K_+ = - \sum_{E_n < 0} u_n(x_1)\bar{u}_n(x_2) \exp[-iE_n(t_2 - t_1)], \quad \text{for } t_2 < t_1$$

$$= - \sum_{E_n < 0} u_n(x_1)u_n(x_2) \exp[-i|E_n||t_2 - t_1|], \quad \text{for } t_2 < t_1. \quad (11)$$

If a potential is present, an integral equation which is the analogue of (7) can be written. (K_+ replaces K_0 .) The various terms in the series expansion of this integral equation can

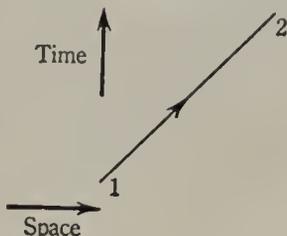

Fig. 1.

be visualized by means of space-time *Feynman diagrams*. The first term $K_+(2,1)$ represents a free particle traveling from 1 to 2 and will be represented by a directed straight line (Figure 1). The second term

$$(-i) \int K_+(2,3)V(3)K_+(3,1)d^4x_3 \quad (12)$$

represents a single scattering. If the region where V is different from zero is represented by a bounded region S in a space-time plot, then this term (12) can be represented by the diagram indicated in Figure 2.

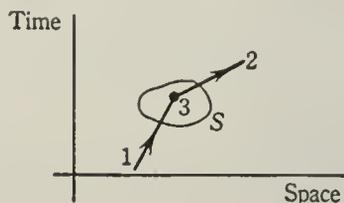

Fig. 2.

The diagrams drawn in Figure 3 represent the two possibilities represented by the third term in the perturbation expansion:

$$(-i)^2 \int d^4x_3 K_+(2,3)V(3)K_+(3,4)V(4)K_+(4,1). \quad (13)$$

Case (a). As one follows the world line from 1 to 2 time always increases, so that in K_+ only positive energies occur.

Case (b). As one follows the world line, in going from 4 to 3 time goes "backward" and

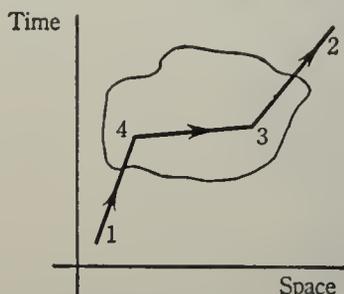

Fig. 3a. Case (a).

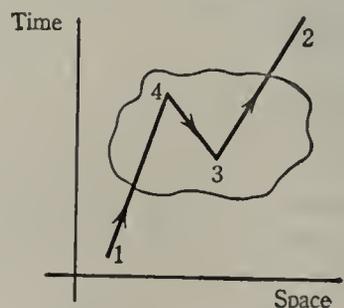

Fig. 3b. Case (b).

in K_+ (4,3) negative energy sums occur. In Feynman's interpretation this represents a positron propagating from 3 to 4. Alternatively, proceeding in the direction of increasing time one can interpret the sequence of events as follows: An electron-positron pair is created at 3; the electron propagates toward 2, the positron propagates toward 4, at which point it annihilates the incoming electron.

Both situations are included in the single term (13) since one is to integrate over all times 3 and 4. The term (13) is therefore only represented by a single diagram, either Figure 3a or 3b, since whichever is chosen the other can be obtained from it by letting the time component of 3 move relative to that of 4.

The above prescription for the propagation kernel K_+ can be shown to be equivalent to the hole theoretic formulation, the minus sign in 10(b) being a reflection of the **Pauli principle**. The formalism can be extended to the case of many particles interacting through the quantized electromagnetic field.

The connection of the Feynman formalism to the quantized electron-positron field can be established as follows:

In the presence of an external electromagnetic field, the electron-positron field is described by a Heisenberg field operator $\psi(x)$ which obeys the following field equation and equal time anticommutation rules

$$(-i\gamma^\mu\partial_\mu + m)\psi_e(x) = \frac{e}{\hbar i}\gamma^\mu A_\mu^e(x)\psi_e(x)$$

$$\{\psi(x), \psi^*(x')\}_{x_0 = x'_0} = \delta(\mathbf{x} - \mathbf{x}')$$

and which has the following expansion in terms of creation and annihilation operators

$$\psi_F(x) = \sum_{n, E^+} b_n \phi_n(x) + \sum_{n, E^-} \phi_n(x) d_n^*$$

where the first term runs over the positive energy solutions and the second over negative energy solutions of the Dirac equation in this external field; b_n is a destruction operator for an electron in the positive energy state $\phi_n(x)$ and d_n^* a creation operator for a positron. We shall assume A^e time independent and sufficiently weak so that stationary solution $\phi_n(x) = u_n(x) \exp(-iE_n t)$ can be defined for which a gap exists between positive and negative energy eigenvalues. Under these circumstances a vacuum state Ψ_0 exists which has the property that $b_n \Psi_0 = d_n \Psi_0 = 0$, for all n . The

probability amplitude of finding an electron at time t_2 at \mathbf{x}_2 if there was one at time t_1 at \mathbf{x}_1 with $t_2 > t_1$ can then be obtained from the quantity

$$(\bar{\psi}(2)\Psi_0, \bar{\psi}(1)\Psi_0) = (\Psi_0, \psi(2)\gamma_0\psi(1)\Psi_0)$$

or more generally from the quantity

$$S_{Fe}(2,1) = (\Psi_0, T(\psi(2)\bar{\psi}(1)\Psi_0)$$

where T is the Wick **chronological product**. One can verify that $-1/2iS_{Fe}(2,1) = K_+(2,1)$ where K_+ is the Feynman propagator in the presence of the potential $\gamma^\mu A_\mu^e$.

FEYNMAN THEORY OF LIQUID HELIUM. An extension of the Landau theory of liquid helium II, in which the liquid is treated as more like a solid than a gas. The presence of phonons and rotons is predicted as well as the "freezing out" of the rotons below 0.6°K .

FIBER STRESS. Lines parallel to the axis of a **bar** are called fibers. The normal stress on the cross section of a bar is called the fiber stress. In the elastic range, the extreme fiber stress in a straight bar bent about a principal axis is given by $P/A + Mc/I$ where P is the axial force, A , the cross-sectional area, M , the bending moment, I , the moment of inertia about the principal axis of bending and c , the distance of the extreme fiber from the neutral axis.

FICKIAN DIFFUSION. Diffusion in which the transfer of a quantity Q is in a direction down the gradient of Q at a rate proportional to the gradient. The flux of Q across unit area perpendicular to the unit vector \mathbf{l} is $\kappa \mathbf{l} \cdot \text{grad } Q$, κ being the diffusion coefficient which is, however, usually the same in all directions, in which case

$$\frac{\partial Q}{\partial t} = \kappa \text{div grad } Q = \kappa \nabla^2 Q.$$

But if the medium is not isotropic κ may vary with direction, and then the lines of flow of Q are not parallel to the gradient of Q .

FICK LAW OF DIFFUSION. See **Fickian diffusion**; **diffusion**, **Fick law of**.

FIDUCIAL INFERENCE. A type of estimation which, in a defined probabilistic sense, locates a parameter in a certain range; or a

type of inference which purports to decide questions of significance in the light of a "fiducial probability" distribution.

Intervals of estimation based on fiducial probability are different in general from **confidence** intervals, but the two are sometimes confused. The fiducial argument has been subject to much controversy.

FIELD. A set of elements for which addition and multiplication are defined (and lead to elements in the set) such that: both operations are **commutative** and **associative**, and multiplication is **distributive** over addition; also there are two elements, conveniently called 0 and 1, such that $0 + a = 1a = a$ for all a in the set; finally, subtraction and division are always possible and unique (except that division by zero is not possible); that is, for every a there exists a unique x such that $a + x = 0$ and a unique y (unless $x = 0$) such that $ay = 1$. Well-known examples of fields are: the set of real numbers, of complex numbers, of rational numbers, of residue classes modulo a prime, and so forth. (See also entries following.)

FIELD, ELECTRIC. (1) The attraction (or repulsion) exerted by one electric charge on another can be described quantitatively in terms of the electric field produced by the first charge. By definition, the field at any point is the force (a vector, having magnitude and direction) that would be exerted on a unit positive test charge placed at that point. Hence an electric field is a specific type of **field of force**. The path that would be followed by an inertia-less test particle is called a "line of force." It follows from the **Coulomb law** that the field of a point charge in free space has the magnitude

$$E = \frac{q}{4\pi\epsilon_0 r^2}$$

where q is the charge, ϵ_0 is the **permittivity**, r is the distance from the charge, and rationalized units are employed. (See **flux, electric**.)

(2) An electric field is produced also by a varying magnetic field. (See **Maxwell's equations**; **Faraday law of electromagnetic induction**; **field of moving charge in space**.)

FIELD EQUATIONS, LAGRANGE. See **Lagrange field equations**.

FIELD EQUATIONS, RELATIVISTIC. See **relativity, general**.

FIELD, FREE. A field (wave or potential) in a homogeneous, isotropic medium free from boundaries. In practice it is a field in which the effects of the boundaries are negligible over the region of interest. In acoustics, the actual pressure impinging on an object (e.g., electroacoustic transducer) placed in an otherwise free **sound field** will differ from the pressure which would exist at that point with the object removed, unless the acoustic impedance (see **impedance, acoustic**) of the object matches the acoustic impedance of the medium.

FIELD, IMPRESSED. The **electromagnetic field** which would exist if the body of interest were not present, or the field that would exist in free space with the given source distribution.

FIELD, INDUCTION. See the discussion under **field, radiation**.

FIELD, LEPTON. In the **Fermi theory of beta-decay**, the nuclear transition involving the emission of an electron and an antineutrino is treated in a way which is analogous to the treatment of electromagnetic transitions. As an analog to the electromagnetic field, Fermi introduced the concept of the electron-neutrino field or, as it is now called, the **lepton field**. This field is described mathematically as being the sum of products of electron and antineutrino **wave functions** plus a sum of products of positron and neutrino wave functions.

FIELD OF FORCE. Electric charges exert force upon other electric charges, magnets exert forces upon other magnets, matter exerts gravitational force upon other matter. All these action-at-a-distance phenomena are conveniently described in terms of the "force field" set up by a source. The force exerted on a unit test-particle (unit charge, unit pole, unit mass) is a vector function of position of the test-particle. That is, the force on a unit test-particle has a definite magnitude and direction for each possible location of the test-particle. The totality of these force vectors, or the vector function of position, is called a "field of force." Any path that would be followed by an inertia-less test-particle in a force field is called a "line of force." It is con-

venient to decide arbitrarily how close together possible lines of force are independent, so that there will be a finite number of lines, and the concept can be made quantitative. Conventionally a unit source radiates 4π lines, or one per unit solid angle in unrationalized systems, and a single line ($1/4\pi$ per unit solid angle) in rationalized systems.

FIELD OF MOVING CHARGE IN SPACE.

It is assumed that the charge density $\rho(\mathbf{r}, t)$ and the current density $\rho\mathbf{v} = \mathbf{g}(\mathbf{r}, t)$ are known functions of space and time. It is furthermore assumed that the charges are imbedded in empty space. Maxwell's equations are in this case:

$$\text{curl } \mathbf{H} = \frac{1}{c} \frac{\partial \mathbf{E}}{\partial t} + \frac{4\pi}{c} \rho \mathbf{V}; \quad \text{div } \mathbf{E} = 4\pi\rho$$

$$\text{curl } \mathbf{E} = -\frac{1}{c} \frac{\partial \mathbf{H}}{\partial t}; \quad \text{div } \mathbf{H} = 0.$$

To solve these equations, one introduces the scalar potential ϕ and the vector potential \mathbf{A} where

$$\mathbf{H} = \text{curl } \mathbf{A}$$

$$\mathbf{E} = -\frac{1}{c} \frac{\partial \mathbf{A}}{\partial t} - \text{grad } \phi$$

and

$$\text{div } \mathbf{A} + \frac{1}{c} \frac{\partial \phi}{\partial t} = 0 \quad (\text{Lorentz gauge condition}).$$

The potentials satisfy the equations

$$\nabla^2 \mathbf{A} - \frac{1}{c^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} = -\frac{4\pi}{c} \mathbf{g}$$

$$\nabla^2 \phi - \frac{1}{c^2} \frac{\partial^2 \phi}{\partial t^2} = -4\pi\rho.$$

The solutions (retarded potentials) are

$$\mathbf{A}(x, y, z, t) = \frac{1}{c} \iiint \frac{\mathbf{g}(\xi, \eta, \zeta, t - r/c)}{r} d\xi d\eta d\zeta$$

$$\phi(x, y, z, t) = \frac{1}{c} \iiint \frac{\rho(\xi, \eta, \zeta, t - r/c)}{r} d\xi d\eta d\zeta$$

$$r = \sqrt{(x - \xi)^2 + (y - \eta)^2 + (z - \zeta)^2}.$$

If the charge is a point charge of magnitude e the solution reduces to the so-called Liénard-Wiechert potentials:

$$\mathbf{A} = \frac{e}{c} \left[\frac{\mathbf{v}}{r - \frac{\mathbf{r} \cdot \mathbf{v}}{c}} \right]_{\tau = t - \frac{r}{c}}$$

$$\phi = \left[\frac{e}{r - \frac{\mathbf{r} \cdot \mathbf{v}}{c}} \right]_{\tau = t - \frac{r}{c}}$$

\mathbf{r} and \mathbf{v} are the "effective" position and velocity of the charge at the retarded time $t - \frac{r}{c}$.

FIELD OF VIEW. The region constituted by all points on which the gaze can be fixed when the eye is allowed to move while the head is kept immobile. The field of view may be monocular or binocular. (See **Lunenburg geometry**.)

FIELD OPERATOR. In quantized field theory, an operator which represents the creation or annihilation of a particle.

FIELD QUANTIZATION. The transition from a classical field theory to a quantized field theory. To any quantized field theory there corresponds a semi-classical field theory with the same field equations. The quantized field theory is obtained from this classical field theory by replacing the classical field quantities by operators satisfying simple **commutation** or **anti-commutation** relations. (See **field theory, quantized** and **quantum electrodynamics**.)

FIELD, QUASI-STATIC. See the discussion under **field, radiation**.

FIELD, RADIATION. The electromagnetic field associated with oscillating **electric** and **magnetic dipoles** can be written as the sum of three components. The first of these has an inverse-cube dependence on distance from the dipole, resembling the static field of the dipole but multiplied by a time-varying factor. It is in phase with the source current and is often called the "*quasi-static*" field. The second component falls off inversely as the square of the distance and is in quadrature with the source current. For this reason there is no net loss of energy due to this component. It is called the "*induction*" field, a term which emphasizes its reactive character. The last component is again in phase with the source current but varies inversely as the distance, thus

predominating over the other two at large distances. The in-phase relation represents real power loss, and its dependence on distance means that its contribution to the integral of the **Poynting vector** does not vanish for extremely large distances. This component is called the "*radiation*" field. A somewhat similar decomposition of the field occurs also in the more general case of an accelerated charge. (See also **dipole radiation, electric**; and **dipole radiation, magnetic**.)

FIELD RAY. Two linearly independent **optical paths**, one from an axial object point and one from an off-axis object point, determine all paraxial optical paths in the **Gaussian optics** of a system. These are referred to as the *axial* and *field rays*, respectively. The field ray is usually taken parallel to the axis in object space.

FIELD, SELF-CONSISTENT. See **self-consistent field**.

FIELD STRENGTH. The **vector** characterizing a **field**. Thus an electric field has a strength (volts per meter) at a given point, as well as a direction; its strength is, therefore, the magnitude of its **electric field vector**, **E**. (See **field of force**.)

FIELD STRENGTH TRANSFORMATION LAWS. See **transformation laws for field strengths**.

FIELD, TENSOR. See **tensor field**.

FIELD THEORY. Theory of the dynamical motion of a set of electromagnetic or matter fields, in which the electromagnetic potentials A_μ and the matter wave functions ψ_a are represented by functions of position and time. Usually but not always a field theory is developed in accordance with the postulates of special relativity theory so that if it is designed to describe nuclear forces the principle of relativity will be extended to include the impossibility of detecting absolute uniform motion of the laboratory by means of nuclear experiments conducted therein. In this type of field theory the equations of motion are derived from a **Lagrangian density**

$$L\left(\psi_a, A_\mu, \frac{\partial\psi_a}{\partial x_\nu}, \frac{\partial A_\mu}{\partial x_\nu}\right)$$

being, for the ψ_a ,

$$\sum_{\mu=1}^4 \frac{\partial}{\partial x_\mu} \left(\frac{\partial L}{\left(\frac{\partial\psi_a}{\partial x_\mu}\right)} \right) = \frac{\partial L}{\partial\psi_a}$$

For other properties of L see **gauge invariance**, **energy-momentum tensor**. Since it is possible to derive the **Maxwell equations** and the **Dirac electron theory** in this way, it has been hoped to formulate in analogous fashion a satisfactory meson theory of nuclear forces.

Field theories may also be developed as **relativistic** and as non-relativistic theories, as well as for quantized and non-quantized descriptions.

FIELD THEORY, QUANTIZED. Classical field theories, like that of the electromagnetic field, have to be modified in quantum theory in order to include the description of quantum phenomena. In the same way as in particle mechanics the classical quantities are replaced by operators in the transition to quantum mechanics, the classical field quantities become field operators in a quantized field theory. The particles appear in the theory as the quanta of the field. Photons are the quanta of a radiation field, electrons the quanta of a quantized electron field, the different mesons quanta of meson fields. If the particles obey **Bose-Einstein statistics**, the quantized field operators satisfy simple **commutation** relations; if the particles are fermions obeying **Fermi statistics**, the field operators satisfy analogous anti-commutation relations. The best known example of quantized field theory is **quantum electrodynamics** which describes the interaction of electrons and the radiation field. Nuclear forces are related to the interaction of nucleons with meson fields. Many problems of elementary particle physics belong to quantum field theory. The quantum field equations satisfied by the field operators are in general non-linear equations, which means that it is a difficult mathematical problem to arrive at quantitative predictions. In quantum electrodynamics, the coupling between the fields is weak, and one can apply perturbation methods. In many other important cases, however, the coupling between the fields is strong, and the perturbation techniques which have been developed in recent years in quantum field theory are of little help.

FIELD THEORY, WEYL UNIFIED. Theory of gravitation and electromagnetism based on a non-Riemannian geometry in which the length of a vector may change under parallel displacement.

$$\frac{dl}{l} = A_\mu dx^\mu.$$

The A_μ are interpreted as the electromagnetic potentials. With this interpretation, multiplying a length as (r,t) by $\exp[X(r,t)]$ leads to the gauge transformation

$$A'_\mu = A_\mu + \partial_\mu X.$$

(See **gauge invariance**, second kind.)

FIGURED SURFACE. In lens design and fabrication, a surface that departs from a specified surface (often a sphere) by small amounts (of the order of a few wavelengths).

FIGURE OF MERIT. (1) General term for various graphical relationships which summarize certain desirable features of amplifying devices. (2) The current required to produce one division deflection (usually 1 mm on a scale at a distance of 1 m) of a galvanometer. (3) Any quantity which expresses quantitatively the performance of a measuring device.

FILM. In **heat transfer**, the name given to the **boundary layer**.

FILM TEMPERATURE. In **heat transfer**, the mean between the temperature of a duct or an immersed body, and the **bulk temperature**.

FILMWISE CONDENSATION. See **dropwise condensation**.

FILTER. An electrical **network** designed to eliminate certain frequencies in a signal by attenuation, leaving the remaining frequencies little changed. Specific adjectives, e.g., low-pass, high-pass, band-pass and band-elimination indicate the particular behavior for which the filter was designed.

FILTERING APPROXIMATIONS. A set of mathematical approximations introduced into a system of hydrodynamical partial differential equations to filter out or exclude solutions corresponding to those physical disturbances which are believed to contribute only negligibly to the problem at hand.

FINAL VERTEX. See **vertex**, final.

FINE STRUCTURE. A. Rotational fine structure in band spectra (see **molecular spectra**).

B. Multiplet splitting

(I) Atomic Spectra

An energy level with a given electronic angular orbital momentum \mathbf{L} and electron spin $\mathbf{S} \neq 0$ will split into a number of fine structure components with different total electronic angular momenta \mathbf{J} . The corresponding quantum numbers are

$$J = (J + S), (J + S - 1), \dots, (J - S).$$

The number of fine structure components is $2S + 1$ for $J > S$, and $2J + 1$ for $J < S$.

Transitions between fine structure levels follow the selection rule

$$\Delta J = 0, \pm 1, \quad \text{and} \quad J = 0 \leftarrow \rightarrow J = 0.$$

The magnitude of the fine structure splitting depends on the **coupling** between \mathbf{S} and \mathbf{L} . For strict **Russell-Saunders coupling** the energy of the fine structure levels is given by

$$W = W_0 + A \frac{J(J + 1) - L(L + 1) - S(S + 1)}{2}$$

where A is a constant characteristic of the multiplet considered (see Γ -value). In this case the interval between successive fine structure components (J and $J + 1$) is proportional to $J + 1$ (**Landé's interval rule**). (See also **hydrogen fine structure**, **multiplet**.)

(II) Molecular Spectra

The total angular momentum \mathbf{J} is the vector sum of the angular momentum of the nuclear frame, the electronic orbital angular momentum \mathbf{L} in the direction of the internuclear axis, and the electron spin \mathbf{S} . The total angular momentum apart from spin is designated \mathbf{N} . For the corresponding quantum numbers we have

$$J = (N + S), (N + S - 1), \dots, (N - S).$$

The interaction of rotation and electron spin (which increases with increasing rotation) causes a variation of the multiplet splitting with N or J . The following formulas give the rotational term values for some important cases

referring to diatomic and linear polyatomic molecules:

$^2\Sigma$ states ($\Lambda = 0, S = \frac{1}{2}$)

$$F_1(N) = B_v N(N + 1) + \frac{1}{2}\gamma N$$

$$F_2(N) = B_v N(N + 1) - \frac{1}{2}\gamma(N + 1).$$

Here $F_1(N)$ and $F_2(N)$ refer to the levels with $J = N + \frac{1}{2}$ and $J = N - \frac{1}{2}$, respectively, and γ is a small coupling constant ($\gamma \ll B_v$).

$^3\Sigma$ states ($\Lambda = 0, S = 1$) (Schlapp's formula).

$$F_1(N) = B_v N(N + 1) + (2N + 3)B_v - \lambda$$

$$- \sqrt{(2N + 3)^2 B_v^2 + \lambda^2 - 2\lambda B_v}$$

$$- \gamma(N + 1)$$

$$F_2(N) = B_v N(N + 1)$$

$$F_3(N) = B_v N(N + 1) - (2N - 1)B_v - \lambda$$

$$+ \sqrt{(2N - 1)^2 B_v^2 + \lambda^2 - 2\lambda B_v}$$

$$- \gamma N.$$

Here $F_1(N)$, $F_2(N)$, $F_3(N)$ refer to the levels with $J = N + 1$, $J = N$, and $J = N - 1$, respectively, and λ and γ are small coupling constants.

$^2\Pi$, $^2\Delta$, \dots states ($\Lambda = 1, 2, \dots, S = \frac{1}{2}$) (Hill and Van Vleck's formula).

$$F_1(J) = B_v[(J + \frac{1}{2})^2 - \Lambda^2$$

$$- \frac{1}{2}\sqrt{4(J + \frac{1}{2})^2 + Y(Y - 4)\Lambda^2}]$$

$$- D_v J^4$$

$$F_2(J) = B_v[(J + \frac{1}{2})^2 - \Lambda^2$$

$$+ \frac{1}{2}\sqrt{4(J + \frac{1}{2})^2 + Y(Y - 4)\Lambda^2}]$$

$$- D_v(J + 1)^4.$$

Here $Y = A/B_v$, where the coupling constant A is a measure of the strength of the **coupling** between the spin \mathbf{S} and the orbital angular momentum $\mathbf{\Lambda}$; $F_1(J)$ is the term series that forms for large rotation the levels with $J = N + \frac{1}{2}$, while $F_2(J)$ forms for large rotation the levels with $J = N - \frac{1}{2}$.

FINE STRUCTURE CONSTANT. See **Sommerfeld fine structure constant**.

FINE STRUCTURE, HYDROGEN. See **hydrogen fine structure**.

FINITE AMPLITUDE EQUATIONS (ACOUSTIC). For plane waves of infinitesimal amplitude travelling in an ideal gas, the particle displacement ξ obeys the wave equation

$$\frac{\partial^2 \xi}{\partial t^2} = \frac{\gamma p_o}{\rho_o} \frac{\partial^2 \xi}{\partial x^2} \quad (1)$$

where γ is the ratio of the specific heats, p_o is the mean pressure, and ρ_o is the mean density. Such waves are propagated with constant velocity $c_o = \sqrt{(\gamma p_o / \rho_o)}$. For waves of finite amplitude, (1) becomes

$$\frac{\partial^2 \xi}{\partial t^2} = c_o^2 \left(1 + \frac{\partial \xi}{\partial x} \right)^{-(\gamma+1)} \frac{\partial^2 \xi}{\partial x^2}. \quad (2)$$

The velocity of propagation c is then given by

$$c = c_o \left(1 + \frac{\partial \xi}{\partial x} \right)^{-(\gamma+1)/2}$$

and c thus depends on the amplitude. Thus, waves of large amplitude travel faster than waves of smaller amplitude, and as a finite disturbance is propagated through a gas, a shock front develops. (See **wave, shock**.)

FINITE ELASTICITY THEORY. The theory of the relation between the forces and deformation in bodies of elastic or perfectly-elastic material, in which it is not assumed that the displacement gradients are infinitesimally small (cf. **classical elasticity theory**).

FINITE GRAPH. See **graph, finite**.

FIRST BETTI NUMBER. See **graph, nullity**.

FIRST CURVATURE OF A SURFACE. See **curvature**.

FIRST FLIGHT COLLISION PROBABILITY. See **collision probability, first flight**.

FIRST FLIGHT ESCAPE PROBABILITY. See **escape probability, first flight**.

FIRST FOCAL POINT. The first focal point F in **Gaussian optics** is the object point so situated that all rays through F have image rays parallel to the axis of the system.

FIRST FUNDAMENTAL THEOREM. In nuclear reactor theory, the statement that in a critical bare reactor, (a) the neutron flux—averaged over angle—is separable in space

and energy, i.e., $\Phi(r, E) = \chi(E)\psi(\mathbf{r})$; and (b), the spatial factor satisfies the equation:

$$(\nabla^2 + B^2)\psi(\mathbf{r}) = 0$$

with the condition that $\psi(\mathbf{r})$ be everywhere positive and vanish on the boundary. B^2 , the lowest eigenvalue of the equation, is called the **buckling**.

FIRST LAW OF THERMODYNAMICS. See **thermodynamics, first law of**.

FIRST LIMIT THEOREM. If a sequence of **distribution functions** $\{F_n\}$ converges to a limit F then the corresponding sequence of **characteristic functions** $\{\phi_n\}$ converges to a limit ϕ and ϕ is the characteristic function of F . This is the first limit theorem of probability and statistics.

FIRST ORDER OPTICS. See **Gaussian optics**.

FIRST ORDER SOLUTION THEORY. See **conformal solutions**.

FISHER'S DISTRIBUTION. If s_1^2, s_2^2 are two independent estimates of variance, with degrees of freedom ν_1 and ν_2 , in data from a normal population, the distribution of one half the logarithm of their ratio,

$$z = \frac{1}{2} \log (s_1^2/s_2^2)$$

is called Fisher's z -distribution. It has the form

$$dF = \frac{2\nu_1^{1/2}\nu_2^{1/2} e^{\nu_1 z} dz}{B(\frac{1}{2}\nu_1, \frac{1}{2}\nu_2) (\nu_1 e^{2z} + \nu_2)^{1/2(\nu_1 + \nu_2)}},$$

$$-\infty \leq z \leq \infty.$$

Fisher chose the logarithm, rather than the ratio $F = s_1^2/s_2^2$ itself, to facilitate interpolation in tables. The ratio F has a **beta distribution** of the second kind. Tests of significance based on F or z are widely used in the **analysis of variance**.

FISHER-YATES TEST. A test of independence of data arranged in a 2×2 **contingency table**. It is an exact test, used for small frequencies where the **chi-square** test is feared to be too approximate.

FISSION SPECTRUM. The distribution in energy of prompt neutrons emitted at fission, measured in the coordinate system of the fissioning nucleus. Within present experimental

accuracy the probability that a neutron is emitted in the range $E, E + dE$ is:

$$f(E) = \frac{a^{3/2}}{\Gamma(\frac{3}{2})} \sqrt{E} e^{-aE}, \quad a = 0.775$$

where E is to be measured in Mev. (See also **Watt spectrum**.)

FISSION YIELD CURVE. A curve obtained by plotting the fraction of fissions, usually expressed as a percentage, which give rise to a particular nuclide, against the mass number of that nuclide. Since there are two product nuclei per fission, the total fission yield is usually taken to be 200%. The typical fission yield curve contains two broad peaks around mass numbers 90 and 140 owing to the fact that fission is predominantly asymmetric. The trough between them, representing symmetric fission, may correspond to only 0.1% of the most probable yield, but this depends rather sensitively upon the actual fission process considered (for example, upon the energy of the neutrons giving rise to fission).

FIX. The point of intersection of two **lines of position** is known as a fix. This fix may be the actual position of the ship or plane if the lines of position are obtained by observation of celestial objects (celestial navigation), or by radio or other electronic means (electronic navigation), or by observations of terrestrial objects in known geographic positions (pilotage).

FIXED ARCH. See **arch**.

FIXED-ENDED BEAM. See **beam, fixed-ended**.

FIXED-END MOMENTS. A term used in the **moment distribution** procedure to describe the moments which would be produced by the transverse loads if the ends of the elastic beam were fully restrained against rotation. Clockwise end moments are taken as positive.

FIXED POINT. (1) A system of computing in which all quantities must be scaled so as to be representable by a fixed number of digits and with the **radix** point in a fixed position. It may be contrasted with floating-point computations in which a scale factor is explicitly computed and associated with each number, and represented as a power of the radix. In some **digital computers** floating-point operations are automatic; in others they are not.

(2) In the analysis of beams, fixed points are points of zero moment (points of inflection or contraflexure) in an unloaded portion of a continuous elastic beam with supports $A, B, C, D \dots$ when a moment is applied at A . They are fixed points in the sense that the point of zero moment in open CD will not change as the loads on ABC are altered.

FIXED POINT THEOREM. See **Brouwer fixed point theorem**.

FIXED THERMOMETRIC POINTS. See **temperature**.

FLAME VELOCITY. See **combustion**.

FLAT SPACE-TIME. Space-time for which the Riemann-Christoffel tensor vanishes. The metric can then always be chosen thus

$$g_{\mu\nu} = \delta_{\mu\nu}, \text{ if } x_4 = ict.$$

FLEXURE. A term used to denote the bending of beams, plates, and shells.

FLEXURE PROBLEM. In the theory of the bending of a beam of isotropic elastic material, satisfying the generalized Hooke's law, by a force applied to its end and perpendicular to its length, the tangential components of strain and stress in the cross-sectional planes are determined by a two-dimensional stress function. This may be expressed in terms of the torsion function for the beam and another harmonic function of position on the cross section of the beam, often denoted χ and called the *flexure function*, the normal derivative $\partial\chi/\partial n$ of which is given by

$$\frac{\partial\chi}{\partial n} = \left[-\frac{1}{2}\sigma x^2 + \left(1 - \frac{1}{2}\sigma\right)y^2\right]l - (2 + \sigma)zym$$

on the cylindrical surface of the beam, where the xy -planes are the cross-sectional planes of the beam, l and m are the direction cosines of the outward-drawn normal to the surface of the beam, σ is Poisson's ratio for the material of the beam and it is assumed that the applied force acts parallel to the x -axis. The problem of determining χ is called the *flexure problem*.

FLEXURE, SIMPLE (OF A BEAM). Also called *pure flexure*, *simple bending* or *pure bending*. A state of deformation of the beam in which straight lines parallel to the length of the beam become arcs of circles all of which lie parallel to a plane, called the *plane of*

bending or *plane of flexure*, and in which planes normal to the length of the beam remain plane and intersect in a single line. Usually, the state of *deformation* is one in which the cylindrical surface of the beam is force-free. Then, for isotropic elastic materials and for elastic materials with certain other types of symmetry, such a deformation may be supported by equal and opposite *couples*, applied to the two ends of the beam, provided that the plane of bending is normal to one of the principal axes of inertia of the cross-section of the beam. These couples are called the *bending couples* or *flexural couples*. For an isotropic elastic material obeying the generalized Hooke's law, the bending couple is EI/R , where E is Young's modulus for the material of the beam, I is the square of the radius of gyration of the cross section of the beam about an axis perpendicular to the plane of bending, and R is the radius of curvature of the beam (i.e., the radius of curvature of the arc into which a line parallel to the length of the beam is bent). This relation between the bending couple and the curvature $1/R$ is called the *Bernoulli-Euler law*. The constant of proportionality EI is called the *modulus of flexural rigidity* for the beam.

FLOATING POINT. See **fixed point**.

FLOQUET THEOREM. Given a second-order linear differential equation with periodic coefficients that are one-valued functions of the independent variable, such as **Mathieu's equation**, then there exists a solution of the form $y = e^{\mu x}P(x)$, where $P(x)$ is a periodic function and μ is a constant. The general solution of the differential equation is $y = Ae^{\mu x}P(x) + Be^{-\mu x}P(-x)$, where the constants of integration are A and B .

FLORY-HUGGINS EFFECT. See **polymer mixtures**.

FLOW DIAGRAM. A graphical representation of a sequence of operations. In machine computation, a diagram with labeled boxes, arrows, etc., showing the logical pattern of a problem, but not ordinarily including machine commands.

FLOW, ENERGY EQUATION FOR STEADY ADIABATIC. See **energy equation for steady adiabatic flow**.

FLOW, FREE-MOLECULE. See free-molecule flow.

FLOW, HYPERSONIC. See hypersonic flow.

FLOW IN A PIPE OR CHANNEL, TRANSITION TO TURBULENT. See transition to turbulent flow in a pipe or channel.

FLOW IN PIPE, LAMINAR. See pipe, laminar flow in.

FLOW IN PIPE, TURBULENT. See pipe, turbulent flow in.

FLOW OF GAS IN NOZZLE OR DUCT. See nozzle or duct, flow of gas in.

FLOW OF GAS IN STREAM TUBE. See nozzle or duct, flow of gas in.

FLOW PAST ROTATING CYLINDER. See rotating cylinder, flow past.

FLOW, PLUG. See plug flow.

FLOW RULE. A rule which establishes the relation between strain-rate and stress for plastic flow. For a prescribed yield limit $f(\sigma_{11}, \sigma_{12}, \dots)$, the flow rule is given by the plastic potential principle:

$$\dot{\epsilon}_{ij} \propto \frac{\partial f}{\partial \sigma_{ij}}$$

FLOW, SLIP. See slip flow.

FLows OF IRREVERSIBLE PROCESSES. See rates of irreversible processes.

FLOW THEORY OF PLASTICITY. Synonymous with incremental theory.

FLOW THROUGH GAUZE. See gauze, flow through.

FLOW, TURBULENT, IN A BOUNDARY LAYER, TRANSITION OF. See transition of turbulent flow in a boundary layer.

FLOW WORK. The product pV . The origin of the term is as follows: when writing the first law of thermodynamics for an open system operating at a steady state and admitting the working fluid at a (constant) state 1 and discharging it at a (constant, but different) state 2, it is necessary to select a hypothetical closed system. This is usually done by adding the two cylinders and piston shown in broken line

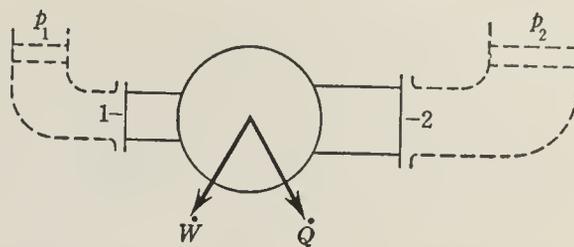

Fig. 1.

in Figure 1. The rate at which work is performed at the boundaries of the closed system is then

$$\dot{W}_c = \dot{W} - p_1 \dot{V}_1 + p_2 \dot{V}_2.$$

Here \dot{W} is the rate at which work is done by the open system, $-p_1 \dot{V}_1$ is the rate at which the surroundings ("the atmosphere") perform work on the closed system (left-hand cylinder and piston) pressure p_1 , and $+p_2 \dot{V}_2$ is the rate at which the closed system performs work on the surroundings ("against the atmosphere"). Consequently in many flow problems which are conveniently analyzed in terms of an open system the product

$$pV \text{ or } pv \text{ (per unit mass)}$$

appears. Since it has dimensions of work, and since it is associated with flow problems, it is called flow work. It must be realized that in the preceding argument it has been assumed that the state of the working fluid is uniform across sections 1 and 2 ("one-dimensional flow") and that no shearing stresses are involved in the flow through the additional hypothetical cylinders.

A similar term occurs in the analysis of a reciprocating-engine cylinder. When the valves are closed the work of expansion or compression is equal to

$$W_{12} = \int_1^2 p dV.$$

In addition to expanding (or compressing) the working fluid, it is necessary to induce it

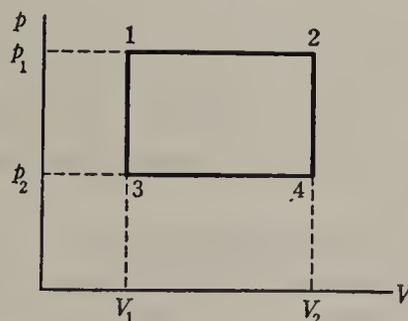

Fig. 2 Ideal pV cycle.

through the open inlet valve when “the atmosphere” performs work $-p_1V_1$ on the piston, and to expel it through the open exhaust valve when the piston performs work $+p_2V_2$ “against the atmosphere.” Hence the total work of a complete cycle of operations is equal to

$$W = \int_1^2 pdV - p_1V_1 + p_2V_2 = - \int_1^2 Vdp.$$

The total work, sometimes called technical work (particularly in German textbooks) consists of the work of expansion (or compression) and the two flow-work terms pV .

FLUCTUATION(S). In thermodynamics one deals with matter in bulk and hence usually considers uniform systems. However, all matter is built up of atoms and its atomistic nature will produce fluctuations which can be studied by statistical means.

For most physical quantities a system consisting of a large number of particles will show a Gaussian or **normal distribution**, and the relative fluctuations of a quantity G will usually be given by an equation of the type

$$\frac{\langle G^2 \rangle - \langle G \rangle^2}{\langle G \rangle^2} = \frac{1}{\langle G \rangle} \quad (1)$$

where the $\langle \rangle$ indicate average values. As most $\langle G \rangle$ will be proportional to the number of particles in the system, the relative fluctuations will usually be negligibly small.

There are, however, cases where fluctuations become experimentally observable. The first case is that of Brownian motion where small particles in suspension will undergo fluctuations in the uniform pressure and hence show a **random walk** phenomenon. The second case is where Equation (1) breaks down. This will happen near a critical temperature when, for instance, critical opalescence occurs.

If we are dealing with systems of **bosons** or **fermions**, Equation (1) must be slightly changed, but the conclusion that the left hand side is usually very small for systems consisting of many particles remains valid.

FLUCTUATION (FROM AN EQUILIBRIUM STATE). See **natural and unnatural processes**.

FLUCTUATION-DISSIPATION THEOREM. A general relation between the amplitude of fluctuations, the spectral distribution of the resistance for such fluctuations, and

the absolute temperature. An example is the **Nyquist theorem**.

FLUCTUATIONS, ZERO POINT. See **zero point fluctuations**.

FLUORESCENCE. Luminescence that persists for less than about 10^{-8} second after excitation.

FLUORESCENCE YIELD. The probability that an atom in an excited state will emit an x-ray photon, rather than an Auger electron (see **Auger effect**). The value of the fluorescence yield lies between 0 and 1, characteristic of the particular state of excitation of the atom. The K -shell fluorescence yield increases with increasing atomic number, and is the sum of the $K \rightarrow L_{II}$, $K \rightarrow L_{III}$... transitions.

FLUTTER (IN STRUCTURES). Resonant vibration of any part of an aircraft, or of any structural element, in a fluid stream, maintained by oscillatory aerodynamic or hydrodynamic forces induced by deflection of the structure.

FLUX. (1) A quantity proportional to the surface integral of the normal (perpendicular) force field intensity over a given area.

$$\text{Flux} = K \int F_N dS$$

where F_N is the normal component of a **field** (e.g., gravitational, electric, magnetic), and K is the constant of proportionality between the field and the flux density (**permittivity, permeability, etc.**). (See also **electric flux density; magnetic flux density**.) (2) A term which denotes the volume or mass of fluid or particles transferred across a given area perpendicular to the direction of flow in a given time.

There are many specific applications in science of the term flux. For electromagnetic radiation, it signifies the energy per unit time, or the power passing through a surface. For photons or particles, flux is the number per unit time passing through a surface. In nuclear science, flux commonly means the product nv , where n is the number of particles per unit volume and v is their mean velocity.

FLUX, ADJOINT. In the general formulation of time-dependent neutron transport theory, the substitution $\Phi(r, E, \hat{\Omega}, t) = \phi(r, E, \hat{\Omega})e^{\lambda t}$ leads to an eigenvalue problem of the form:

$$\mathcal{L}\phi_n = \lambda_n v^{-1} \phi_n + \text{boundary conditions.}$$

Here, the operator will depend upon the mathematical model under consideration (multi-group diffusion theory, one-velocity transport theory, ...) and v is the neutron velocity variable. Using the conventional scalar product notation, the adjoint operator, \mathfrak{M} is defined through $(\phi, \mathfrak{M}\psi) = (\psi, \mathcal{L}\phi)$ and the adjoint flux satisfies $\mathfrak{M}\phi_n = \lambda_n v^{-1} \psi_n + \text{boundary conditions}$. It is generally assumed in neutron transport theory that the eigenvalues of \mathfrak{M} are identical with those of \mathcal{L} . From the foregoing, it is easy to prove the orthogonality relationship

$$(\psi_m, v^{-1} \phi_n) = \delta_{nm}.$$

In special cases, e.g., one-group diffusion theory, the operator \mathcal{L} is self-adjoint, $\mathcal{L} \equiv \mathfrak{M}$ and $\psi_n \equiv \phi_n$.

FLUX DENSITY. A vector representing the flux passing per unit area normal to the vector. (See **electric flux density**; **magnetic flux density**; **Poynting vector**.)

FLUX DENSITY, INTRINSIC (B_i) (INTENSITY OF MAGNETIZATION). The intrinsic flux density (induction) or magnetic polarization of a medium is the vector difference between the **magnetic flux density** at the point of interest, and the flux density which would exist at that point, for the same magnetizing force, if the medium were a vacuum:

$$\mathbf{B} = \mu_0 \mathbf{H} + \mathbf{B}_i,$$

where μ_0 is the magnetic permeability of free space. In unrationalized systems of units, the intrinsic flux density is defined by

$$\mathbf{B}_i = 4\pi\mu_0 \mathbf{M},$$

whereas in rationalized systems,

$$\mathbf{B}_i = \mu_0 \mathbf{M}$$

where \mathbf{M} is the **magnetization** of the medium.

FLUX DENSITY, PEAK (B_m). The maximum flux density in a magnetic material in a specified cyclically magnetized condition.

FLUX DENSITY, RESIDUAL (B_r). The magnetic flux density at which the magnetizing force is zero when the material is in a symmetrically cyclically magnetized condition.

FLUX, ELECTRIC. See **electric displacement vector**.

FLUXES OF IRREVERSIBLE PROCESSES. See **rates of irreversible processes**.

FLUX LINKAGE. Since **magnetic flux density** is solenoidal

$$(\nabla \cdot \mathbf{B} = 0),$$

any closed contour links a definite amount of flux. This flux linkage

$$\phi = \int \mathbf{B} \cdot d\mathbf{S}$$

plays an important role in the basic relations of electromagnetism.

FLUX, LUMINOUS. See **luminous flux**.

FLUX, MAGNETIC. See **magnetic flux**.

FLUX, NEUTRON, ANGULAR. Let $N(r, E, \hat{\Omega}, t) dV dE d\hat{\Omega} dt$ be the number of neutrons in volume element dV of matter, located at position r , which, during the time interval between t and $t + dt$ have energies lying between E and $E + dE$ and travel in directions lying within the element of solid angle $d\hat{\Omega}$ about unit vector $\hat{\Omega}$. The quantity Nv , where v is the neutron velocity corresponding to E , is the neutron angular flux.

FLUX, NEUTRON, TOTAL. The total neutron flux is the integral of the angular flux over all energies and angles. Thus,

$$\Phi(r, t) = \int_0^\infty dE \int d\hat{\Omega} N(r, E, \hat{\Omega}, t) v.$$

FLUX VECTORS. In a gas which is not at equilibrium, there exist either separately or simultaneously gradients of density, of molecular momentum or of temperature. These gradients lead to molecular transports of mass (m), molecular momentum (mv) or kinetic energy ($mv^2/2$) through the gas. Let $\phi(\mathbf{V})$ design any *scalar* quantity such as m , mv_x , mv_y , mv_z , $mv^2/2$, etc. The amount of ϕ which crosses in unit time a surface element dS moving with the mass average velocity of the gas is:

$$(\mathbf{n} \cdot \int \phi f \mathbf{V} d\mathbf{V}) dS = (\mathbf{n} \cdot \Psi) dS. \quad (1)$$

f is the distribution function, \mathbf{V} the difference between the molecular velocity and the mass average velocity, and \mathbf{n} a unit vector normal to dS .

Ψ is called the flux vector associated with the property ϕ . The transport of vectorial quantities (mv for example) leads to the introduction of *three* flux vectors, one for each component of the vectorial property. The components of these three flux vectors form a tensor.

(1) *Mass flux vector.* For the j^{th} component of a mixture,

$$\Psi_{mj} = m_j \int f_j \mathbf{V}_j d\mathbf{V}_j = n_j m_j \bar{\mathbf{V}}_j. \quad (2)$$

$\bar{\mathbf{V}}_j$ is the difference between the average velocity of the molecules j and the mass average velocity of the gas. It is called the *diffusion velocity* of component j . Because of the definition of \mathbf{V} , the mass flux vector in a pure gas is always 0.

(2) *Momentum flux vectors.* If $\phi = mV_x$ (V_x is the difference between the x component of the molecular velocity and that of the mass average velocity), the flux vector is:

$$\Psi(mV_x) = m_j \int V_x \mathbf{V} f d\mathbf{V} = nm \overline{V_x \mathbf{V}}. \quad (3)$$

The nine scalar quantities appearing in the right hand side of (3) and of the similar equations for the transport of mV_y and mV_z form the *pressure tensor*. They have the form

$$r_{ij} = nm \overline{V_i V_j}.$$

When $i = j$, these components are called the *normal stresses* p_{xx} is the pressure in the x -direction across a surface which is itself normal to the x -axis.

When $i \neq j$, the components of the pressure tensor are called the *shearing stresses*, because they cause neighboring layers of the gas to slip with respect to each other.

In a gas at equilibrium, the shearing stresses are always 0, and the normal stresses are equal. The shearing stresses are important for viscous flow.

(3) *The flux vector associated with the transport of kinetic energy* ($\phi = mv^2/2$).

$$\begin{aligned} \Psi_{\frac{1}{2}mv^2} &= \mathbf{q} = \left(\frac{1}{2}\right)m \int V^2 \mathbf{V} f dV \\ &= \left(\frac{1}{2}\right)nm \overline{V^2 \mathbf{V}} \end{aligned} \quad (4)$$

It is usually called the *heat flux vector*, but it is only for monoatomic gases in their fundamental electronic state that (4) represents the total heat carried through the gas. For polyatomic molecules, one must introduce *internal energy flux vectors* which also contribute to

the energy flow in the gas. (See **Eucken correction**.)

f/NUMBER. The angle of projection of a camera lens is measured by the **f/number** which is the ratio of the **effective focal length** to the diameter of the **exit pupil**. Thus, the **f/number** is the reciprocal of twice the tangent of the **angle of projection**. The reciprocal of the square of the **f-number** of a lens is a measure of the speed of the lens. Following the recommendation of a committee of the Royal Photographic Society of Great Britain, at ratios greater than 1:4 ($f/4$) lenses are marked so that the exposures increase as the power of 2. Thus:

f/number	4	5.6	8	11.3	16	22
Relative exposure	1	2	4	8	16	32

FOCAL LENGTH. The distance from the object or image **principal point** to its corresponding **focal point** is the *object* or *image focal length*, respectively, of an optical system. If the term focal length is used without qualification then the image focal length is meant.

FOCAL LENGTH, BACK. See **back focal length**.

FOCAL LENGTH, REDUCED. See **reduced focal length**.

FOCAL LINES. The rays of a **normal congruence** in the neighborhood of a ray R intersect to the first order in two focal lines, one through each focus of R . The focal lines are called the *tangential* and the *sagittal focal lines* of R . Normals to a wave-front belonging to the congruence do not, in general, intersect to the first order. However, the normals to a line of curvature on the wave-front do intersect to the first order in a focal line. Thus R and the focal lines are mutually orthogonal.

FOCAL PLANES. In the **Gaussian optics** of an axially symmetrical optical system, planes perpendicular to the axis passing through the **focal points**.

FOCAL POINT, FIRST. See **first focal point**.

FOCAL POINTS. In **Gaussian optics**, the **object** and the **image points** conjugate to infinity in the system. They are referred to as the **first** and **second**, respectively, **focal points**.

FOCAL POINT, SECOND. See **second focal point**.

FOKKER-PLANCK EQUATION. An equation representing one of the limiting cases of an **additive stochastic process**. It first occurred in the theory of diffusion when drift is present and may be written

$$\frac{\partial}{\partial t} v(x,t) = -2c \frac{\partial}{\partial x} v(x,t) + D \frac{\partial^2}{\partial x^2} v(x,t)$$

where v is the probability density for displacement at time t , D is the diffusion coefficient and c represents drift.

The Fokker-Planck equation describes the Brownian motion of a free particle in velocity space.

FOLDY-WOUTHUYSEN REPRESENTATION. In the Dirac theory for a spin $\frac{1}{2}$ particle, a positive energy particle can realize two independent states for each value of its physical momentum. These correspond to the two possible directions of the spin. According to quantum mechanics each such pair of physical states is to be represented by exactly two vectors in Hilbert space. There therefore exists a redundancy in the representation of these vectors in the usual formulation of the Dirac theory, where the corresponding wave functions have four components. It must therefore be possible to find a transformation such that the wave functions of a free Dirac electron of definite momentum have just two components, as in the **non-relativistic Pauli theory**. This problem was solved by Foldy and Wouthuysen by performing the canonical transformation

$$\begin{aligned} \psi &\rightarrow e^{iS} \psi = \psi' \\ H &\rightarrow e^{iS} H e^{-iS} = H' \end{aligned}$$

$$S = - \left(\frac{i}{2mc} \right) \beta \boldsymbol{\alpha} \cdot \mathbf{p} \frac{mc}{|\mathbf{p}|} \tan^{-1} \frac{|\mathbf{p}|}{mc}$$

on the Dirac equation

$$(\boldsymbol{\alpha} \cdot \mathbf{p} + \beta mc) \psi = E \psi$$

with the result that $H' = \beta \sqrt{m^2 + \mathbf{p}^2}$. In the representation in which β is diagonal the equation $H' \psi' = E \psi'$ has solutions where the upper components represent positive energies and the lower components negative energies. Furthermore, they have only two non-vanishing components. In this F - W representation the physical content of the Dirac equation is

greatly clarified. For example, in the F - W representation the position operator \mathbf{X}_{FW}

$$\mathbf{X}_{FW} = e^{-iS} \mathbf{x} e^{iS}$$

has the property that its time rate of change is given by \mathbf{p}/E , the velocity of the particle (in contrast to the old representation where the time rate of \mathbf{x} was $c\boldsymbol{\alpha}$ which would imply a velocity c for the particle, and different components of the velocity not being simultaneously measurable since $[\alpha_x, \alpha_y] \neq 0$). Furthermore $\mathbf{X}_{FW} \times \mathbf{p}$ the orbital angular momentum is a constant of the motion (in contrast to $\mathbf{x} \times \mathbf{p}$ which is not, in the Dirac representation). In the F - W representation there exists a spin angular momentum which is also separately a constant of the motion (in contrast to Σ which was not a constant of the motion in the Dirac representation).

FOOT-CANDLE. A unit of **illuminance** or **luminous flux density** when the foot is taken as the unit length. It is the illuminance on a surface one square foot in area on which there is a uniformly-distributed flux of one **lumen**, or the illuminance at a surface all points of which are at a distance of one foot from a uniform source of one **candle**. The term is synonymous with lumen per square foot.

FOOTING. A **foundation** structure used to distribute wall or column loads to the bearing soil or to the piling.

FOOT-LAMBERT. A unit of **luminance** equal to $1/\pi$ **candle** per square foot, or to the uniform luminance of a perfectly diffusing surface emitting or reflecting light at the rate of one **lumen** per square foot. A foot-candle is a unit of incident light and a foot-lambert is a unit of emitted or reflected light. For a perfectly reflecting and perfectly diffusing surface, the number of foot-candles is equal to the number of foot-lamberts.

FOOT-POUND. See **mechanical units**.

FORBIDDEN TRANSITION. In quantum mechanical terms, a transition between two states of a system for which the change in quantum numbers is one that, under the appropriate **selection rules**, makes the transition less probable than competing allowed transition (see **transition, allowed**)—other things, such as the energy change, being equal. As a case in point, transitions involving changes of 2 or more in angular momentum, in units of

$h/2\pi$, have often a smaller probability of occurrence than a possible competing "allowed" transition involving a change of only 1. Cases in which "forbidden" transitions occur are:

(1) Intercombination lines such as the 2537 Å line ($2^3P_1 - 1^1S_0$) in the spectrum of mercury violate the selection rule of $\Delta S = 0$. However, this rule is true only for pure Russell-Saunders coupling (see **coupling, Russell-Saunders**), and with increase in atomic number, spin-orbit interaction becomes more effective.

(2) The selection principles are deduced by analogy of the behavior of an electrical dipole, and therefore systems having a **quadrupole** moment exhibit the effects of transitions forbidden for dipoles, but not for **quadrupole radiation**.

(3) Forbidden transitions may occur as the result of variable magnetic dipole moment.

(4) Forbidden transitions may occur by the action of strong electric fields, either applied externally or produced by neighboring atoms or ions (enforced dipole moment).

FORBIDDEN TRANSITION, NUCLEAR.

The term forbidden transition has been taken over from optical spectra and applied to β -ray spectra. Those transformations of a nucleus which result in a change of more than one unit of angular momentum are characterized by this term even when they are highly probable as a result of the orbital angular momentum of the electron and the neutrino.

FORCE. (1) In dynamics, the physical agent which causes a change of momentum, measured by the time rate of change of momentum. If the speeds involved are low compared with that of light, a force may be defined as proportional to the mass m of a body and to the acceleration a of the body which is produced by the force. Thus $\mathbf{f} = kma$, where k is a constant for a given system of units, and has the dimensionless value unity in length-mass-time systems or $1/g$ in length-force-time systems, g being the acceleration due to gravity. Force is a vector quantity, requiring both a magnitude and a direction for its complete specification.

(2) In statics, the physical agent which produces a strain in a body.

(3) From its initial conception, which was purely mechanical as expressed in (1) and (2), above, the term force extends to denote loosely

any operating agency. (See special entries under this term which follow.)

FORCE, ACTIVE. See **force, external or active**.

FORCE, APPLIED. Forces exerted on a body by bodies in contact or bodies at a distance (as, for example, the earth). When the body is considered together with its support, the supporting **reactions** exerted on the body are not considered applied forces.

FORCE, CENTRAL. (1) A force which is always directed toward a fixed point. If a particle is acted upon by a central force only, its **angular momentum** with respect to the fixed point is a constant vector. The motion, therefore, must be **plane motion**. (2) The term is used in regard to **nuclear forces** to denote a force which acts along the line joining a pair of particles.

FORCE, CENTRIFUGAL. See **centrifugal force**.

FORCE, CENTRIPETAL. See **centripetal force**.

FORCE, CONCENTRATED. See **concentrated force**.

FORCE, CONSERVATIVE. See **conservative force**.

FORCE CONSTANT. In an elastic system obeying the **Hooke law**, the magnitude of the applied force F , and the elongation x , are related by $F = kx$, where the constant k is called the force constant.

FORCE CONSTANTS OF LINKAGES. Expressions of the forces acting between nuclei to restrain relative displacement. They provide the means of measurement of the resistance to stretching of the valence bond and the resistance to deformation of the valence angle, and they express these factors mathematically.

FORCE, CORIOLIS. See **Coriolis force**.

FORCED CONVECTION. See **heat transfer**.

FORCE, DISTRIBUTED. A force which acts over a line, surface, or volume of a body is called a distributed force. A *concentrated force* is an idealization in which the total force is considered to act at a point.

FORCED VIBRATIONS. See vibrations, forced.

FORCED WAVE. Any wave which is required to fit irregularities at the boundary of a system or satisfy some impressed force within the system. The forced wave will not in general be a characteristic mode of oscillation of the system. It cannot be exhibited independently unless the system admits of no free waves. (A homogeneous incompressible fluid bounded by two rigid surfaces is an example of such a system.)

The gravity lee wave in the atmosphere is an example of mixed forced and free waves.

FORCE, EFFECTIVE (EFFECTIVE MECHANOMOTIVE FORCE). The root mean square of the instantaneous force (see force, instantaneous) over a complete cycle. The unit is the dyne.

FORCE, EXTERNAL OR ACTIVE. A force applied to the given system by bodies in contact or at a distance.

FORCE FACTOR. (a) The force factor of an electromechanical transducer is: (1) the complex quotient of the force required to block the mechanical system divided by the corresponding current in the electric system; (2) the complex quotient of the resulting open-circuit voltage in the electric system divided by the velocity in the mechanical system. Force factors (a1) and (a2) have the same magnitude when consistent units are used and the transducer satisfies the principle of reciprocity. (See reciprocity theorem, acoustical.) It is sometimes convenient in an electrostatic or piezoelectric transducer to use the ratios between force and charge or electric displacement, or between voltage and mechanical displacement.

(b) The force factor of an electroacoustic transducer is: (1) the complex quotient of the pressure required to block the acoustic system divided by the corresponding current in the electric system; (2) the complex quotient of the resulting open-circuit voltage in the electric system divided by the volume velocity in the acoustic system. Force factors (b1) and (b2) have the same magnitude when consistent units are used and the transducer satisfies the principle of reciprocity.

FORCE FIELD. See field of force.

FORCE FIELD, CONSERVATIVE. A field whose force can be derived by taking the negative gradient of a scalar potential function, V , i.e., $\mathbf{F} = -\nabla V$. The work done by a conservative force on a particle in its motion between two given points is independent of the path. Alternative definitions are (a) that $\oint \mathbf{F} \cdot d\mathbf{s} = 0$ (see integral, line), and (b) that $\nabla \times \mathbf{F} = 0$ (see Stokes theorem). An example of a conservative force field is the inverse square law field of electric charges or of gravitational masses.

FORCE, GENERALIZED. Moment, pressure, force pairs, etc., may be considered as generalized forces (see displacement, generalized). The product of generalized force and corresponding generalized displacement gives a virtual or real work term.

FORCE, HEISENBERG. See Heisenberg force.

FORCE, IMPRESSED. Any external force acting on a particle in a dynamical system. The resultant force on each such particle can always be resolved into a resultant external impressed force and a resultant internal constraint force.

FORCE, INTERNAL. The equal and opposite forces between particles or bodies of a system. Their vector sum is zero so that they do not contribute to the total impulse and do not change the momentum of the system. They do enter into the energy balance because mechanical energy may be dissipated or stored.

FORCE, LORENTZ. See Lorentz force.

FORCE, "LOST." In the application of the d'Alembert principle by the method of Mach, the "lost" force on the j th particle of a dynamical system is equal to the difference between the external impressed force and the effective force, the latter being equal to the mass times the acceleration of the j th particle.

FORCE ON A CONDUCTOR. A charge dq moving with velocity \mathbf{v} through a steady magnetic field of flux density \mathbf{B} experiences a force

$$\mathbf{F} = dq(\mathbf{v} \times \mathbf{B}).$$

If the charge is moving along a conductor, $dq\mathbf{v} = Id\mathbf{l}$, so the force on an element $d\mathbf{l}$ of a conductor is

$$\mathbf{F} = Id\mathbf{l} \times \mathbf{B}.$$

FORCE ON A RIGID CIRCUIT. (See **energy of a system of current circuits**.) If the circuits are rigid, motion will change the **mutual inductances**, M_{ij} , but not the **self-inductances**, $L_i \equiv M_{ij}$. The change of energy of the current system, with motion of the circuits, is:

$$\begin{aligned} dU &= \sum \sum M_{ij} I_i dI_j + \sum \sum I_i I_j dM_{ij} - \sum F_l d\xi_l \\ &= \sum \sum M_{ij} I_i dI_j + \sum \sum \sum I_i I_j \frac{dM_{ij}}{d\xi_l} d\xi_l \\ &\quad - \sum F_l d\xi_l \end{aligned}$$

so for constant currents:

$$\left(\frac{\partial U}{\partial \xi_l} \right)_I = \sum \sum I_i I_j \frac{dM_{ij}}{d\xi_l} - F_l$$

and

$$\left(\frac{\partial U}{\partial \xi_l} \right)_I = \frac{1}{2} \sum \sum I_i I_j \frac{dM_{ij}}{d\xi_l}$$

from the expression for the energy of a system of circuits. Therefore

$$F_l = \frac{1}{2} \sum \sum I_i I_j \frac{dM_{ij}}{d\xi_l}$$

and the forces are such as to increase the mutual inductances. As in the case of a charged system, the energy of the system increases as it does work; the set of electromotive forces maintaining the currents does work at twice the rate that mechanical work is done. Substitution of torque for force, and rotation for displacement, in the foregoing yield the torques on the rigid elements of a system of circuits.

FORCE ON A SUBMERGED SURFACE.

Consider a *plane* surface of area A , submerged in a stationary liquid. Let the surface intersect the free surface of the liquid in a line XX . Then the force on the plane surface due to fluid pressure is pA , where p is the pressure at the centroid. The center of pressure is at a distance from XX equal to the ratio of the second and first moments of the surface area about XX .

The component in any required direction of the force on a *curved* surface due to fluid pressure is the same, in magnitude and line of action, as that computed for the projection of

the given surface on a plane normal to the required direction.

FORCE ON MOVING CHARGES AND CURRENTS. A charge dq moving with velocity \mathbf{v} through a steady magnetic field of flux density \mathbf{B} experiences a force

$$\mathbf{F} = dq(\mathbf{v} \times \mathbf{B}).$$

If the charge is moving along a conductor, $dq\mathbf{v} = Id\mathbf{l}$, so the force on an element $d\mathbf{l}$ of a conductor is

$$\mathbf{F} = Id\mathbf{l} \times \mathbf{B}.$$

FORCE POLYGON (POLYGON OF FORCES). The figure obtained by considering force vectors as free vectors and adding them successively in any order by placing the tail of each additional one at the head of the previous one. The resultant force is given in magnitude and direction by the line from the tail of the first to the head of the last. Closure of the force polygon is a necessary but not sufficient condition for equilibrium. The resultant may be a couple. (See **funicular polygon**.)

FORCE, RESTORING. The force which acts on a particle or portion of a mechanical system when displaced from equilibrium and whose direction is such as to return the system to equilibrium. In simple cases, the restoring force is linear, i.e., proportional to the first power of the distance. (See **Hooke law; force constant**.) For some physical systems, however, the restoring force may be proportional to the second or higher power of the distance.

FORCES, COMPOSITION OF. The combination of two or more forces to a simpler system with the same **resultant** force and the same **moment** about any point or axis.

FORCES, CONCURRENT. Forces which meet at a point. **Equilibrium** is assured if a sufficient number of independent equations are satisfied, for example,

$$\sum \mathbf{F}_i = 0,$$

or in three-dimensional space

$$\sum F_x = 0$$

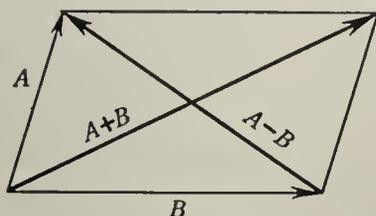

$$\sum F_y = 0$$

$$\sum F_z = 0.$$

FORCES, COPLANAR. A system of forces such that the lines of action of all the forces lie in a single plane.

FORCES IN THERMODYNAMICS OF IRREVERSIBLE PROCESSES. A number of causes can give rise to the occurrence of irreversible phenomena. These causes are, for example, temperature gradients, concentration gradients or **chemical affinities**. In the thermodynamics of irreversible processes, these quantities are usually called "forces" or "generalized affinities" and are denoted by X_i .

FORCES, PARALLELOGRAM OF. A geometrical representation by which the sum or difference of two concurrent forces **A** and **B** can be considered as the diagonals of a parallelogram. The two adjacent sides are proportional in length to the magnitude of the forces and their directions coincide with the lines of action of the forces. The diagonal represent-

Parallelogram of forces.

ing the sum passes through the origin of the two vectors. The diagonal representing the difference passes through the extremities of the two vectors.

FORCES, RESOLUTION OF. Replacement of a force by two or more **components** whose **resultant** is the given force. (See **composition of forces**.)

FORCES, RESULTANT OF. See **resultant**.

FORCES, TRIANGLE OF. Three concurrent forces which act such that the common point is in translational equilibrium, can be represented by a triangle. The sides of the triangle are proportional in length to the magnitude of the forces and the directions of the sides coincide with the lines of action of the forces. (See **equilibrium of a point; statics**.)

FORCE, SURFACE. See **surface force**.

FORCE SYSTEMS, EQUIVALENT. See **equivalent force systems**.

FORCE, TANGENTIAL. A force parallel to and in a surface under consideration, e.g., frictional force between a belt and a pulley wheel, or shear force on a cross-sectional plane.

FORCE, TRANSMISSIBILITY OF. See **transmissibility of force**.

FORCE, UNITS OF. See **mechanical units**.

FORCE WITHIN A CHARGED SYSTEM. If the conductors of a charged set are allowed to move, hence to let the system do work, the energy change of the system is given by:

$$dU = \sum V_i dq_i - \sum F_i d\xi_i$$

where F_i is the force, in the direction of the displacement $d\xi_i$, on the i th conductor. If the charges are held constant, $dq_i = 0$, and we have

$$\left(\frac{\partial U}{\partial \xi_i}\right)_q = -F_i.$$

If the potentials are held constant, write

$$d(U - \sum V_i q_i) = -\sum q_i dV_i - \sum F_i d\xi_i$$

but

$$U - \sum V_i q_i = \frac{1}{2} \sum V_i q_i - \sum V_i q_i = -U$$

(see **energy of a charged system**) so that

$$dU = \sum q_i dV_i + \sum F_i d\xi_i$$

and

$$\left(\frac{\partial U}{\partial \xi_i}\right)_V = F_i.$$

Note that for constant potential, the energy of the system increases at the same rate mechanical work is done; the sources of potential supply twice as much energy as needed for the mechanical work. The derivatives

$$\left(\frac{\partial U}{\partial \xi_i}\right)_q \quad \text{and} \quad \left(\frac{\partial U}{\partial \xi_i}\right)_V$$

can readily be expressed in terms of

$$\frac{\partial p_{ij}}{\partial \xi_i} \quad \text{and} \quad \frac{\partial c_{ij}}{\partial \xi_i},$$

using the expressions for the energy of a charged system in terms of coefficients of potential and induction. Replacing force (F_i) by torque (T_i), and linear displacement ($d\xi_i$) by rotation ($d\theta_i$), the foregoing relations yield the torques of the charged system.

FOREST. The set of **trees** formed by choosing a tree for each maximal connected **subgraph** of a graph G . If G has v **vertices**, e **edges** and P maximal connected subgraphs, the number of **elements** in a forest is $v - P$. The number of elements not in a forest is equal to $\mu = e - v + P$.

FORM. A homogeneous polynomial in two or more variables. A form in two variables, e.g., $a_{11}x_1^2 + 2a_{12}x_1x_2 + a_{22}x_2^2$ is called a binary form; the corresponding adjectives for a greater number of variables are ternary, quaternary, quinary, senary, etc. A form is definite if all its values are of one sign, except that its value for $x_1 = x_2 = \dots = x_n = 0$ is, of course, zero.

A form of degree two is quadratic, the adjectives for higher degrees being cubic, quartic, quintic, sextic and so forth.

FORM, BILINEAR. A homogeneous polynomial in $2n$ variables $x_1, x_2, \dots, x_n; y_1, y_2, \dots, y_n$, which is linear in the x 's and in the y 's considered separately; thus $a_{11}x_1y_1 + a_{12}x_1y_2 + a_{21}x_2y_1 + a_{22}x_2y_2$ is a bilinear form. If the x_i are identified with the y_i , the result is a quadratic form.

FORM, DIFFERENTIAL. See differential form.

FORM DRAG. See drag.

FORM FACTOR. (1) Factor introduced into a theory, usually by physical and non-rigorous arguments, to allow consequences of the theory to be computed without contributions from values of a parameter for which the theory is not applicable (see **cut-off**). (2) A means for describing one attribute of the shape of an **alternating-current** wave. The strength of a-c constantly varies in magnitude and direction. The effective value of a-c is the root-mean-square (rms) value. The form factor is the ratio of the rms value of the wave to its full-wave rectified average value; the factor is unity for a square wave, and 1.11 for a pure sine wave. It is of importance in the measurement of waves containing harmonics, for it is the ratio of the reading on an rms meter to that on an ideal rectifier-type meter.

FORM PARAMETER FOR TURBULENT BOUNDARY LAYER. The form parameter for a **turbulent boundary layer** is usually defined as

$$H = \frac{\delta^*}{\theta},$$

where δ^* is the **displacement thickness** and θ is the **momentum thickness**.

In calculations on turbulent boundary layers the usual assumption is that the velocity profile, expressed non-dimensionally, depends only on H . The value of H varies from about 1.4 in zero pressure gradient to about 2 or more at separation. (See also **turbulent boundary layer**.)

FORWARD DIFFERENCE OPERATOR. See **difference operators**.

FORWARD INTERPOLATION. See **Newton interpolation formulas**.

FORWARD SCATTER. The scattering of **radiant energy** into the hemisphere of space bounded by a plane normal to the direction of the incident radiation and lying on the side toward which the incident radiation was advancing; the opposite of **backward scatter**.

In **Rayleigh scattering**, forward scatter accounts for half of the total. As the particle size increases above the Rayleigh limit, an increasing fraction of the total scattering is forward scattering.

FOSTER REACTANCE THEOREM. For a two-terminal, dissipationless network, consisting of n meshes, the driving point impedance has a reactance which is zero at frequencies $f_1, f_3 \dots f_{2n-1}$, and which is infinite at frequencies $f_2, f_4 \dots f_{2n-2}$; the reactance is proportional to the expression

$$\frac{(f^2 - f_1^2)(f - f_3^2) \dots (f^2 - f_{2n-1}^2)}{(f^2 - f_2^2)(f^2 - f_4^2) \dots (f^2 - f_{2n-2}^2)};$$

where $0 < f_1 < f_2 \dots < f_{2n-1} < \infty$.

Since the derivative of the reactance with respect to frequency is greater than zero for frequency values between zero and infinity, its **poles** and **zeros** alternate.

FOUNDATION, ELASTIC. See **elastic foundation**.

FOUNDATION MODULUS. The ratio of the local pressure to the local deformation for the simplest type of **elastic foundation**. (See **beam on elastic foundation**.)

FOUR-DIMENSIONAL VECTOR ANALYSIS. See **Minkowski world**.

FOUR-FACTOR FORMULA. In chain reacting systems, the infinite multiplication factor, k_x can often be represented by the product $\eta\epsilon pf$. η is the average number of fast fission neutrons emitted as a result of the capture of one thermal neutron in the fuel material, ϵ is the **fast-fission factor**, p is the **resonance escape probability** for an infinite system, and f is the **thermal utilization** for an infinite system.

FOUR-FORCE. The **four-vector** describing the rate of change of four-momentum along the space-time path of a particle:

$$m_0 \frac{dv_\mu}{ds}$$

(m_0 is the rest mass.)

FOURIER ANALYSIS. The process of finding the representation of a function as a **Fourier series**. (See **harmonic analysis**.)

FOURIER-BESSEL TRANSFORM. The functions defined by

$$f(y) = \int_0^\infty F(x) J_m(xy) x dx;$$

$$F(x) = \int_0^\infty f(y) J_m(xy) y dy$$

are a pair of Fourier-Bessel transforms, the function J_m being a **Bessel function** of order m .

FOURIER EQUATION. See **Fourier law**.

FOURIER LAW. An empirical law relating to the conduction of heat. It states that the heat flux (rate of heat transfer per unit time and area) is proportional to the temperature gradient, or

$$\frac{\dot{Q}}{A} = \dot{q} = -k \text{ grad } T$$

or, in one dimension

$$\dot{q} = -k \frac{dT}{dn}$$

where n is the normal.

The coefficient of proportionality k is called the (*coefficient of*) **thermal conductivity**; it is a property of the medium conducting the heat, and depends on the local state.

The Fourier law leads to the formulation of the Fourier equation for heat conduction:

$$\frac{\partial T}{\partial t} = a \nabla^2 T$$

where t is time, and where

$$a = \frac{k}{\rho c_p}$$

is called the (*coefficient of*) **thermal diffusivity** of the material conducting the heat.

The Fourier law, and hence the Fourier equation, gives a description of the process of heat conduction which agrees well with experiment. However, it has been pointed out that the equation is parabolic, implying an infinite rate of propagation of local changes in temperature, which is physically improbable. When the changes in temperature are extremely rapid, the Fourier equation must be expected to break down. It has been proposed to replace the Fourier law by an alternative empirical assumption.

When dealing with problems of heat conduction in liquids and gases, as opposed to solids, it must be borne in mind that the above equations describe the physical phenomena adequately only in very thin layers of fluid. When the extent of the fluid is not extremely small, the temperature field causes density gradients to appear. In turn, these will cause the fluid to move in the gravitational field of the earth. The resulting motion attributable to conduction causes much larger rates of heat transfer than those termed *natural convection*.

FOURIER SERIES. A single-valued function, continuous except possibly for a finite number of finite discontinuities in the interval $-\pi$ to π , and with only a finite number of **maxima** or **minima** in that interval, may, according to the Fourier theorem, be represented by a **Fourier series**

$$f(x) = \sum_{n=1}^{\infty} a_n \sin nx + \frac{b_0}{2} + \sum_{n=1}^{\infty} b_n \cos nx$$

where the coefficients are given by

$$\pi a_n = \int_{-\pi}^{\pi} f(t) \sin ntdt;$$

$$\pi b_n = \int_{-\pi}^{\pi} f(t) \cos ntdt.$$

A change of variable may be made so that the interval extends from 0 to n , 0 to $2n$, L to $-L$, etc. The series may be generalized to permit the expansion of a function of several variables. Fourier analysis is the process of representing a function in a Fourier series.

If the range of the variable is $-\infty < x < \infty$, the Fourier **integral** is

$$2\pi f(x) = \int_{-\infty}^{\infty} f(z)e^{iy(x-z)}dydz$$

or, in a more common form, if $f(x)$ is real the exponential function may be replaced by $\cos y(x - z)$.

FOURIER SERIES, COMPLEX. If in the Fourier series

$$f(x) = \sum_{n=1}^{\infty} a_n \sin nx + \frac{b_0}{2} + \sum_{n=1}^{\infty} b_n \cos nx,$$

we set

$$\begin{aligned} 2\beta_n &= b_n - ia_n & n > 0 \\ 2\beta_n &= b_{-n} + ia_{-n} & n < 0 \\ 2\beta_0 &= b_0 \end{aligned}$$

then the series takes the convenient complex form

$$f(x) = \sum_{-\infty}^{\infty} \beta_n e^{inx}.$$

FOURIER SERIES, HALF-RANGE. In a full-range Fourier series the length of the fundamental interval being $2L$, the $f(x)$ is expanded in terms of the functions $\sin \frac{n\pi x}{L}$ and $\cos \frac{n\pi x}{L}$, the coefficients being given by integrals taken over the fundamental interval. In a half-range series, $f(x)$ is expanded either in terms of $\sin \frac{n\pi x}{L}$ or of $\cos \frac{n\pi x}{L}$, the coefficients being given by integrals taken over an interval of length L .

FOURIER SYNTHESIS. The process of computing the form of a function from the values of its Fourier coefficients.

FOURIER TRANSFORM. Subject to certain restrictions, $f(y)$ is the Fourier transform of $F(x)$, where

$$f(y) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{ixy} F(x) dx;$$

$$F(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{-ixy} f(y) dy.$$

In some applications, the factors $1/\sqrt{2\pi}$ are modified. (See also **integral transform**.)

In feedback and control-system theory the Fourier transform is used almost exclusively for converting a function of time t , $f(t)$, into a function of angular frequency ω , $F(i\omega)$, which is the Fourier transform of $f(t)$ and defined by

$$F(i\omega) = \int_{-\infty}^{+\infty} e^{-i\omega t} f(t) dt$$

the integral existing provided $\int_{-\infty}^{+\infty} |f(t)| dt$ converges. Then

$$f(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{+i\omega t} F(i\omega) d\omega.$$

The convergence limitation on $f(t)$ excludes many frequent functions, notably the **step function**, a fact which is partly responsible for the much wider use of the **Laplace transform**.

FOURIER TRANSFORM THEOREMS.

(a) *Even and odd relationships.* If $f(t)$ is a real, even function of t , $F(i\omega)$ is a real, even function of ω .

If $f(t)$ is a real, odd function of t , $F(i\omega)$ is an imaginary, odd function of ω .

(b) *Conjugacy relationships.* If $f(t)$ is real, $F(i\omega)$ and $F(-i\omega)$ are complex conjugates.

(c) *Time-shift theorem.* If $F(i\omega)$ is the Fourier transform of $f(t)$ then the Fourier transform of $f(t + t_0)$ is $e^{+i\omega t_0} F(i\omega)$, where t_0 is real and finite.

(d) *Frequency-shift theorem.* If $F(i\omega)$ is the Fourier transform of $f(t)$ then $F(i\omega + \omega_0)$ is the Fourier transform of $e^{-it\omega_0} f(t)$.

(e) *Parseval's theorem.* If $F_1(i\omega)$, $F_2(i\omega)$ are the Fourier transforms of $f_1(t)$, $f_2(t)$ then

$$\begin{aligned} \int_{-\infty}^{\infty} F_1(i\omega) F_2(i\omega) d\omega &= 2\pi \int_{-\infty}^{\infty} f_1(t) f_2(-t) dt \\ &= 2\pi \int_{-\infty}^{\infty} f_1(-t) f_2(t) dt \end{aligned}$$

and conversely

$$\begin{aligned} \int_{-\infty}^{\infty} f_1(t) f_2(t) dt &= \frac{1}{2\pi} \int_{-\infty}^{\infty} F_1(i\omega) F_2(-i\omega) d\omega \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} F_1(-i\omega) F_2(i\omega) d\omega. \end{aligned}$$

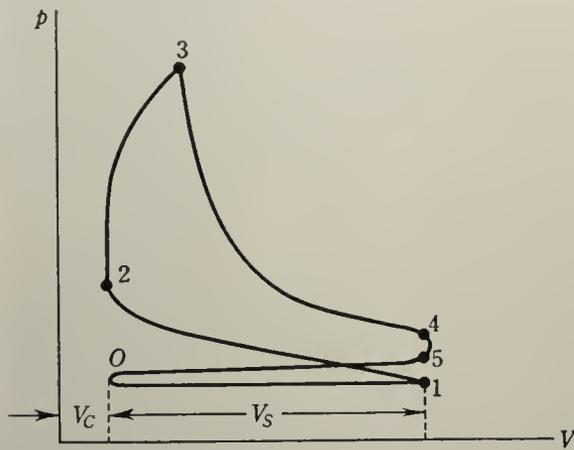

In particular, if $f_1(t) \equiv f_2(t) \equiv f(t)$ and $f(t)$ is real

$$\int_{-\infty}^{\infty} \{f(t)\}^2 dt = \frac{1}{2\pi} \int_{-\infty}^{\infty} F(i\omega)F(-i\omega)d\omega$$

$$= \frac{1}{2\pi} \int_{-\infty}^{\infty} |F(i\omega)|^2 d\omega.$$

FOUR-MOMENT EQUATION. A relation between the four end moments of two adjacent beams which takes into account the possibility of more than two members meeting at a joint. It reduces to the **three-moment equation** when the moment is continuous through the joint. Stability and vibration problems of frames lead to and are solved conveniently by four-moment equations.

FOUR-STROKE ENGINE. A reciprocating engine in which one working stroke is executed per two revolutions (four strokes). A four-stroke engine (see schematic figure) is

Four-stroke engine cycle.

equipped with an inlet valve i and an exhaust valve e and the sequence of operations is as follows:

- 0-1. Introduction of working fluid (air in diesel engine, combustible mixture in gasoline engine). Valve i open, valve e closed. First stroke.
- 1-2. Compression of working fluid. Valves i and e closed. Second stroke.
- 2-3-4. Combustion and expansion. Combustion nearly at $V = \text{constant}$ in gasoline engine and nearly at $p = \text{constant}$ in diesel engine. Valves i and e closed. Third stroke.

4-5-0. Release and subsequent expulsion of burnt gases. Valve e open. Fourth stroke.

In practice the i and e valves do not open at dead centers, as assumed in the idealized description above. They open earlier and close later to allow for the finite time of opening and closing and for the acceleration of gas columns, etc.

FOUR-VECTORS AND TENSORS. The four-dimensional line element is assumed to have the form

$$(ds)^2 = g_{ik}dx^i dx^k$$

$$= -[(dx)^2 + (dy)^2 + (dz)^2] + c^2 dt^2$$

$$g_{11} = g_{22} = g_{33} = -1 \quad g_{44} = c^2$$

$$g_{ik} = 0 \quad \text{for } i \neq k \quad \det g_{ik} = |g| = -c^2.$$

The relationship between the covariant and contravariant components of a four-vector are ($i, k = 1, 2, 3$)

$$a_i = -a^i$$

$$a_4 = c^2 a^4$$

the relationships between the components of a tensor t of second rank are

$$t_{ik} = t^{ik} \quad t_k^i = -t^{ik}$$

$$t_{i4} = -c^2 t^{i4} \quad t_4^i = c^2 t^{i4}$$

$$t_{44} = c^4 t^{44} \quad t_i^4 = -t^{4i}$$

$$t_4^4 = c^2 t^{44}.$$

If it is assumed that Σ' moves with the velocity v relative to Σ in the direction of the positive x -axis, the transformation laws for the contravariant components a^i are

	a^1	a^2	a^3	a^4
$a^{1'}$	$\frac{1}{\sqrt{1 - \beta^2}}$	0	0	$-\frac{v}{\sqrt{1 - \beta^2}}$
$a^{2'}$	0	1	0	0
$a^{3'}$	0	0	1	0
$a^{4'}$	$-\frac{v}{c^2 \sqrt{1 - \beta^2}}$	0	0	$\frac{1}{\sqrt{1 - \beta^2}}$

Under this motion, the transformation matrix for the contravariant components t^{ik} of a tensor of rank 2 is:

	11	12	13	14	21	22	23	24	31	32	33	34	41	42	43	44
11	$\frac{1}{1-\beta^2}$	0	0	$\frac{v}{1-\beta^2}$									$\frac{-v}{1-\beta^2}$	0	0	$\frac{v^2}{1-\beta^2}$
12	0	$\frac{1}{\sqrt{1-\beta^2}}$	0	0									0	$\frac{-v}{\sqrt{1-\beta^2}}$	0	0
13	0	0	$\frac{1}{\sqrt{1-\beta^2}}$	0									0	0	$\frac{-v}{\sqrt{1-\beta^2}}$	0
14	$\frac{-v}{c^2(1-\beta^2)}$	0	0	$\frac{1}{1-\beta^2}$									$\frac{\beta^2}{1-\beta^2}$	0	0	$\frac{-v}{1-\beta^2}$
21					$\frac{1}{\sqrt{1-\beta^2}}$	0	0	$\frac{-v}{\sqrt{1-\beta^2}}$								
22					0	1	0	0								
23		0			0	0	1	0				0			0	
24					$\frac{-v}{c^2\sqrt{1-\beta^2}}$	0	0	$\frac{1}{\sqrt{1-\beta^2}}$								
31									$\frac{1}{\sqrt{1-\beta^2}}$	0	0	$\frac{-v}{\sqrt{1-\beta^2}}$				
32									0	1	0	0				
33		0				0			0	0	1	0			0	
34									$\frac{-v}{c^2\sqrt{1-\beta^2}}$	0	0	$\frac{1}{\sqrt{1-\beta^2}}$				
41	$\frac{-v}{c^2(1-\beta^2)}$	0	0	$\frac{\beta^2}{1-\beta^2}$									$\frac{1}{1-\beta^2}$	0	0	$\frac{-v}{1-\beta^2}$
42	0	$\frac{-v}{c^2\sqrt{1-\beta^2}}$	0	0									0	$\frac{1}{\sqrt{1-\beta^2}}$	0	0
43	0	0	$\frac{-v}{c^2\sqrt{1-\beta^2}}$	0									0	0	$\frac{1}{\sqrt{1-\beta^2}}$	0
44	$\frac{\beta^2}{c^2(1-\beta^2)}$	0	0	$\frac{-v}{c^2(1-\beta^2)}$									$\frac{-v}{c^2(1-\beta^2)}$	0	0	$\frac{1}{1-\beta^2}$

An antisymmetric tensor of rank 2 is also called a six-vector. The transformation matrix

for a contravariant six-vector is, in the case of the motion stated above:

	14	24	34	23	31	12
14	1	0	0	0	0	0
24	0	$\frac{1}{\sqrt{1-\beta^2}}$	0	0	0	$\frac{+v}{c^2\sqrt{1-\beta^2}}$
34	0	0	$\frac{1}{\sqrt{1-\beta^2}}$	0	$\frac{-v}{c^2\sqrt{1-\beta^2}}$	0
23	0	0	0	1	0	0
31	0	0	$\frac{-v}{\sqrt{1-\beta^2}}$	0	$\frac{1}{\sqrt{1-\beta^2}}$	0
12	0	$\frac{+v}{\sqrt{1-\beta^2}}$	0	0	0	$\frac{1}{\sqrt{1-\beta^2}}$

Transformation law for a symmetric contravariant tensor of rank 2:

$$\begin{aligned}
 t^{11'} &= \frac{t^{11} - 2vt^{14} + v^2t^{44}}{1 - \beta^2} \\
 t^{22'} &= t^{22}; \quad t^{33'} = t^{33} \\
 t^{44'} &= \frac{\beta^2t^{11} - 2vt^{14} + c^2t^{44}}{c^2(1 - \beta^2)} \\
 t^{12'} &= \frac{t^{12} - vt^{24}}{\sqrt{1 - \beta^2}}; \quad t^{13'} = \frac{t^{13} - vt^{34}}{\sqrt{1 - \beta^2}} \\
 t^{23'} &= t^{23} \\
 t^{14'} &= \frac{-vt^{11} + (c^2 + v^2)t^{14} - c^2vt^{44}}{c^2\sqrt{(1 - \beta^2)}} \\
 t^{24'} &= \frac{-vt^{12} + c^2t^{24}}{c^2(1 - \beta^2)}.
 \end{aligned}$$

Relativistic invariants are

$$t^{11} + t^{22} + t^{33} - c^2t^{44} = -g_{i\lambda}t^{i\lambda}$$

and

$$\begin{aligned}
 (t^{11})^2 + (t^{22})^2 + (t^{33})^2 + c^4(t^{44})^2 \\
 + 2 \left[(t^{12})^2 + (t^{23})^2 + (t^{31})^2 \right. \\
 \left. - c^2(t^{14})^2 - c^2(t^{24})^2 - c^2(t^{34})^2 \right] \\
 = g_{i\mu}g_{\lambda\rho}t^{i\lambda}t^{\mu\rho}.
 \end{aligned}$$

For further details, see Erwin Madelung, *Die mathematischen Hilfsmittel des Physikers*, Third Edition, 1936, Springer (Berlin).

FOWLER FUNCTION. The photoelectric yield for a metallic surface can be expressed as $y = \alpha AT^2\phi(x)$, where $\phi(x)$ is the Fowler function. A is the constant appearing in the **Richardson-Dushman equation**. The parameter x is given by $x = (h\nu - h\nu_0)/kT$, where ν_0 is the photoelectric threshold frequency. The fraction of those electrons incident at the surface per unit area per unit time that absorb a quantum and escape (for unit intensity of incident radiation) is denoted by α .

FRACTIONAL BOND ORDER. See **bond character**; **mobile bond order**.

FRACTIONAL PARENTAGE COEFFICIENT. A coefficient introduced by Raeh in the theory of spectroscopy to describe the way in which several particles obeying **Fermi-Dirac statistics** (e.g., electrons) can be coupled

together to form antisymmetric states. Suppose Φ_β denotes a set of antisymmetric eigenfunctions for $n - 1$ particles moving independently in a common field of force, and let ϕ_γ denote the eigenfunctions for a single particle in the same field of force. Then any of the products $\Phi_\beta\phi_\gamma$ are eigenfunctions for the whole collection of n particles. However, these products are not in general antisymmetric; only certain linear combinations

$$\Psi_\alpha = \sum_{\beta\gamma} c_{\beta\gamma} \Phi_\beta\phi_\gamma$$

will be antisymmetric. The coefficients c are the fractional parentage coefficients, each eigenfunction α of the n -particle problem possessing a set of "parent" eigenfunctions β of the $(n - 1)$ -particle problem. In practice, the summation is restricted to those eigenfunctions which are degenerate in energy in the common field of force. Straightforward methods then exist for computing their values.

FRACTION, CONTINUED. A continued fraction is an infinite **sequence** $\{s_n\}$ with members formed from the sequences a_1, a_2, \dots and b_0, b_1, b_2, \dots according to the following directions. The term s_n is found by replacing the denominator of s_{n-1} by $(b_{n-1} + a_n/b_n)$. When written in the conventional way such a fraction is rather awkward, for it would read

$$\begin{aligned}
 b_0 + \frac{a_1}{b_1 + \frac{a_2}{b_1 + \frac{a_3}{b_3 + \dots}}}
 \end{aligned}$$

It can be simplified by writing it on one line with the plus sign properly placed, as

$$b_0 + \frac{a_1}{b_1} + \frac{a_2}{b_2} + \frac{a_3}{b_3} + \dots$$

or, in a two-line form

$$\left(\begin{array}{c} a_1, a_2, \dots \\ b_0, b_1, b_2, \dots \end{array} \right).$$

Some modifications of these notations also appear. (See use of $\overline{\quad}$ on next page.)

When there are a finite number of terms, the fraction is called **terminating**; if there are an infinite number of terms, **non-terminating**. **Convergence** behavior of such fractions can be studied by generalization of the methods used for **series**.

Sometimes continued fractions are suitable as solutions of a linear second-order **differential equation**, which will be assumed given in the form

$$y = A_0(x)y' + B_1(x)y''.$$

If this equation is differentiated n times the result is

$$y^{(n)} = A_n y^{(n+1)} + B_{n+1} y^{(n+2)},$$

where

$$A_n = (A_{n-1} + B'_n)/(1 - A'_{n-1})$$

and

$$B_{n+1} = B_n/(1 - A'_{n-1}).$$

The ratio y/y' is a continued fraction and it is the reciprocal of the logarithmic derivative of the solution to the differential equation. The result is found to be

$$y/y' = A_0 + \frac{B_1}{A_1} + \frac{B_2}{A_2} + \dots$$

The method does not seem to be readily extended to differential equations of higher order. Its most familiar application in mathematical physics is to the **Mathieu equation**.

In the systematic evaluation of continued fractions, consider the (possibly infinite) system of differences

$$\begin{aligned} x_0 &= b_0x_1 + a_1x_2, \\ x_1 &= b_1x_2 + a_2x_3, \\ x_2 &= b_2x_3 + a_3x_4, \\ &\dots \end{aligned}$$

So long as no x_i vanishes or becomes infinite one can write

$$\begin{aligned} x_0/x_1 &= b_0 + a_1/(x_1/x_2), \\ x_1/x_2 &= b_1 + a_2/(x_2/x_3), \\ x_2/x_3 &= b_2 + a_3/(x_3/x_4), \end{aligned}$$

and with repeated substitution

$$x_0/x_1 = b_0 + a_1/\overline{b_1} + a_2/\overline{b_2} + \dots$$

where each horizontal bar signifies the inclusion of all that follows. The right-hand number is a continued fraction. If one arbitrarily sets $x_{i+1} = 0$ and $x_i = 1$, considering only the first i equations, the finite continued fraction can be evaluated by solving the i th equation for x_{i-1} ; substituting in the preceding and solving

for x_{i-2}/x_{i-1} ; and continuing until x_0/x_1 is obtained. In many applications the a_i and b_i are functions of a variable x , and one truncates and evaluates in the manner just described.

A finite continued fraction

$$F_n = b_0 + a_1/\overline{b_1} + \dots + a_n/b_n \equiv A_n/B_n,$$

where A_n and B_n are polynomials in the a_i and b_i can be otherwise evaluated by means of the recursions (see **continuant**)

$$\begin{aligned} A_n &= b_n A_{n-1} + a_n A_{n-2}, \\ B_n &= b_n B_{n-1} + a_n B_{n-2}. \end{aligned}$$

These relations, however, though of great theoretical importance, are not to be recommended for computation in general since they tend to be highly unstable numerically.

The fraction F_n is called the n th approximant to F ; A_n and B_n the n th numerator and denominator. If all A_n and B_n are given, and if

$$A_n/B_n \neq A_{n+1}/B_{n+1}$$

for every n , then the a_n and b_n are determined uniquely. In particular the approximants F_{2n} are called the even parts, F_{2n+1} the odd parts, of F , and it is possible to form a continued fraction whose approximants are the even parts of F , and one whose approximants are the odd parts.

For applications of continued fractions, see **reciprocal differences**; **Padé table**.

FRACTION, PARTIAL. When a given rational fraction is resolved into a sum of simpler fractions the individual terms in the sum are called partial fractions. The process of resolving a fraction in this way is the inverse process to that of reducing to a common denominator. If the fraction is of the form $f(x)/g(x)$, where the degree of the numerator is less than that of the denominator, $g(x)$ may be written as

$$g(x) = a_0(x - x_1)^{r_1}(x - x_2)^{r_2} \dots$$

$$(x^2 + 2b_1x + c_1)^{s_1}(x^2 + 2b_2x + c_2)^{s_2} \dots$$

Then the fraction $f(x)/g(x)$ may be written as the sum of $r_1 + r_2 + \dots + s_1 + s_2 + \dots$ in the form

$$\frac{A_1}{x - a} + \frac{A_2}{(x - a)^2} + \dots + \frac{A_r}{(x - a)^r}$$

with constant partial numerators, and $s_1 + s_2 + \dots$ in form

$$\frac{B_1 + C_1x}{Q} + \frac{B_2 + C_2x}{Q^2} + \dots + \frac{B_s + C_sx}{Q^s}$$

with linear partial numerators where the partial denominators have the form $Q = (x^2 + 2bx + c)$. The undetermined coefficients A_i, B_i, C_i in these fractions may be obtained by clearing of fractions and equating coefficients of like powers of x on both sides of the equality, which is an identity in x ; or by other special devices, such as substituting special values of x . An **integral** may often be evaluated by converting the integrand into a sum of partial fractions.

FRACTURE, BRITTLE. See **brittle fracture**.

FRACTURE LINE THEORY. See **rupture line theory**.

FRAME. A structure composed of **beams** and **beam-columns** joined in such a manner that load can be carried only if the joints are able to transmit or take appreciable moment (see **framework**). In a *rigid frame* the rotation of all members framing into a joint is the same. The word rigid refers to the absence of relative rotation at a joint, whereby the frame itself would deform. (See **inequalities, method of**.)

FRAME OF REFERENCE. A coordinate system in which position measurements can be made.

FRAME OF REFERENCE, INERTIAL. A frame of reference in which a free body (i.e., one subject to no forces) is not accelerated. Newton's laws of motion are obeyed in all inertial frames. The special theory of relativity is based on the postulates: (a) that all inertial frames of reference are equivalent for the description of physical phenomena, and (b) that the speed of light has the same value in all inertial frames of reference.

FRAME, PORTAL. See **portal frame**.

FRAMES, MECHANISM METHOD OF ANALYSIS. See **mechanism method of analysis of frames**.

FRAMEWORK. A system of rigid or deformable bodies of arbitrary sizes and shapes fastened together to form a whole, which can be in equilibrium under the action of suitable forces. For example, a bridge truss. Moment carrying capacity at the joints is not essential, as it is for a frame.

FRANCK-CONDON PRINCIPLE. The Franck-Condon principle forms the basis for an understanding of the intensity distribution in a molecular **band-system** (see also **Condon parabola**). In its elementary form the F.C.P. is based on the fact that an electron "jump" in a molecule takes place so rapidly in comparison with the vibrational motion that immediately afterwards the nuclei have very nearly the same relative position and velocity as before. A transition between two different electronic levels of a molecule therefore takes place between points on the respective potential curves (see **potential functions of a molecule**) which lie very nearly vertically above each other, that is, for vibrational levels for which the nuclear distance at the turning point of the vibrational motion is nearly the same.

In the wavemechanical form of the F.C.P. the transition probability depends on the magnitude of the overlap integral of the vibrational eigenfunctions $\psi_{v'}$ and $\psi_{v''}$

$$R^{v'v''} = \bar{R}_e \int \psi_{v'} \psi_{v''} dr$$

where \bar{R}_e is the mean electronic transition moment which varies only very slowly with the internuclear distance r . The intensity of an electronic (vibronic) band is given in emission by

$$I_{em.}^{v'v''} = \frac{64}{3} \pi^4 c N_{v'} v^4 \bar{R}_e^2 \left[\int \psi_{v'} \psi_{v''} dr \right]^2$$

and in absorption

$$I_{abs.} = \frac{8\pi^3}{3hc} I_o \Delta x N_{v''} v \bar{R}_e^2 \left[\int \psi_{v'} \psi_{v''} dr \right]^2$$

where $N_{v'}$ and $N_{v''}$ are the numbers of molecules in the vibrational levels v' and v'' respectively, I_o , the intensity of the incident beam of light, Δx , the thickness of the absorbing layer, h , Planck's constant, and c , the velocity of light.

FRANKLIN EQUATION. The energy level E of sound in a room decays exponentially with time t . Thus

$$E = E_o e^{-\mu t}$$

where μ is the decay constant, and E_o is the initial sound level. The Franklin equation states that

$$\mu = c\bar{\alpha}S/4V$$

where c is the velocity of sound, $\bar{\alpha}$ is the mean sound absorption coefficient, S is the exposed surface, and V is the volume of the room. For dead rooms (i.e., rooms which are exceptionally non-reverberant and $\bar{\alpha}$ is comparable with unity), Franklin's equation must be replaced by the **Eyring equation**, where $\bar{\alpha}$ is replaced by $\log(1 - \bar{\alpha})$, thus

$$\mu = -c \log(1 - \bar{\alpha})S/4V.$$

F-RATIO. See **degrees of freedom**.

FRAUNHOFER DIFFRACTION. Diffraction phenomena observed when both the point of observation and (usually) the source are effectively at infinite distance from the aperture or other diffracting agency. (For the Fraunhofer diffraction pattern of a circular aperture, see the discussion of the **Airy disc**; see also **rectangular aperture** and **slit**.)

FREDHOLM DETERMINANT. Consider a Fredholm integral equation of the second kind:

$$\phi(x) = f(x) + \lambda \int_a^b K(x, \xi) \phi(\xi) d\xi.$$

The Fredholm determinant for the kernel $K(x, \xi)$ is

$$D(\lambda) = 1 - \lambda \int_a^b K(\xi_1, \xi_1) d\xi_1 + \frac{\lambda^2}{2!} \int_a^b \int_a^b \begin{vmatrix} K(\xi_1, \xi_1) & K(\xi_1, \xi_2) \\ K(\xi_2, \xi_1) & K(\xi_2, \xi_2) \end{vmatrix} d\xi_1 d\xi_2 + \dots$$

If we write

$$D(x, \xi; \lambda) = \lambda K(x, \xi) - \lambda^2 \int_a^b \begin{vmatrix} K(x, \xi) & K(x, \xi_1) \\ K(\xi_1, \xi) & K(\xi_1, \xi_1) \end{vmatrix} d\xi_1 + \dots,$$

then the solution of the above integral equation is given by

$$\phi(x) = f(x) + \int_a^b f(\xi) \frac{D(x, \xi; \lambda)}{D(\lambda)} d\xi,$$

in analogy with **Cramer's rule** for n equations in n unknowns.

FREDHOLM THEOREM (FOR INTEGRAL EQUATIONS). The theorem of the alternative for integral equations (*cf.* **alternative, theorem of**), namely: for fixed λ , a Fredholm equation of the second kind

$$\phi(x) = f(x) + \lambda \int_a^b K(x, z) \phi(z) dz$$

either has a unique continuous solution $\phi(x)$ for every continuous $f(x)$ or else the corresponding equation of the first kind (i.e., with $f(x) \equiv 0$) has a positive finite number r of linearly **independent** solutions $\psi_1(x), \dots, \psi_r(x)$, the number λ then being said to be an eigenvalue of multiplicity r of the kernel $K(x, z)$. In this case the transposed equation

$$\chi(x) = \lambda \int_a^b K(z, x) \chi(z) dz$$

also has r linearly independent solutions $\chi_1(x), \chi_2(x), \dots, \chi_r(x)$ and the original (non-homogeneous) equation is solvable only if $f(x)$ is orthogonal to every $\chi_i(x)$, that is, only if

$$\int_a^b f(x) \chi_i(x) dx = 0, \quad (i = 1, 2, \dots, r),$$

the solution $\phi(x)$ being then uniquely determined except that any linear combination of the $\chi_i(x)$ may be added to it.

FREE ATMOSPHERE. (Sometimes called free air.) That portion of the earth's atmosphere, above the **planetary boundary layer**, in which the effect of the earth's surface friction on the air motion is negligible, and in which the air is usually treated (dynamically) as an **ideal gas**. The base of the free atmosphere is usually taken as the **geostrophic wind level**.

FREE-BODY DIAGRAM. A diagram of an isolated body or system of bodies showing all the external forces acting.

FREE CONVECTION. See **heat transfer**.

FREEDOM, DEGREES OF. See **degrees of freedom**.

FREE ENERGY. There are two quantities to which this term has been applied. (1) The Gibbs free energy, G , which is also called the **Gibbs function** or free enthalpy to distinguish it from (2) the Helmholtz free energy, A , which is also called the work function.*

* Note that most American writers use F for the Gibbs function and A (as above) for the Helmholtz function, while the usage elsewhere is generally G (as above) for the Gibbs function and F for the Helmholtz function. To avoid confusion, the symbol F was avoided in this book by use of the mixed notation.

(1) The Gibbs free energy is defined by the equation

$$G = U - TS + pV = H - TS$$

where U is the internal energy, T , the absolute temperature, S , the entropy, p , the pressure, V , the volume and G , the Gibbs free energy.

(2) The Helmholtz free energy which is also called the **Helmholtz function** is defined by the equation

$$A = U - TS$$

where U is the internal energy, T , the absolute temperature, S , the entropy and A , the Helmholtz free energy. For a constant-temperature, reversible change in which the work is due to expansion only, $dG = Vdp$ and $dA = -pdV$. In terms of the partition function, $A = -RT \ln Z$. Like the Gibbs free energy, the Helmholtz free energy is a thermodynamic potential. (See also **thermodynamics, characteristic functions of.**)

FREE ENERGY OF GERM FORMATION.

The difference in the **Helmholtz functions** in the presence and in the absence of a germ or nucleus. (See **germs, kinetics of phase formation.**)

Gibbs has given different explicit expressions for this quantity, which depends essentially on the surface tension γ and the size of the germ. One of them is

$$(\Delta A)_{T,V} = \frac{1}{3}\gamma\Omega > 0 \quad (1)$$

where Ω is the area of the germ. This free energy is positive. Therefore the formation of a germ can only be due to *statistical fluctuations*. Moreover its value is proportional to

$$N_g^{2/3} \quad (2)$$

where N_g is the number of molecules in the germ.

The free energy of germ formation plays, in the kinetics of phase formation, a role somewhat similar to that of the free energy of activation in the kinetics of ordinary reactions. (See **absolute reaction rate theory.**)

FREE ENTHALPY. See **Gibbs function.**

FREE MASS POINT. See **dynamics of a free mass point.**

FREE-MOLECULE FLOW. Flow of a gas in which collisions between molecules have no appreciable effects, so that the only collisions of importance are those between the gas mole-

cules and the solid boundaries. Free-molecule flow occurs for values of the **Knudsen number** greater than about 10. (See also **rarefied gas dynamics; slip flow.**)

FREE STREAMLINES. The boundaries of a region of stagnant fluid in the wake of a body, the fluid outside being in steady motion. The free streamlines are presumed to originate at sharp (or salient) edges on the body. Many problems in two-dimensional flow are soluble assuming free streamlines to exist, the pressure along them being constant. The free streamlines are on **vortex sheets** which are in fact unstable configurations of motion; but nevertheless the solutions obtained are of value in the neighborhood of the body.

FREE VALENCE INDEX. Daudel and other workers have calculated the bond character of benzene and other aromatic molecules taking into account, not only the Kekulé formula, but also more excited configurations. (See **benzene, structure of.**) In the case of benzene, for instance, they obtain a double bond character of 0.462 for each bond, whereas assuming only Kekulé formulae, one would calculate a bond character of 0.500. This means that at each corner of the benzene hexagon, there remains approximately .076 of an electron which is not used in the double or single bonds. The "Dewar" bonds across the hexagon are not true bonds, but rather free electrons with opposite spins; Daudel defines then a free valence index of .076 for each corner of the benzene molecule. Similar free valence indices have been calculated for each corner of more complicated molecules; the knowledge of these indices is important for the theoretical prediction of the reactivity of aromatic molecules. (See **free valency; molecular diagrams; double bond character.**)

FREE VALENCY. Refined molecular models indicate that the total **bond character** (see also **valence bond method**) or the total **mobile bond order** (see also **molecular orbital method**) are smaller than the value predicted under the assumption that each **bonding electron** participates in a bond.

In the molecular orbital theory, the free valency of an atom has been defined by Coulson as the difference between the maximum bond number which that atom can manifest and the sum of the mobile bond orders of the bonds in which it participates. Although nu-

merical values of the free valency thus defined and of the **free valence index** calculated by the valence bond method differ, they are usually proportional to each other.

FREE VECTORS. See **affine tensors and free vectors.**

FREE VIBRATIONS. See **vibrations (free) of undamped system.**

FREE VOLUME THEORY OF LIQUIDS. See **cell model of the liquid state.**

FREE-VORTEX BLADE. See **blade, twisted.**

FREE WAVE. Any wave not acted upon by any external force except for the initial force that created it; a wave solution satisfying a homogeneous equation of motion and homogeneous boundary conditions. In a system with no impressed forces, a free wave has zero amplitude at the boundaries of the system. The phase speed, wavelength, etc. of the free wave or waves are characteristics of the system. A simple example of such a wave in meteorology is a **billow cloud** layer over level ground.

In a **steady-state** solution, free waves have arbitrary amplitude. These may be specified by **initial conditions** to determine the solution completely.

FREEZING IN OF DEGREES OF FREEDOM. Some **degrees of freedom** will be related to energies which are large compared to kT (k is Boltzmann's constant; T is absolute temperature). In that case the system will behave as if it possessed fewer degrees of freedom. A diatomic molecule will, for instance, behave like a particle of 5 degrees of freedom (3 translational and 2 rotational) instead of 6, the vibrational degree of freedom corresponding to a change in the distance between the two atoms being frozen in.

FRENET FORMULAE. See **Serret-Frenet formulae.**

FRENKEL DEFECT. A lattice **vacancy** created by removing an ion from its site and placing it at an **interstitial position** within the lattice. The equilibrium concentration of Frenkel defects is

$$n = C_F(NN')^{1/2}e^{-W/2kT}$$

where N , N' are the densities of lattice points and interstitial positions, W is the work

necessary to make the defect, and C_F is a numerical factor of the order of 100.

FREQUENCY, ATOMIC. See **atomic frequency.**

FREQUENCY, COMPLEX. The constant of proportionality relating the time rate of change of an exponential wave to its value at every instant. The real part of a complex frequency expresses the growth of the wave in **nepers** per unit time (and is sometimes called the *neper frequency*) and the imaginary part, the angular velocity in radians per unit time (sometimes called the *radian frequency*).

As used in this book, the complex frequency is denoted by the symbols:

$$s = \sigma + j\omega.$$

No standard notation has ever been adopted for the complex frequency. The earlier literature in network theory made almost exclusive use of the symbol p , and whereas some authors still prefer this notation, modern usage favors the symbol, s . The symbol, λ (lambda), at one time had limited acceptance.

FREQUENCY EQUATION. (Also called dispersion equation.) An equation relating **phase speed** to **wavelength** and to the physical parameters of the system (fluid depth, current speed, temperature, etc.) in a linear oscillation.

Mathematically, the frequency equation is the result of substituting a simple harmonic solution in the homogeneous differential **equations of motion** and the homogeneous **boundary conditions**. The frequency equation thus describes the **free waves** of the system. If the wavelength does not appear in the expression for the phase speed, the system is non-dispersive.

FREQUENCY FACTOR. The rate of an elementary chemical reaction can usually be written as a product of a function of the concentrations of the participants, and of a **rate constant** k_r which depends on temperature. k_r itself can be written in the form: $k_r = A \cdot \exp(-E_a/kT)$, where k is the **Boltzmann constant**, T , the **absolute temperature**, E_a , the **activation energy** and A is called the **frequency factor**.

The frequency factor depends on the **collision number**, and on the entropy of activation. This latter dependence is often called the

“steric factor,” since in an oversimplified image, it expresses the fact that the mutual orientation of the collision partners during the collision may be unfavorable for the reaction to take place.

FREQUENCY FACTOR FOR CHEMICAL REACTION. See collision theory.

FREQUENCY FUNCTION. See distribution.

FREQUENCY, INSTANTANEOUS. The time rate of change of the phase of a traveling wave.

FREQUENCY MODULATION. A type of modulation in which the frequency of a continuous radio carrier wave is varied in accordance with the properties of a second (modulating) wave.

FREQUENCY, NATURAL. Of a body or system, a frequency of free oscillation. This term is commonly applied to coils and antennas in communication circuits. In the former it designates the frequency at which the inductance of the coil and its distributed capacity produce resonance. Referred to the antenna, it means the lowest frequency at which there will be a standing wave on the antenna.

FREQUENCY OF A PERIODIC QUANTITY. The frequency of a periodic quantity, in which time is the independent variable, is the number of periods occurring in unit time. If a periodic quantity, y , is a function of the time, t , such that

$$y = f(t) = A_0 + A_1 \sin(\omega t + a_1) + A_2 \sin(2\omega t + a_2) + \dots,$$

then the frequency is $\omega/2\pi$. Unless otherwise specified, the unit is the cycle per second.

FREQUENCY OF ENERGY RESONANCE. For a forced harmonic oscillator the frequency for which the velocity and the energy dissipation of the system are maxima is given by

$$f = \frac{1}{2\pi} \sqrt{\frac{k}{m}}$$

where k is the stiffness and m is the effective mass.

FREQUENCY OF OSCILLATIONS. See oscillation, frequency of.

FREQUENCY, PLASMA (LANGMUIR FREQUENCY). A characteristic frequency of a plasma defined by

$$\omega_p = \left(\frac{4\pi n e^2}{m} \right)^{1/2}$$

where n is the electron density, m , the electron mass, and e , the electronic charge.

FREQUENCY RESPONSE. In general, the relationship between output and input in a system, or, by extension, between any two system quantities, on the assumption that both quantities are sinusoids (or cisoids) of the same frequency. If, due to the system interrelations, the relation between two quantities $q_1(t)$ and $q_2(t)$ is expressible by

$$a \left(\frac{d}{dt} \right) \cdot q_1(t) = b \left(\frac{d}{dt} \right) \cdot q_2(t)$$

(where, in a real system, a and b are real functions of $\frac{d}{dt}$) and if it is supposed that $q_1(t) = \bar{q}_1 e^{i\omega t}$, $q_2(t) = \bar{q}_2 e^{i\omega t}$ where \bar{q}_1 , \bar{q}_2 may be complex, then

$$a(i\omega)\bar{q}_1 = b(i\omega)\bar{q}_2$$

or

$$\frac{\bar{q}_2}{\bar{q}_1} = \frac{a(i\omega)}{b(i\omega)} \equiv G(i\omega), \text{ say.}$$

The frequency response is therefore obtained from the differential equation connecting output and input by expressing the ratio $q_2(t)/q_1(t)$ in operational form, i.e., as a function of the operator $\frac{d}{dt}$, and substituting $i\omega$ for $\frac{d}{dt}$ as the argument of this function.

Alternatively, for the above differential relationship, taking Laplace transforms subject to the condition $q_1(t) = 0 = q_2(t)$ for $t < 0$

$$a(s)Q_1(s) = b(s)Q_2(s)$$

and

$$\frac{Q_2(s)}{Q_1(s)} = \frac{a(s)}{b(s)} = G(s)$$

the transfer function of Q_2 to Q_1 . Hence the frequency response is obtained by substituting $i\omega$ for s in the transfer function relating the two quantities.

Indeed, using the transfer function relationship of the last equation, and, as before, writing $q_1(t) = \bar{q}_1 e^{i\omega t}$ so that $Q_1(s) = \frac{\bar{q}_1}{s - i\omega}$,

$$\begin{aligned} \frac{Q_2(s)}{\bar{q}_1} &= \frac{G(s)}{s - i\omega} \\ &= \frac{G(i\omega)}{s - i\omega} + \text{other partial fractions with} \\ &\quad \text{denominators corresponding} \\ &\quad \text{to the poles of } G(s) \end{aligned}$$

on the supposition that $G(s)$ is bounded as $s \rightarrow \infty$ and does not have poles at $s = \pm i\omega$. Thus, taking inverse Laplace transforms, $\frac{q_2(t)}{\bar{q}_1} = G(i\omega)e^{i\omega t} + \text{terms involving normal modes of the system.}$ Thus the only component of $q_2(t)$ at frequency ω is

$$G(i\omega)\bar{q}_1 e^{i\omega t} = G(i\omega)q_1(t)$$

showing again that the frequency response, as defined, is the value of the transfer function $G(s)$ with s replaced by $i\omega$. This is still true if $G(s)$ is unstable, i.e., if some of the normal modes tend to infinity with t , though the value of this information for unstable systems is questionable. If $G(s)$ is stable, however, and the normal modes therefore $\rightarrow 0$ as $t \rightarrow \infty$, $G(i\omega)$ gives the "steady-state" relationship between the cisoids representing q_2 and q_1 .

Finally, it should be noted that if $\bar{q}_2 = |\bar{q}_2|e^{i\phi_2}$ and $\bar{q}_1 = |\bar{q}_1|e^{i\phi_1}$ then

$$G(i\omega) = \left| \frac{\bar{q}_2}{\bar{q}_1} \right| e^{i(\phi_2 - \phi_1)}$$

so that the modulus and phase of the frequency response give respectively the amplitude ratio and the relative phase of the output and input cisoids (or sinusoids).

If $q_1(t)$ is expressed by its **Fourier transform**, if this exists,

$$q_1(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} Q_1(i\omega) e^{i\omega t} d\omega$$

each elemental component of the right-hand side is a cisoid of frequency ω and amplitude $Q_1(i\omega)d\omega/2\pi$. Such an element is therefore multiplied by $G(i\omega)$ in forming its contribution to $q_2(t)$. Thus

$$q_2(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} Q_1(i\omega)G(i\omega)e^{i\omega t}d\omega$$

or, more concisely,

$$Q_2(i\omega) = G(i\omega)Q_1(i\omega).$$

FREQUENCY RESPONSE REPRESENTATION. (a) *Nyquist Locus.* If, as ω varies, the frequency response $G(i\omega)$ is plotted as a complex quantity in its own complex plane, the locus traced out by the point representing G is called the *Nyquist locus* of G (or, similarly, of any other function of frequency). The range of ω for a complete Nyquist locus is from $-\infty$ to $+\infty$. In this connection, if G is a real function (as it always is for a real system) $G(i\omega)$ and $G(-i\omega)$ are complex conjugates; hence the part of the Nyquist locus corresponding to the negative range of ω is, point for point, the mirror image in the real axis of the part-locus for the positive range of ω .

The complete Nyquist locus should be provided also with a scale of ω along the locus.

Similar loci drawn for the function $G(s)$ with $s = \alpha + i\omega$ (α constant) are sometimes used to determine the degree of damping associated with the normal modes of the system and may be referred to as modified Nyquist loci. Whereas the Nyquist locus is the conformal map of the imaginary axis of the s -plane ($s = \alpha + i\omega$), such modified loci are the corresponding maps of vertical lines in the s -plane. Since constant ω loci (with variable α) are horizontal lines in the s -plane, it follows that the constant $-\omega$ loci will cut the modified Nyquist loci orthogonally except at points corresponding to **singularities** of $G(s)$ in the s -plane.

In control system analysis, the frequency function plotted is usually that relating the output $\theta_o(t) = \bar{\theta}_o e^{i\omega t}$ to the error $\theta_e(t) = \bar{\theta}_e e^{i\omega t}$. Denoting therefore

$$\frac{\theta_o(t)}{\theta_e(t)} = \frac{\bar{\theta}_o}{\bar{\theta}_e} \equiv G(i\omega)$$

and remembering that $\theta_i(t) = \theta_e(t) + \theta_o(t)$ and therefore $\bar{\theta}_i = \bar{\theta}_e + \bar{\theta}_o$, it is clear that, in the diagram for the plane of G shown in Figure 1,

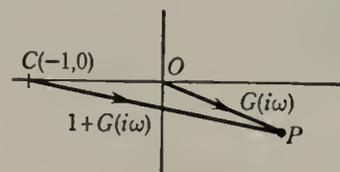

Fig. 1.

if P is any point on the Nyquist locus for a particular frequency so that OP is the phasor $G(i\omega)$, then CP drawn from the point C is the phasor $1 + G(i\omega)$. In other words since OP represents $\bar{\theta}_o/\bar{\theta}_e$, CP represents $1 + \bar{\theta}_o/\bar{\theta}_e = \bar{\theta}_i/\bar{\theta}_e$, CO being the phasor $+1$. Multiplying these phasors CO , OP , CP by $\bar{\theta}_e$, which does not alter the shape of the triangle, we obtain the important property that the directed sides of the triangle CO , OP , CP , represent the relative magnitudes and relative phases of the cisoids (or sinusoids) representing error, output and input respectively.

(b) *Log |G| - Log ω and Phase G - Log ω Graphs (Bode Diagrams)*. Here instead of plotting $G(i\omega)$ in a complex Cartesian plane, using ω as a parameter, $\log |G(i\omega)|$ and $\text{ph } G(i\omega)$ are plotted separately on a base of $\log \omega$, the base of the logarithms being usually 10, $\log |G|$ being normally expressed in decibels. It is to be noted that $\log_e |G|$ and $\text{ph } G$ are respectively the real and imaginary parts of $\log_e G$.

If the function $f(\omega) = \log(i\omega \pm A)$, with A real, is considered, then $f(\omega) = \frac{1}{2} \log(\omega^2 + A^2)$. The following properties of the graph of $f(\omega)$ to a base of $\log \omega$ are immediately deducible:

(i) It is asymptotic to the constant value $\log |A|$ as $\log \omega \rightarrow -\infty$.

(ii) It is asymptotic to the straight line through the origin, $f(\omega) = \log \omega$ as $\log \omega \rightarrow \infty$; the slope of this line is unity but is more often expressed as 6 (more correctly $20 \log_{10} 2$) decibels per octave (i.e., two-fold increase in frequency) or 20 decibels per decade (ten-fold increase in frequency).

(iii) The asymptotes meet at $\omega = |A|$ called the *break- or knee-frequency*, and the height of the graph above the two-line profile formed by the asymptotes is, at this value of ω , $\frac{1}{2} \log 2$ (3.010 db) which is its maximum value; the slope of the graph at this point is 3 db per octave.

(iv) The shape of the graph is not affected by A , which only modifies the position of the break point.

These properties are shown in Figure 2.

Thus if the transfer function $G(s)$ were expressible as $(s + A_1)(s + A_2) \cdots / (s + B_1)(s + B_2) \cdots$ in which all A 's and B 's were real, so that $\log |G(i\omega)| = \log |K| + \sum_r \log |s + A_r| - \sum_r \log |s + B_r|$, the resultant graph of $\log |G(i\omega)|$ could be obtained by adding or sub-

tracting the identically shaped but differently positioned graphs corresponding to individual terms in each of the summations, finally dropping the origin by $\log |K|$. As a preliminary

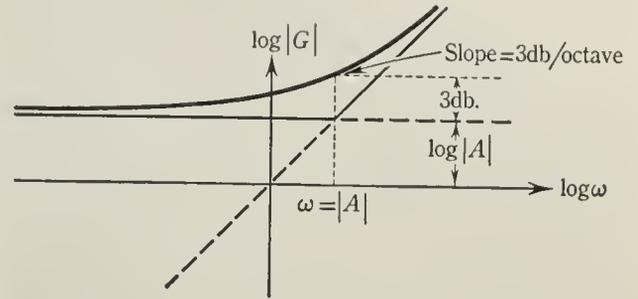

Fig. 2.

approximation at any rate, the two-asymptote approximation to the individual graphs could be used. However, $G(s)$ more generally has complex zeros and poles as well as real ones, occurring in conjugate complex pairs.

If the function $g(\omega) = \log |(i\omega)^2 + 2kA i\omega + A^2|$ is therefore considered, with A real as before and with $|k| < 1$ (if $|k| \geq 1$ the quadratic form can be factorized into linear factors of the form already considered), it is found that the graph of $g(\omega)$ on a base of $\log \omega$ has the following essential properties:

(i) It is asymptotic to the constant value $2 \log |A|$ as $\log \omega \rightarrow -\infty$.

(ii) It is asymptotic to the straight line through the origin $g(\omega) = 2 \log \omega$ (slope 12 db per octave) as $\log \omega \rightarrow \infty$.

(iii) The asymptotes cut at $\omega = |A|$ and at this frequency $g(\omega) = \log K(2A^2|k|) = 2 \log |A| + \log 2|k|$, the height of the graph at this frequency being therefore $\log 2|k|$ (which may be positive or negative) above the asymptote profile, but this is not in general the maximum deviation between the two; the slope of the graph at this point is always 6 db/octave.

Thus the graph of $g(\omega)$ although it has the asymptotes which might be expected from the analysis of $f(\omega)$ may diverge considerably from the asymptote profile (say for values of $|k| < 0.3$). Provided due attention is paid to this point, if $G(s)$ can be expressed in the form considered previously but with some A 's and B 's now occurring in conjugate complex pairs, the graph of $\log |G|$ may still be obtained by superposing the log modulus graphs of the component factors (linear or quadratic) as previously. The use of the asymptote outlines is, however, dangerous as an approximation except where $\log \omega \rightarrow \pm\infty$.

With the same precautions, the $\text{ph } G$ graphs

may also be obtained by a superposition process, for if $G(s)$ as before is in the form $K(s + A_1)(s + A_2) \cdots / (s + B_1)(s + B_2) \cdots$, then

$$\text{ph } G(i\omega) = \sum_r \text{ph } (i\omega + A_r) - \sum_r \text{ph } (i\omega + B_r).$$

Moreover $\text{ph } (i\omega + A)$, with A real, increases from 0 to $\frac{\pi}{2}$ when $A > 0$, having the value $\frac{\pi}{4}$ at the break-frequency $\omega = |A|$ and similarly decreases from π to $\frac{\pi}{2}$ with a break-frequency value of $\frac{3\pi}{4}$ when $A < 0$; again the *shape* of the graph is not affected by A , though in this case changing the sign of A turns the graph upside down. The phase of a quadratic factor, $\text{ph } \{(i\omega)^2 + 2i\omega kA + A^2\} = \text{ph } (A^2 - \omega^2 + 2i\omega kA)$ is always zero at $\omega = 0$ and is $\pm\pi$ as $\omega \rightarrow \infty$ according as $kA \gtrless 0$; it has the value $\pm \frac{\pi}{2}$ at break-frequency $\omega = |A|$ according as $kA \gtrless 0$ but the shape of its graph depends on $|k|$.

However, the phase graph is not very widely used since the value of $\text{ph } G(i\omega)$ in the case of **minimum-phase G functions**, can be derived from $\log |G(i\omega)|$ from a relationship established by Bode for such functions:

$$\{\text{ph } G(i\omega)\}_{\omega=\Omega} = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{d \log |G|}{du} \cdot \log_e \coth \frac{|u|}{2} \cdot du$$

where $u = \log_e \left(\frac{\omega}{\Omega}\right)$. In the integrand, the first factor is the slope of the $\log |G| - \log \omega$ graph at any frequency ω , the second factor constituting a weighting factor associated with these slopes which has a peak value at $\omega = \Omega$ and decays rapidly and symmetrically on either side (when plotted on a $\log \omega$ base). Thus the phase at $\omega = \Omega$ is largely determined by the slope of the $\log |G| - \log \omega$ graph in the neighborhood of $\omega = \Omega$, though the contributions from the slopes at more remote values, particularly if these are high compared with that at $\omega = \Omega$, can seldom be neglected. With some practice, however, it is not difficult to sketch the phase graph reasonably accurately from the graph of $\log |G|$, the phase being roughly $\frac{\pi}{2}$ per unit slope of the $\log |G|$ graph at any point.

FREQUENCY RESPONSE TO INDICIAL RESPONSE CONVERSION. If the frequency response relating output to input for a system is $G(i\omega)$, so that $\Theta_o(i\omega) = G(i\omega)$ $\Theta_i(i\omega)$, the corresponding normal response in the time domain to an input $\delta(t)$, unit impulse function at $t = 0$, may be found from the fact that the **Fourier transform** of $\delta(t)$ is unity. Hence with this input

Fourier transform of $\theta_o(t) = \Theta_o(i\omega) = G(i\omega)$ and hence

$$\theta_o(t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} e^{i\omega t} G(i\omega) d\omega.$$

If $\theta_o(t)$ is required and if the evaluation of the integral is a complicated process or if $G(i\omega)$ is obtained experimentally so that G is not known in functional form, the evaluation of $\theta_o(t)$ may be achieved, generally to a high degree of accuracy, by Floyd's method.

The expression for $\theta_o(t)$ is first simplified by writing

$$G(i\omega) \equiv R(\omega) + iI(\omega)$$

in which, since G is a real function, $R(\omega)$ and $I(\omega)$, its real and imaginary parts, are respectively even and odd functions of ω . Hence

$$\begin{aligned} \theta_o(t) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} (\cos \omega t + i \sin \omega t)(R + iI) d\omega \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} (R \cos \omega t - I \sin \omega t) d\omega \\ &= \frac{1}{\pi} \int_0^{\infty} (R \cos \omega t - I \sin \omega t) d\omega. \end{aligned}$$

Further, it is known that if $G(i\omega)$ is the frequency response function of a physical system, $\theta_o(t)$ must vanish for $t < 0$. It follows that

$$\int_0^{\infty} R \cos \omega t d\omega = \int_0^{\infty} I \sin \omega t d\omega, \quad t < 0$$

and hence, since the left-hand side is even in t but the right-hand side is odd,

$$\int_0^{\infty} R \cos \omega t d\omega = - \int_0^{\infty} I \sin \omega t d\omega, \quad t > 0.$$

Hence

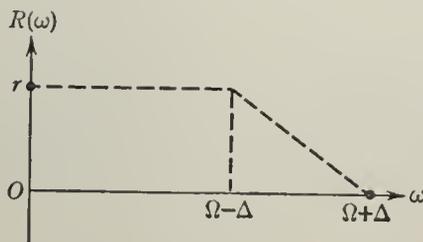

$$\theta_o(t) = \frac{2}{\pi} \int_0^{\infty} R \cos \omega t d\omega, \quad t > 0.$$

The graph of $R(\omega)$, which is at once obtainable from a knowledge, graphical or functional,

of $G(i\omega)$, is next approximated to by a polygonal outline. In this connection, since for most systems $G(i\omega) \rightarrow 0$ as $\omega \rightarrow \infty$, the upper bound of frequency for the polygonal approximation is fixed at such a value, say ω_m that the range of integration ω_m to ∞ is judged to contribute a negligible amount to the above expression for $\theta_0(t)$, i.e., ω_m is such that

$$\theta_0(t) \doteq \frac{2}{\pi} \int_0^{\omega_m} R \cos \omega t d\omega, \quad t > 0.$$

Floyd next analyzes the contribution made to the integral on the assumption that the graph of $R(\omega)$ is of the trapezoidal form shown in the diagram.

For this value of R

$$\int_0^{\infty} R \cos \omega t d\omega = r \int_0^{\Omega-\Delta} \cos \omega t d\omega + r \int_{\Omega-\Delta}^{\Omega+\Delta} \frac{\Omega + \Delta - \omega}{2\Delta} \cos \omega t d\omega$$

which on evaluation simplifies to

$$r\Omega \cdot \frac{\sin \Omega t}{\Omega t} \cdot \frac{\sin \Delta t}{\Delta t}$$

and can therefore easily be evaluated for any value of t and given Ω and Δ by using tables of $(\sin x)/x$.

Finally therefore, if the polygonal approximation to the graph of $R(\omega)$ is considered as made up of a number of elements of the above form,

$$\theta_0(t) = \frac{2}{\pi} \sum_k r_k \Omega_k \frac{\sin \Omega_k t}{\Omega_k t} \cdot \frac{\sin \Delta_k t}{\Delta_k t}$$

the summation extending over all the elemental trapezoids.

If the value of the output is required when the input is unit step-function at $t = 0$ (the **indicial response**), then the above expression for the output must be integrated with respect to t over the range 0 to t , either graphically or analytically.

FREQUENCY-SHIFT THEOREM. See Laplace transform theorems.

FRESNEL. A unit of frequency equal to 10^{12} cycles per second.

FRESNEL DIFFRACTION. The diffraction pattern in a plane near the **aperture**.

FRESNEL EQUATIONS. Equations giving the intensity of each of the two polarization components of light in a less dense medium reflected at the surface of a denser transparent medium.

If the light is polarized in the plane of incidence, i.e., the magnetic vector is in the plane of incidence:

$$\frac{I}{I_o} = \frac{\sin^2 (i - r)}{\sin^2 (i + r)}$$

If the light is polarized in a plane perpendicular to the plane of incidence:

$$\frac{I}{I_o} = \frac{\tan^2 (i - r)}{\tan^2 (i + r)}$$

These may be combined for normal incidence into the more familiar equation

$$\frac{I}{I_o} = \left(\frac{n - 1}{n + 1} \right)^2$$

for air as one medium.

FRESNEL EQUATIONS FOR METALLIC REFLECTION. For strongly absorbing materials like metals, the index of refraction n of the simple Fresnel equation should be replaced by its complex form

$$\bar{n} = n(1 - ik),$$

where k is the **absorption index**. Introducing this gives for the reflection coefficient of light normally incident *in vacuo* onto a metallic medium

$$R = \frac{(n - 1)^2 + n^2 k^2}{(n + 1)^2 + n^2 k^2}$$

Note that when k is very large, the reflection coefficient is nearly unity.

FRESNEL INTEGRALS. See Cornu spiral; noise level reduction of barriers.

FRESNEL INTEGRALS, TABLE OF. See noise level reduction of barriers.

FRESNEL ZONE. See half-period element.

FRICTION. The resistance offered to the motion of one body upon or through another.

FRICTION, ANGLE OF. The limiting angle between the direction of the force resisting sliding and the normal to the surface of sliding is called the angle of friction ϕ ; $\tan \phi = \mu$, the coefficient of friction. (See **friction, coefficient of**.)

FRICTION, COEFFICIENT OF. The maximum ratio of the frictional or tangential force F to the normal force N between two bodies at rest with respect to each other is called the coefficient of static friction, μ . $F \leq \mu N$. When there is sliding motion between the bodies, μ is called the coefficient of kinetic friction and $F = \mu N$. The coefficient of kinetic friction is generally less than the coefficient of static friction, and tends to decrease with the speed of sliding. The static coefficient, as stated by Coulomb, is essentially independent of the area of contact for ordinary surfaces. For steel on steel, a value of 0.15 is reasonable, reducing to 0.03 at appreciable relative motion.

FRICTION, CONE OF. A conical surface which always contains the resultant of the force of friction between two surfaces and the normal force pressing the two surfaces together. The half angle at the apex of the cone is equal to the angle of friction.

FRICTION, INTERNAL. A generic term for the processes in solids which result in the conversion of elastic energy into heat or other forms of energy which are neither kinetic nor elastic. The most general method of measuring internal friction is in terms of the specific damping capacity or specific loss. This is defined as the ratio $\Delta W/W$ where ΔW is the energy loss when a specimen is taken round a stress cycle, and W is the maximum elastic energy stored in it during the cycle. Internal friction can be measured in other ways, such as the logarithmic decrement Δ' of free vibrations, where the specimen is the elastic element in the vibrating system (see **logarithmic decrement**); the breadth at half amplitude (ΔN) of the resonance peak (see **resonance, sharpness of**) of such a system; or the loss angle δ for forced vibrations (see **loss factor, mechanical**). It can also be measured by the amplitude attenuation coefficient (see **acoustic attenuation coefficient**), of elastic waves in

the solid. For low dissipation coefficients ($\Delta W/W < 0.1$), the following approximate relations can be used between the different quantities listed above. For harmonic motion at one frequency,

$$\frac{\Delta W}{W} = 2\Delta' = \frac{2\pi}{\sqrt{3}} \frac{\Delta N}{N} = 2\pi \tan \delta = \frac{4\pi\alpha c}{\omega}$$

α is here the amplitude attenuation coefficient for waves of angular frequency ω whose phase velocity of propagation is c .

FRICTION VELOCITY. A velocity v_* derived from the shearing stress τ_0 at a boundary and the fluid density ρ .

$$v_* = (\tau_0/\rho)^{1/2}$$

In the turbulent flow of an incompressible fluid of uniform density parallel to a plane boundary, in which the shearing stress is the same at all distances from the boundary and is equal to the Reynolds stress,

$$\tau_0 = \overline{u'w'}$$

and v_* is thus related to the velocity fluctuations u' and w' along and parallel to the boundary; and if the viscous shearing stresses are negligible compared with the **Reynolds stresses** in the turbulent region, v_* gives a measure of the "velocity of slip" in the laminar boundary layer. (See also **logarithmic profile** and **skin friction**.)

FRINGE. A local extreme of an interference or diffraction pattern.

FRINGES, VISIBILITY OF. See **visibility of fringes**.

FROBENIUS METHOD. See **indicial equation**.

FRÖHLICH-BARDEEN THEORY (1955). An attempt to explain superconductivity in terms of the interaction between the conduction electrons and the lattice vibrations of the metal, as suggested by the isotope effect. (See **Bardeen-Cooper-Schrieffer theory of superconductivity**.)

FRONTAL HOROPTER. See **horopter**.

FRONTOGENETICAL FUNCTION. A kinematic measure of the tendency of the flow in an air mass to increase the horizontal gradient

of a conservative property α , defined by the equation

$$F = \frac{d}{dt} |\nabla \alpha|.$$

FROUDE EFFICIENCY. See **Froude momentum theory**.

FROUDE MOMENTUM THEORY. In this theory the steady-flow momentum equation (see **momentum equation for boundary layer**) is used to obtain an expression for the thrust of a screw propeller. The theory is also applicable to any other propulsive device, such as a turbo-jet or ram-jet engine, which takes in fluid from the stream and discharges it again with increased total pressure.

In the simplest form of the theory it is assumed that the velocity is uniform across the slipstream or jet. At a station far downstream, where the static pressure is the same as in the undisturbed stream, let the velocity in the slipstream or jet relative to the propulsive device be $V + v$, where V is the free-stream velocity. Then, if m is the mass of fluid passing through the propulsive device per unit time, the propulsive thrust is

$$T = mv. \quad (1)$$

The power required ideally, to produce the slipstream or jet, is equal to the rate of increase of kinetic energy of the stream. This is

$$E = \frac{1}{2}m[(V + v)^2 - V^2] = TV + \frac{1}{2}mv^2.$$

The useful propulsive power is TV , and the *Froude efficiency* is defined as

$$\frac{TV}{E} = \frac{1}{1 + \frac{1}{2} \frac{v}{V}}.$$

FROUDE NUMBER. A non-dimensional number, F , representing the ratio of the inertia forces to mechanical forces. In particular the name is used in connection with gravity forces so that

$$F^2 = u^2/gh$$

where u is a representative velocity and h a representative height. For horizontal flow in a stream of uniform density, of depth h , flow of speed u is **super-undal** if $F > 1$.

In a stably stratified fluid of static stability β

$$F^2 = u^2/g\beta h^2$$

where h is a suitably chosen representative length, which might be the wavelength of standing waves.

The Froude number also represents the ratio of the kinetic energy to the potential energy of the mechanical forces or to the energy dissipated by them. The **Reynolds number** is a special case of the Froude number, the mechanical forces being due to viscosity in that case. The **Richardson number** is a case in which the kinetic energy available is represented by the shear.

FROZEN EQUILIBRIUM. Owing to the slowness of attainment of some chemical equilibria, it can happen that the reaction rates are negligible during a time sufficient for other kinds of equilibria (i.e., thermal equilibria) to be reached. The system is then in a metastable equilibrium sometimes called frozen equilibrium.

F-TEST. A statistical test of significance based on the ratio of two independent quadratic estimators of variance. The name derives from the initial letter of the surname of Sir Ronald Fisher, who introduced it. (See **Fisher's distribution**.)

FUCHS THEOREM. If a second-order linear differential equation has regular singular points at ∞ and at x_k , $k = 1, 2, \dots, n$, and no other singularities, its general form is

$$y'' + \frac{p_{(n-1)}(x)y'}{F(x)} + \frac{p_{2(n-1)}(x)y}{F^2(x)} = 0$$

where $F(x) = (x - x_1)(x - x_2) \cdots (x - x_n)$ and $p_i(x)$ is a polynomial in x of degree $\leq i$. Such an equation is said to be of Fuchsian type. The theorem may be extended to equations of any order.

FUEL. See **combustion**.

FUGACITY. In a mixture of perfect gases (see **perfect gas mixtures**; **partial pressure**) the **chemical potential** may be written in the form

$$\mu_i = \mu_i^+(T) + RT \ln p_i \quad (1)$$

where p_i is the partial pressure of component i . By analogy one may write for a mixture of real gases

$$\mu_i = \mu_i^+(T) + RT \ln p_i^z \quad (2)$$

where $\mu_i^+(T)$ is the same function as for the perfect gas, while all the effects of molecular

interactions are included in the p_i^x . The function $p_i^x(T, p, n_1 \cdots n_c)$ is called the fugacity of component i . This definition, due to G. N. Lewis, permits the preservation for **real gases** of the general form of the equations for perfect gases, with the fugacities replacing partial pressures.

In the low pressure limit, p_i^x reduces to p_i

$$\lim_{p \rightarrow 0} \frac{p_i^x}{p_i} = 1. \quad (3)$$

FULL LINEAR GROUP. The collection of all non-singular **matrices** of order n , with matrix multiplication as the law of combination. Its order is infinite since its elements are the infinite number of linear **transformations** of one n -dimensional **vector** into another.

It contains several subgroups, also of infinite order: (1) The *unitary group*, with elements all n -dimensional unitary matrices. (2) The *orthogonal group*, with elements all real n -dimensional square orthogonal matrices. The determinants of these matrices can only be ± 1 ; if $+1$, they are proper orthogonal matrices, if -1 , improper orthogonal matrices. The subgroup of the orthogonal group containing only proper orthogonal matrices is the *rotation group* or order n . If $n = 3$, the proper orthogonal matrices correspond to rotations in three-dimensional **Euclidean space**, while the improper matrices correspond to such rotations followed by reflections in a plane perpendicular to the axis of rotation. These conceptions may be generalized for n -dimensions and specialized for two dimensions. (See **Lie group**.)

FULL RADIATOR (BLACK BODY). The thermal radiator which absorbs completely all incident radiation, whatever the wavelength or direction of incidence. This radiator has the maximum spectral concentration of radiant **emittance** at a given temperature.

FULLY-ROUGH FLOW. Turbulent flow for which

$$\frac{v_* \epsilon}{\nu} \geq 100,$$

where v_* is the **friction velocity**, ν is the **kinematic viscosity** and ϵ is the average height of the surface irregularities. When a flow is fully rough, it becomes almost independent of the viscosity.

FUNCTION. A mathematical expression describing the relation between **variables**; the function taking on a definite value, or values, when special values are assigned to certain other quantities, called the arguments, or independent variables of the function. If there is one independent variable, the dependent variable y may be determined explicitly by the equation $y = f(x)$ or implicitly by $f(x, y) = 0$. If there are several independent variables the forms are $y = f(x_1, x_2, \cdots, x_n)$ or $f(x_1, x_2, \cdots, x_n, y) = 0$. The precise definition of a function, namely as a set of ordered pairs, the first element of each pair being an argument of the function and the second its corresponding value, was first introduced by Dirichlet. A set-theoretical definition is simply a many-one relation, that is, a relation which to any **element** in its **domain** relates exactly one element in its **range**. (For various functions, **elliptic**, **algebraic**, etc., see the relevant terms.)

FUNCTIONAL. A functional is a real-valued function $F(f)$ defined for some set X of functions (usually X is a **Banach space**). A functional is linear if $F(f_1 + f_2) = F(f_1) + F(f_2)$ and bounded if $|F(f)| \leq M \|f\|$ for some constant M . If $f(x)$ is continuous and $g(x)$ is of bounded variation, the **Stieltjes integral** $\int_0^1 f(x) dg(x)$ is a continuous linear functional of f on C . A theorem of Riesz says that every continuous linear functional can be so represented by suitable choice of $g(x)$.

FUNCTIONAL ITERATION. See **iterative methods**.

FUNCTION, EVEN. See **even function**.

FUNCTION, ODD. See **odd function**.

FUNDAMENTAL AFFINE CONNECTION. The aggregate of sets of **Christoffel three-index symbols** of the second kind defined in every coordinate system. The Christoffel symbols Γ_{ij}^k of the second kind in a specified coordinate system x are *the components of the fundamental affine connection* in the system x .

FUNDAMENTAL BANDS. The bands in the **infrared spectrum of a molecule** corresponding to transitions from the vibrationless ground state to a state in which one **normal vibration** is singly excited.

FUNDAMENTAL CIRCUITS. See **circuits, fundamental.**

FUNDAMENTAL COMPONENT. The fundamental frequency component in the **harmonic analysis** of a wave.

FUNDAMENTAL CONTRAVARIANT TENSOR. Contravariant metric tensor. (See **metric tensor.**)

FUNDAMENTAL COVARIANT TENSOR. Covariant metric tensor. (See **metric tensor.**)

FUNDAMENTAL CUT SETS. See **cut sets, fundamental.**

FUNDAMENTAL EQUATIONS OF HYDRODYNAMICS. The **equations of motion**, the **equation of continuity**, the **energy equation**, the **equation of state**, and the **equation of continuity** for water, considered together as a **closed system** of equations.

A simplified physical model can dispense with certain of these equations without sacrificing completeness, e.g., in two-dimensional homogeneous incompressible flow, kinetic energy is the only form of energy, and the equations of motion and continuity form a closed system.

FUNDAMENTAL EQUATIONS OF THERMODYNAMICS. When a certain number n of properties of a thermodynamic system (in particular a homogeneous system) are fixed, the state of the system is fixed, and all remaining properties are fixed. It does not follow, however, that it is possible to calculate all equilibrium thermodynamic properties of a system, when one equation of state is given. In general, this is not the case, but it is possible to indicate several general relations, called fundamental equations (or fundamental equations of state) which have this property. An **equation of state** is called fundamental if all equilibrium properties of the system can be derived from it mathematically by processes which do not involve integration. All thermodynamic consistency relations involve partial derivatives. In the case of simple systems, these are of the form

$$\left(\frac{\partial z}{\partial y}\right)_x = \phi(x,y)$$

where z is the dependent, and x,y are the independent properties. In this case

$$z = \int \phi(x,y)dy + \psi(x).$$

Here, the integral can be evaluated, but the arbitrary (from the mathematical point of view) function $\psi(x)$ cannot be determined from the equation of state.

In the case of simple systems, the only four forms which allow us to calculate all equilibrium properties by processes involving differentiation and algebraic calculations exclusively, are:

$$F_1(U,S,V) = 0$$

$$F_2(H,S,p) = 0$$

$$F_3(A,T,V) = 0$$

$$F_4(G,T,p) = 0.$$

Here U is the **internal energy**, $H = U + pV$, is the **enthalpy**, $A = U - TS$ is the **Helmholtz function**, $G = H - TS$ is the **Gibbs function**.

It is noteworthy that the p - V - T relation, $F(p,V,T) = 0$, is not a fundamental equation. (See **equation of state.**)

In the case of complex systems, involving several independent components and phases, the above relations must also contain the masses (or numbers of moles) of the constituents

$$F_1(U,S,V,n_i) = 0, \text{ etc.}$$

In addition, the equation

$$F_5(p,T,\mu_i) = 0$$

where μ_i are the chemical potentials, is also a fundamental equation. (See also **thermodynamics, characteristic functions in.**)

FUNDAMENTAL FORM FOR A SURFACE. See **ground form of a surface.**

FUNDAMENTAL FREQUENCY. See **frequency, fundamental; vibration, fundamental mode of.**

FUNDAMENTAL HORN EQUATION. See **horn equation, fundamental.**

FUNDAMENTAL MAGNITUDES OF THE FIRST ORDER (FOR A SURFACE). See **ground forms of a surface.**

FUNDAMENTAL MAGNITUDES OF THE SECOND ORDER (FOR A SURFACE). See **ground forms of a surface.**

FUNDAMENTAL METRIC TENSOR. See **metric tensor**.

FUNDAMENTAL MODE. See **mode, fundamental**.

FUNDAMENTAL PROBABILITY SET. The basic events and their probabilities forming the units of a probabilistic situation, any other set of events under consideration being expressible in terms of them. It follows that all the probabilities of derived sets are expressible in terms of those of the fundamental set.

FUNDAMENTAL SERIES. See **Bergmann series**.

FUNDAMENTAL STATE. The fundamental state of a system (atom, molecule, or ensemble of particles) is that state of the system which has the lowest possible energy (i.e., the **zero point energy**). The term may be used in a more restricted meaning: a molecule in its fundamental *electronic* state may still pos-

sess vibrational, rotational, and, eventually, translational energy.

FUNDAMENTAL TENSOR. See **metric tensor**.

FUNDAMENTAL THEOREM OF ARITHMETIC. See **unique factorization theorem**.

FUNDAMENTAL THEOREM, REACTOR. See **first fundamental theorem** and **second fundamental theorem**.

FUNICULAR POLYGON. A funicular or string polygon is a geometric figure employed to obtain a point on the line of action of the resultant of a coplanar force system. The **force polygon** gives the magnitude and direction of the resultant force. Funicular polygons are graphical representations of shapes a flexible string would assume when loaded by the actual forces. For equilibrium, both the force and funicular polygons must close.

FUSION. See **solidification**.

f-VALUE. See **oscillator strength**.

G

GAIN-BANDWIDTH PRODUCT. The gain-bandwidth product is equal to the product of the amplification of an amplifier stage at mid-band (its maximum value) and the bandwidth of the amplifier in megacycles. The bandwidth is defined as the difference Δf between the two frequencies at which the power output is a specified fraction, usually one-half, of the midband value.

GAIN, BREEDING. See **breeding gain**.

GAIN, CONVERSION. See **conversion gain**.

GAIN MARGIN. A partial indication of the degree of stability of a feedback loop based upon the extent by which the loop **gain ratio** falls short of unity at the frequency (or frequencies) at which the loop phase shift is zero. Two definitions are in use:

(1) Gain Margin = $1 -$ (loop gain ratio at zero phase shift).

(2) Gain Margin (in decibels) = $-$ (loop gain in decibels at zero phase shift).

Both definitions given zero gain margin for a critically stable system.

Note. To avoid confusion it should be noted that if $Y(s)$ is the output/error transfer function in an error-monitored control system, the loop transfer function is $-Y(s)$. Thus *zero phase* of the loop frequency-function $-Y(i\omega)$ implies 180° *phase* (lag) of $Y(i\omega)$.

GAIN RATIO (GAIN). Measures of amplification used in frequency response work and preferably restricted to the comparison of the amplitudes of one and the same physical quantity (voltage, current, etc.) at two different points of a system.

Gain ratio from point A to point B

$$= \frac{\text{amplitude of specified quantity at } B}{\text{amplitude of specified quantity at } A}$$

Gain from point A to point B

$$\text{in decibels} = 20 \log_{10} (\text{gain ratio})$$

$$\text{in nepers} = \log_e (\text{gain ratio})$$

$$\text{Thus } 1 \text{ neper} = 20 \log_{10} e \text{ or } 8.686 \text{ decibels (dbs)}$$

The bel (and decibel) are strictly units of power amplification, the power amplification in bels being \log_{10} (power gain ratio). When comparing, say, voltages or currents, these are assumed to be applied across, or flowing through, equal hypothetical resistances at A and at B so that the power gain ratio is the square of the voltage or current gain ratio, giving:

Gain (i.e., power gain) in dbs

$$= 10 \log_{10} (\text{power gain ratio})$$

$$= 20 \log_{10} (\text{voltage or current gain ratio})$$

as above.

The use of the above terms and units when comparing, say, a voltage at B with a current at A or *vice-versa* (so that the "gain ratio" is not dimensionless) is to be deprecated, as is also the measurement of gain in dbs when applied to non-electrical quantities other than power.

GALACTIC CLUSTERS. See **star clusters**.

GALERKIN METHOD. See **Ritz method**.

GALERKIN STRESS FUNCTIONS. Any solution for the displacement components u_i ($i = 1, 2, 3$) in a rectangular Cartesian coordinate system x , of the **Navier equations** of equilibrium for a body of isotropic, elastic material satisfying the **generalized Hooke's law**, on which no body forces are acting, may, provided it has sufficient regularity, be written in the form

$$\mu u_i = (1 - \sigma) \nabla^2 F_i - \frac{\partial F_j}{\partial x_j \cdot \partial x_i},$$

where F_i ($i = 1, 2, 3$) are three biharmonic functions of position in space, the Galerkin stress functions. μ and σ are the **rigidity modulus** and **Poisson's ratio** for the material. Such a solution of the Navier equations is called a *Galerkin solution*.

GALILEAN TRANSFORMATION. The transformation to a system moving with constant relative velocity according to non-relativistic kinematics:

$$dx' = dx - v_x dt$$

$$dy' = dy - v_y dt$$

$$dz' = dz - v_z dt$$

$$dt' = dt.$$

GALVANOMAGNETIC AND THERMO-MAGNETIC EFFECTS. There are three other effects similar to the Hall effect (see **Hall coefficient**) which relate flow of electric current, flow of heat, and magnetic field. These are the *Nernst effect*, the *Ettingshausen effect*, and the *Righi-Leduc effect*. All these effects may be summarized mathematically as follows:

Let \mathbf{j} and \mathbf{q} be the vector densities of electric current and heat current, respectively, let \mathbf{H} be the magnetic field strength. Let \mathbf{E}_t and $\nabla_t T$ be the projections of the electric field vector and the temperature gradient, respectively, on the plane normal to \mathbf{j} or \mathbf{q} , whichever is non-vanishing. Then the **Hall coefficient** R_H may be defined by the relation

$$\mathbf{E}_t = R_H \mathbf{j} \times \mathbf{H},$$

the *Nernst coefficient* Q by the relation

$$\mathbf{E}_t = -Q \nabla T \times \mathbf{H}, \quad \text{when } \mathbf{j} = 0,$$

the *Ettingshausen coefficient* P by

$$\nabla_t T = P \mathbf{j} \times \mathbf{H}, \quad \text{under conditions } \mathbf{j} \cdot \nabla T = 0 \text{ and } \mathbf{q} = 0,$$

and the *Righi-Leduc coefficient* S by

$$\nabla_t T = S \mathbf{H} \times \nabla T, \quad \text{when } \mathbf{j} = 0.$$

It may be noted that the Righi-Leduc effect bears the same relation to the Ettingshausen effect as the Nernst effect does to the Hall effect.

GALVANOMETER EQUATION. The equation of motion of a **galvanometer**:

$$P \frac{d^2\theta}{dt^2} + \left(K + \frac{G^2}{R} \right) \frac{d\theta}{dt} + U\theta = \frac{GE}{R},$$

where P is the moment of inertia, K , the mechanical damping coefficient, U , the restoring torque constant, G , the motor constant, E , the applied voltage and R , the total circuit resistance.

GAMES THEORY. The branch of mathematics which deals with the theory of contests

between players under certain specified rules. If the game is such that the winnings of one player are derived solely from the losses of others, so that the algebraical sum of winnings is zero, the game is a *zero-sum game*.

If two players are engaged, and one has a choice of p courses of action, the other a choice of q courses, a $p \times q$ table can be drawn up showing how much one player wins if he chooses the i^{th} course and his adversary chooses the j^{th} . This is called a *pay-off matrix*. The object of the theory is to find the best strategy for a given player to pursue. If he acts so as to minimize his maximum risk of loss the strategy is called *minimax*, while if he acts so as to maximize his minimum chance of gain, the strategy is called *maximin*.

GAMMA. (1) The one-millionth part of a gram. (2) A unit of **magnetic field intensity**. (3) The tangent of the angle of the straight-line portion of the $D \log E$ curve and the $\log E$ axis is a measure of the degree of development and was termed by Hurter and Driffeld the *development factor* and designated by the Greek letter γ (gamma). Gamma may also be defined as

$$\gamma = \frac{D_2 - D_1}{\log E_2 - \log E_1}$$

where D_2 and D_1 are **densities** on the straight-line portion of the $D \log E$ curve produced by $\log E_2$ and $\log E_1$, respectively, and where E_2 and E_1 are exposures (see **exposure-density relationship**). (4) In a color or monochrome television channel, or part thereof, the coefficient expressing the selected evaluation of the slope of the used part of the log vs. log plot relating input (abscissa) and output (ordinate) **signal magnitudes** as measured from the point corresponding to some reference **black level**. As the log vs. log plot is usually not entirely straight in the used region, it is necessary to formalize that evaluation of the slope, for example, by the use of the value at a particular point, maximum, mean, or other value. The method of evaluation should be stated. At some points, the signal may be in terms of **light intensity** or **light transmission**.

GAMMA CORRECTION. The modification of a **transfer characteristic** for the purpose of changing the value of gamma. (See **gamma (4)**.)

GAMMA DISTRIBUTION. A frequency (probability) distribution of the form

$$dF = \frac{e^{-x} x^{\lambda-1}}{\Gamma(\lambda)} dx, \quad 0 \leq x \leq \infty.$$

It is also known as *Pearson's Type III*.

GAMMA FACTOR. See gamma value.

GAMMA FUNCTION. The improper integral, sometimes called Euler's second integral

$$\Gamma(z) = \int_0^{\infty} e^{-t} t^{z-1} dt.$$

It converges for all positive, real values of z . Its properties include:

$$\Gamma(z+1) = z\Gamma(z);$$

$$\Gamma(z)\Gamma(1-z) = \pi \csc \pi z;$$

$$\Gamma\left(\frac{1}{2}\right) = \sqrt{\pi};$$

when $z = n$, a positive integer, $\Gamma(n) = (n-1)!$, hence this is often called the **factorial function**.

The Weierstrass definition of the function is

$$1/\Gamma(z) = ze^{Cz} \prod_{n=1}^{\infty} (1+z/n)e^{-z/n}$$

where C is the **Euler-Mascheroni constant**;

$$C = \lim_{n \rightarrow \infty} \left(1 + \frac{1}{2} + \cdots + \frac{1}{n} - \ln n\right) \\ = 0.577215 \dots$$

Another definition is that of Euler

$$\Gamma(z) = \lim_{n \rightarrow \infty} \frac{(n-1)!}{z(z+1)(z+2)\cdots(z+n-1)} n^z.$$

(See also **beta function**, which is Euler's first integral, and **Stirling formula**.)

GAMMA MATRICES. See Dirac equation.

GAMMA PERMANENCE RULE. See gamma value.

GAMMA SPACE. Phase space of $2fN$ dimensions, the coordinates being f generalized coordinates and f generalized momenta for each of the N particles of the system, each particle having f degrees of freedom. It is the phase space of the whole gas and was called Γ -space by Ehrenfest to distinguish it from the phase space of one molecule (μ -space).

GAMMA SUM RULE. See gamma value.

GAMMA VALUE. The energy of electronic spin-orbit interaction in an atom, designated Γ (sometimes referred to as Γ -factor). Without specific assumptions as to the **coupling conditions**

$$\Gamma = \sum_i a_i l_i s_i \overline{\cos(\mathbf{l}_i \mathbf{s}_i)},$$

where

$$a_i = \frac{R\alpha^2 Z_{eff,i}^4}{n_i l_i (l_i + \frac{1}{2})(l_i + 1)}.$$

For **Russell-Saunders coupling**

$$\Gamma = ALS \cos(\mathbf{LS}) \\ = A \frac{J(J+1) - L(L+1) - S(S+1)}{2},$$

where

$$A = \sum_i a_i \frac{s_i}{S} \overline{\cos(\mathbf{s}_i \mathbf{S})} \frac{l_i}{L} \overline{\cos(\mathbf{l}_i \mathbf{L})}.$$

Here \mathbf{l}_i and \mathbf{s}_i are orbital angular momenta and spins of the individual electrons, \mathbf{L} and \mathbf{S} the resultant electronic orbital angular momentum and the resultant electron spin. l_i , s_i , L , and S are the corresponding quantum numbers. α is **Sommerfeld's fine structure constant**, R the **Rydberg constant**, $Z_{eff,i}$ the **effective atomic number**.

In a weak magnetic field of field strength H the vector \mathbf{J} has a component \mathbf{M} in the field direction, in a stronger field the vectors \mathbf{L} and \mathbf{S} have separate components \mathbf{M}_L and \mathbf{M}_S in the field direction (quantum numbers M , M_L , M_S . $M = M_L + M_S$).

Under these conditions

$$\overline{\cos(\mathbf{SL})} = \overline{\cos(\mathbf{SH})} \overline{\cos(\mathbf{LH})} = \frac{M_S M_L}{SL}$$

and

$$\overline{\cos(\mathbf{SL})} = ALS \cos(\mathbf{LS}) = AM_L M_S.$$

For this case Landé's **Γ -permanence rule** states: for the levels of a given multiplet corresponding to the same value of the quantum number M , the sum of the Γ -values is independent of the field strength.

In a very strong magnetic field the vectors \mathbf{l}_i and \mathbf{s}_i have separate components \mathbf{m}_{l_i} and \mathbf{m}_{s_i} in the field direction (quantum numbers m_{l_i} , m_{s_i} ; $M = \sum_i (m_{l_i} + m_{s_i})$). Under these conditions

$$\Gamma = \sum_i \gamma_i = \sum_i a_i m_{s_i} m_{l_i}$$

where γ_i represents the Γ -value for a single electron.

For this case Goudsmit's Γ -sum rule states: for a given electron configuration the sum of all Γ -values corresponding to a given value of M is independent of the field strength. (For more details see L. Pauling and S. Goudsmit, *The Structure of Line Spectra*, McGraw-Hill, Inc., New York, 1930, p. 157 ff.)

GAS, BOSE-EINSTEIN TREATMENT. See Bose-Einstein gas.

GAS, CLASSICAL MONATOMIC, SECOND VIRIAL COEFFICIENT. See second virial coefficient.

GAS CONSTANT. The constant of proportionality R in the equation of state of a perfect gas $pV = RT$. When referring to one gram-molecule of gas, R has the value, 8.3149×10^7 ergs/mole $^{\circ}\text{C}$ or 2782.77 ft lbf/lbmole $^{\circ}\text{C}$.

Values of the gas constant for real gases, as given in engineering tables, are usually expressed in units of mass, rather than moles. Their equivalent values may be calculated from the (universal) gas constant above by dividing it by the molecular weight of the gas, provided it is recognized that the values so obtained are in error by the departure of the particular gas from ideality over the range given. The gas constant per unit mass for a mixture of non-reactive gases may be obtained by averaging their tabulated gas constants, by multiplying them by their respective percentages in the mixture, and adding the products.

GAS DEGENERACY. See degenerate gas.

GAS DYNAMICS. Aerodynamics of compressible fluid flow. (See also **subsonic and supersonic flow**, **rarefied gas dynamics**.)

GAS DYNAMICS, RAREFIED. See rarefied gas dynamics.

GASES, SEPARATION OF. See reversible separation of gases.

GASES, SPECIFIC HEATS OF. See specific heats of gases.

GAS, FERMI-DIRAC TREATMENT. See Fermi-Dirac gas.

GAS FLOW IN NOZZLE OR DUCT. See nozzle or duct, flow of gas in.

GAS, IDEAL. See perfect gas.

GAS, IMPERFECT. See real gas.

GAS, PERFECT. See perfect gas.

GAS, REAL. See real gas.

GAS-VAPOR MIXTURES. See air-steam mixtures.

GAUGE-INVARIANCE. Classical electromagnetic field theory is invariant under the gauge transformation

$$A_{\mu}(x) \rightarrow A'_{\mu}(x) = A_{\mu}(x) + \frac{\partial \chi(x)}{\partial x^{\mu}} \quad (1)$$

as a consequence of the fact the field strengths

$$F_{\mu\nu} = \frac{\partial A_{\nu}}{\partial x^{\mu}} - \frac{\partial A_{\mu}}{\partial x^{\nu}} \quad (2)$$

(which are the observables of the system) remain invariant under this transformation. The arbitrary function $\chi(x)$ must however satisfy

$$\square \chi(x) = 0 \quad (3)$$

to ensure the **Lorentz condition**

$$\frac{\partial A_{\mu}}{\partial x_{\mu}} = 0. \quad (4)$$

In quantum field theory, gauge invariance is the requirement of the invariance of the theory under the simultaneous transformation

$$A_{\mu}(x) \rightarrow A'_{\mu}(x) = A_{\mu}(x) - \partial_{\mu} \chi(x) \quad (5)$$

$$\phi_C(x) \rightarrow \phi'_C(x) = e^{ie\chi(x)} \phi_C(x) \quad (6a)$$

$$\phi_C^*(x) \rightarrow \phi_C'^*(x) = e^{-ie\chi(x)} \phi_C^*(x) \quad (6b)$$

where ϕ_C is any charged field operator and $\chi(x)$ is a (c -number) function. This requirement determines almost uniquely the interaction of charged fields with the electromagnetic field.

For if one notes that

$$(\partial_{\mu} - ieA'_{\mu})\phi'_C = e^{ie\chi}(\partial_{\mu} - ieA_{\mu})\phi_C \quad (7)$$

it follows that if the replacement

$$\partial_{\mu} \phi_C \rightarrow (\partial_{\mu} - ieA_{\mu})\phi_C \quad (8a)$$

$$\partial_{\mu} \phi_C^* \rightarrow (\partial_{\mu} - ieA_{\mu})\phi_C^* \quad (8b)$$

is made for all charged fields in the Lagrangian without the presence of the electromagnetic field, then the total Lagrangian (includ-

ing the electromagnetic interactions) will remain unchanged by the simultaneous transformations (5) and (6).

GAUGE INVARIANCE AND CONSERVATION LAWS. Assume that a given Lagrangian (and hence the resulting field equations) is invariant under the following gauge transformations: for any field ϕ_i ,

$$\phi_i \rightarrow \phi'_i \equiv \phi_i e^{i\epsilon q_i} \quad (1)$$

where ϵ is a real number and q_i a real number characteristic of the field ϕ_i . For the case ϵ is infinitesimal

$$\phi'_i = \phi_i(1 + i\epsilon q_i)$$

or

$$\delta\phi_i = i\epsilon q_i \phi_i.$$

The observed invariance of \mathcal{L} under (1) means that

$$\begin{aligned} 0 = \delta\mathcal{L} &= \partial_\mu \sum_i \frac{\partial\mathcal{L}}{\partial\phi_{i,\mu}} \delta\phi_i \\ &= i\epsilon \partial_\mu \sum_i q_i \frac{\partial\mathcal{L}}{\partial\phi_{i,\mu}} \phi_i \end{aligned}$$

so that the current

$$J_\mu = i\epsilon \sum_i q_i \frac{\partial\mathcal{L}}{\partial\phi_{i,\mu}} \phi_i$$

is conserved, i.e.,

$$\partial_\mu J^\mu = 0.$$

GAUSS. See **electromagnetic units**.

GAUSS AND CODAZZI, EQUATIONS OF. See **equations of Gauss and Codazzi**.

GAUSS CHARACTERISTIC EQUATION. See **equations of Gauss and Codazzi**.

GAUSS CURVATURE. See **Gauss theorem (on curvature); curvature**.

GAUSS EQUATION OF THE SURFACE. See **equations of Gauss and Codazzi**.

GAUSS FORMULAS. Formulas which provide expressions for the tensor derivatives of the **base vectors** x_α^i ($i = 1, 2, 3$) for a surface coordinate system in terms of the fundamental magnitudes of the second order, $b_{\alpha\beta}$, for the surface and the unit normal n^i :

$$x_{\alpha,\beta}^i = b_{\alpha\beta} n^i.$$

They show that the tensor derivatives of the base vectors are parallel to the **unit normal**.

GAUSS HYPERGEOMETRIC EQUATION.

A canonical form of the **Riemann-Papperitz equation**, where the regular singular points have been shifted to $x = 0, 1, \infty$. Its form is $x(1-x)y'' + [c - (a+b+1)x]y' - aby = 0$, in which a, b, c are parameters related to the exponents of the equation. Its general solution around the point $x = 0$ and convergent for $|x| < 1$, provided c is not a positive or negative integer or zero, is

$$\begin{aligned} y &= AF(a, b, c; x) \\ &+ Bx^{1-c}F(1+a-c, 1+b-c, 2-c; x). \end{aligned}$$

In this solution $F(x)$ is the Gauss hypergeometric function, and A, B are constants of integration.

The Gauss hypergeometric function can be written as an infinite series in the form

$$\begin{aligned} F(a, b, c; x) &= \frac{\Gamma(c)}{\Gamma(a)\Gamma(b)} \sum_{n=0}^{\infty} \frac{\Gamma(a+n)\Gamma(b+n)}{\Gamma(c+n)n!} x^n \end{aligned}$$

where Γ is the **gamma function**. The coefficient of the general term x^k is

$$\frac{a(a+1)(a+2)\cdots(a+k-1)b(b+1)\cdots(b+k-1)}{c(c+1)\cdots(c+k-1)k!}.$$

Many well-known functions, including the **Legendre** and other **polynomials** are compactly represented by the hypergeometric series. Thus $F(1, b, b; x)$ is the ordinary geometric series and $F(a, b, b; x)$ is the **binomial expansion** of $(1-x)^{-a}$.

If one lets $b \rightarrow \infty$ in the hypergeometric equation the singular points at 1 and ∞ merge by **confluence** to give an irregular singular point at ∞ . The result, called the confluent hypergeometric equation (also the Pochhammer-Barnes equation) is

$$xy'' + (c-x)y' - ay = 0.$$

Its general solution is

$$y = AF(a, c; x) + Bx^{1-c}F(1+a-c, 2-c; x)$$

where

$$F(a, c; x) = \frac{\Gamma(c)}{\Gamma(a)} \sum_{n=0}^{\infty} \frac{\Gamma(a+n)x^n}{\Gamma(c+n)n!}$$

is the **confluent hypergeometric series**. The notation ${}_1F_1$ is often used for this series and ${}_2F_1$ for the Gauss hypergeometric series. The first subscript indicates the number of fac-

torial terms in the numerator and the second subscript the number of such terms in the denominator. The more general series ${}_nF_m$ has also been studied.

Any differential equation with three regular singular points or less can be expressed as a special case of the Gauss equation or its confluent form.

GAUSSIAN BRACKETS. In Gauss' *Disquisitiones Arithmeticae* a bracket function is introduced in an algorithm for solving a linear diophantine equation. M. Herzberger has shown that these provide a convenient notational and calculational device for ray tracing an optical system in Gaussian optics.

The Gaussian brackets are defined recursively by

$$[a_1 \cdots a_n] = [a_1 \cdots a_{n-2}] + [a_1 \cdots a_{n-1}]a_n$$

with the initial conditions

$$[] = 1, [a] = a.$$

The principal properties are:

- (1) Symmetry: $[a_n \cdots a_1] = [a_1 \cdots a_n]$.
- (2) The expansions:

$$\begin{aligned} [a_1 \cdots a_m \cdots a_n] &= a_m[a_1 \cdots a_{m-1}][a_{m+1} \cdots a_n] \\ &\quad + [a_1 \cdots a_{m-1} + a_{m+1} \cdots a_n], \end{aligned}$$

$$\begin{aligned} [a_1 \cdots a_m \cdots a_n][a_1 \cdots a_m][a_{m+1} \cdots a_n] & \\ &\quad + [a_1 \cdots a_{m-1}][a_{m+2} \cdots a_n]. \end{aligned}$$

- (3) The determinant rule:

$$\begin{vmatrix} [a_1 a_{n-1}] & [a_2 a_{n-1}] \\ [a_1 a_n] & [a_2 a_n] \end{vmatrix} = (-1)^{n-1}.$$

GAUSSIAN DISTRIBUTION. See normal distribution.

GAUSSIAN ELIMINATION. Matrix inversion by triangularization.

GAUSSIAN INTERPOLATION FORMULAS. (Also called the Newton-Gauss formulas.) In the notation of difference operators, the forward formula is

$$\begin{aligned} E^u &= 1 + u\delta E^{1/2} + \binom{u}{2} \delta^2 \\ &\quad + \binom{u+1}{3} \delta^3 E^{1/2} + \binom{u+1}{4} \delta^4 + \dots \end{aligned}$$

and the backward formula is

$$\begin{aligned} E^{-u} &= 1 - u\delta E^{-1/2} + \binom{u}{2} \delta^2 \\ &\quad - \binom{u+1}{3} \delta^3 E^{-1/2} + \binom{u+1}{4} \delta^4 - \dots \end{aligned}$$

GAUSSIAN KERNEL. See kernel, Gaussian.

GAUSSIAN LENS EQUATION. If u is the object distance, u' the image distance, f the focal length, n, n' the refractive indices of object and image space, then a basic theorem of Gaussian optics states

$$\frac{n}{u} + \frac{n'}{u'} = \frac{n' - n}{f}.$$

GAUSSIAN OPTICS. The manifold of rays through an optical system is four-dimensional. For axially symmetrical systems, the geometrical optics in the tangent hyperplane to the ray coinciding with the axis is Gaussian optics or first order optics.

Expressed otherwise, if the coordinates of a ray are the rectangular coordinates x, y of its intersection with some plane orthogonal to the axis and the optical direction cosines p, q , then the mixed characteristic of an axially symmetric system is a function of

$$u = x^2 + y^2, v = px + qy, w = p^2 + q^2.$$

The constant term of the power series expansion in u, v, w is the characteristic function of Gaussian optics.

Thus, Gaussian optics is the theory of the first order approximation $\sin \theta = \theta$. The next approximation $\sin \theta = \theta - \frac{1}{6}\theta^3$ corresponds to third order optics, the theory of the approximate characteristic W including terms of the second degree in u, v, w .

GAUSSIAN QUADRATURE FORMULA. Any formula of the form

$$\int_a^b w(x)f(x)dx = \sum_0^n \mu_i f(x_i) + R$$

where the density function $w(x) \geq 0$; the coefficients μ_i are constant and depend only upon the function $w(x)$ and the range of integration; and the abscissae x_i are selected so that the remainder R vanishes whenever $f(x)$ is a polynomial of degree $2n + 1$ or less. It can be shown that these x_i exist and satisfy an alge-

braic equation of degree $n + 1$; that they are real; and that when ordered they satisfy $a < x_0 < x_1 < \dots < x_n < b$. They are, in fact, zeros of one of a set of orthogonal polynomials.

If a and b are both finite, one can make a substitution of variable, if necessary, and suppose $b = -a = 1$. Then if $w(x) = 1$, the x_i are zeros of the **Legendre polynomial** of degree $n + 1$, and one has for

$$n = 1: \mu_0 = \mu_1 = 1;$$

$$n = 2: \mu_0 = \mu_2 = \frac{5}{9}, \quad \mu_1 = \frac{8}{9};$$

$$n = 3: \mu_0 = \mu_3 = (18 - \sqrt{30})/36, \quad \mu_1 \\ = \mu_2 = (18 + \sqrt{30})/36.$$

By choosing $w(x)$ appropriately either a or b or both can be infinite. (For tabulation of x_i and μ_i , and for a discussion of the theory, see Zdenek Kopal, *Numerical Analysis*, John Wiley & Sons, Inc., 1955.)

GAUSSIAN REPRESENTATION. See **spherical representation of a surface**.

GAUSSIAN UNITS. A nonrationalized mixed system of units in which electrical quantities, such as electric charge and electric potential, are carried in the esu system, while currents and magnetic quantities are carried in the emu system. The constant c is then carried in the equations where it is needed, as a conversion factor. (See **electromagnetic units**.)

GAUSSIAN WAVE GROUP. A wave group for which

$$q(\kappa) = ae^{-\alpha(\kappa - \kappa_0)^2}.$$

Here κ is the "wavelength constant" but actually the independent variable, while α and κ_0 are arbitrary constants.

GAUSS LAW. The total **electric flux** passing out from a closed surface (c.s.) is (in rationalized units) equal to the total charge, q , enclosed within the surface. In unrationalized units the flux is equal to 4π times the enclosed charge q .

In integral form, the Gauss law may be written (in rationalized MKS units)

$$\int_{c.s.} \mathbf{D} \cdot d\mathbf{A} = \int_{c.s.} \epsilon_0 \mathbf{E} \cdot d\mathbf{A} = q = \int \rho dV,$$

where \mathbf{D} is the electric flux density, \mathbf{E} is the electric field strength, ρ is the electric charge density, and ϵ_0 is the permittivity of free space.

Applying Gauss theorem, the law may be put in the differential form,

$$\nabla \cdot \mathbf{D} = \rho, \quad \text{or} \quad \nabla \cdot \mathbf{E} = \rho/\epsilon_0.$$

Using $\mathbf{E} = -\nabla V = -\rho/\epsilon_0$, the law may be put into still another form, the **Poisson equation**: $\nabla^2 V = -\rho/\epsilon_0$.

GAUSS LAW FOR A MAGNETIC MEDIUM. Applying the Gauss law to the magnetic case:

$$\int \mathbf{B} \cdot d\boldsymbol{\sigma} = 4\pi \int \rho dT$$

$$\nabla \cdot \mathbf{B} = 4\pi\rho$$

where \mathbf{B} is the **magnetic induction**, and ρ the density of magnetic charge. Since free magnetic charge does not exist in nature, $\rho = 0$, and the Gauss law states:

$$\int \mathbf{B} \cdot d\boldsymbol{\sigma} = 0$$

$$\nabla \cdot \mathbf{B} = 0.$$

GAUSS LAW OF NORMAL GRAVITATIONAL FORCE. The surface integral of the normal component of the gravitational force on a particle of unit mass, taken over any closed surface is equal to $-4\pi G$ times the total mass enclosed by the surface.

GAUSS-MARKOV THEOREM. A theorem to the effect that an unbiased linear estimator of a parameter has minimal **variance** when obtained by the method of **least squares**.

GAUSS PLANE. See **Argand plane**.

GAUSS PRINCIPLE OF LEAST CONSTRAINT. See **least constraint**, **Gauss principle of**.

GAUSS-SEIDEL METHOD. A term sometimes applied to the total step iteration for solving linear equations (see **matrix inversion**), although both Gauss and Seidel used a **relaxation method**.

GAUSS-STOKES THEOREMS, FOUR-DIMENSIONAL. See **Minkowski world**.

GAUSS THEOREM. See **integral theorems of vector analysis**.

GAUSS THEOREM ON CURVATURE. The product of the **principal curvatures** of a surface at a point of the surface is a surface invariant (the Gauss curvature).

GAUZE, FLOW THROUGH. Gauzes made of woven wire are commonly used for reducing both the spatial non-uniformity and the **turbulence** of a stream of fluid.

Considering first the effect of a gauze on spatial disturbances in a stream, it is assumed that the scale of these disturbances is large compared with the mesh size. The essential properties of the gauze may be expressed in terms of two dimensionless coefficients, defined as

$$k = \frac{p_1 - p_2}{\frac{1}{2}\rho U^2}$$

and

$$F_\theta = \frac{\left\{ \begin{array}{l} \text{Force component in plane of gauze,} \\ \text{per unit area} \end{array} \right\}}{\frac{1}{2}\rho U^2}$$

U is the velocity of a uniform stream approaching the gauze and $(p_1 - p_2)$ is the pressure drop at the gauze when it is placed normal to the stream. In the definition of F_θ , the normal to the gauze makes an angle θ with the approaching stream. F_θ is, of course, a function of θ , and is zero when $\theta = 0$. It is found from experiments that F_θ may be expressed in the convenient form

$$\frac{F_\theta}{\theta} = 2(1 - \alpha),$$

where α is a constant for small values of θ .

It can be shown theoretically that when a gauze is placed normal to the mean flow the effect on a *small* spatial disturbance is to reduce all longitudinal velocity increments in the ratio

$$\frac{1 + \alpha - \alpha k}{1 + \alpha + k},$$

and to reduce all lateral velocities in the ratio α . It follows that for $k = 1 + 1/\alpha$ small longitudinal disturbances are entirely removed. For the types of gauze normally used this corresponds to a value of k of about 2.8.

The effect of a gauze on the turbulence of a stream is twofold. First, the wakes from the individual wires of the gauze may introduce turbulence into the stream. Secondly, the resistance introduced by the screen causes a

reduction of turbulence. The first effect is small if the gauze is woven from fine wire with a small mesh size, and may even be zero if the Reynolds number based on the wire diameter is sufficiently small. Theoretical studies of the second effect have shown that the reduction in turbulent energy depends on the three-dimensional energy spectrum of the turbulence in the approaching stream. If the turbulence is isotropic upstream of the gauze it becomes axi-symmetric after passing through the gauze.

GAVIOLA CAUSTIC TEST. A test of the deviation of a mirror from a **paraboloid** of revolution, based on the caustic of a parallel axial bundle being the locus of centers of curvature of the parabolic sections. (See **caustic**.)

GAY-LUSSAC LAW. See **Charles law**.

GEE-POUND. The unit of mass which a force of one pound will accelerate by one foot per second per second is called the *slug* or *gee-pound*.

GEGENBAUER FUNCTION. A solution of the **differential equation**

$$(z^2 - 1)u'' + (2n + 1)zu' - a(a + 2n)u = 0.$$

For integral values of a , the solution becomes the Gegenbauer polynomial. This equation is a special case of the **Gauss hypergeometric equation**.

GEIGER-NUTALL RELATION. An empirical relationship between the range of an α -particle in air and **disintegration constant** of natural α -emitting radionuclides of the form:

$$\log R = A + B \log \lambda,$$

where R is the α -particle range, λ is the **disintegration constant**, A is a parameter having different values for the three natural radioactive series, and B is constant. This relationship was more closely applicable to the members of the natural series than it is to the more recently discovered α -emitters, especially those produced artificially. Current theory does not substantiate the relationship except for the general trend.

GENERALIZED AFFINITIES. See **forces in thermodynamics of irreversible processes**.

GENERALIZED COORDINATES AND MOMENTA. See coordinates and momenta, generalized.

GENERALIZED FUNCTION. See distribution.

GENERALIZED HOOKE'S LAW. See Hooke's law, generalized.

GENERALIZED HYDROSTATIC EQUATION. The vertical component of the vector equation of motion in natural coordinates when the acceleration of gravity is replaced by the virtual gravity. For most purposes it is identical to the hydrostatic equation.

GENERALIZED KRONECKER DELTA. See Kronecker delta, generalized.

GENERALIZED PLANE STRESS. A state of stress in a plate, the major surfaces of which are formed by two parallel planes. If a rectangular Cartesian reference system x, y, z is chosen with its z -axis perpendicular to the major surface of the plate and the normal component σ_{zz} of the stress vanishes throughout the plate, while the tangential components σ_{zx} and σ_{yz} vanish on its major surfaces, the plate is said to be in a state of generalized plane stress.

GENERALIZED VELOCITIES. See velocities, generalized.

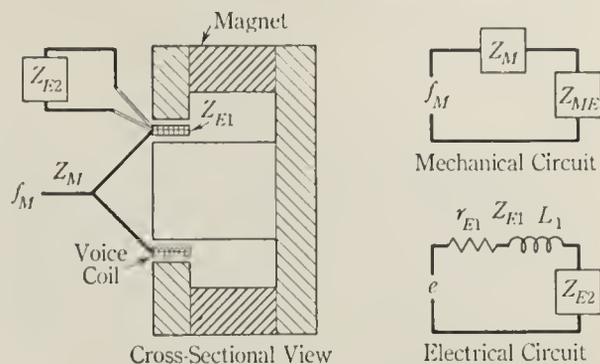

GENERATED ERROR. See error.

GENERATING FUNCTION. If the Taylor expansion of a function $f(x, u)$ expanded in powers of u is

$$f(x, u) = p_0(x) + p_1(x)u + p_2(x)u^2 + \dots$$

then $f(x, u)$ is called a generating function for the sequence of functions $p_0(x)$, $p_1(x)$, $p_2(x)$, \dots . Thus $(1 - 2xu + u^2)^{-1/2}$ is a generating function for the **Legendre polynomials**; $\exp[x^2 - (u - x)^2]$ for the **Bessel functions**; $(1 - u)^{-1} \exp\left(\frac{-xu}{1 - u}\right)$ for the **Laguerre polynomials**; $(1 - xu)(1 - 2xu + u^2)^{-1}$ for the **Chebyshev polynomials**, etc.

GENERATING SYSTEM, ELECTRODYNAMIC. A moving conductor or a moving coil generating system is a generating system in which the electromotive force is developed by motion of a conductor through a magnetic field.

Electrodynamic generating system. In the mechanical circuit f_M is the external driving force; z_M is the total mechanical rectilinear impedance of the mechanical portion of the vibrating system actuated by f_M ; z_{ME} is the mechanical rectilinear impedance due to the electrical circuit. In the electrical circuit e is the internal electromotive force generated in the voice coil; z_{E1} is the damped electrical impedance of the voice coil. $z_{E1} = r_{E1} + j\omega L_1$; L_1 and r_{E1} are the damped inductance and electrical resistance of the voice coil. z_{E2} is the electrical impedance of the external load.

The voltage e , in abvolts, due to the motion of the conductor in the magnetic field (see figure), is

$$e = Bl\dot{x} \quad (1)$$

where B is the flux density, in gaussses, l is the length of the conductor, in centimeters, and \dot{x} is the velocity of the conductor, in centimeters per second.

The velocity of the conductor is governed by the mechanical driving force, the mechanical rectilinear impedance of the mechanical system, and the mechanical rectilinear impedance due to the electrical system. The vibrating system is shown in the figure. In the mechanical circuit z_M represents the mechanical rectilinear impedance, in mechanical ohms, of the mechanical portion of the vibrating system actuated by f_M including the mechanical rectilinear impedance of the coil at the voice coil. f_M represents the mechanomotive force, in dynes, at the voice coil. The mechanical rectilinear impedance z_{ME} , in mechanical ohms, due to the electrical system is, from Equation 7 of driving system, electrodynamic

$$z_{ME} = \frac{(Bl)^2}{z_E} \quad (2)$$

where B is the flux density, in gaussses, l is the length of the conductor, in centimeters, $z_E = z_{E1} + z_{E2}$, z_{E1} is the electrical impedance of the voice coil, in abohms, and z_{E2} is the electrical impedance of the external load, in abohms.

The velocity of the voice coil is

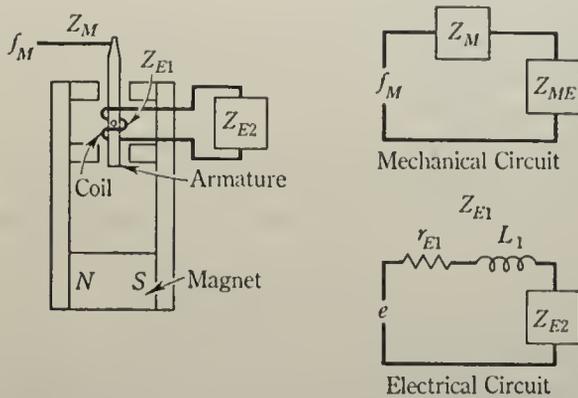

$$\dot{x} = \frac{f_M}{z_M + z_{ME}} \tag{3}$$

From Equations 1 and 3 the generated electromotive force e , in abvolts, is

$$e = Bl\dot{x} = \frac{Blf_M}{z_M + z_{ME}} \tag{4}$$

The generated electromotive force is effectively in series with the electrical impedance z_{E1} of the voice coil and the electrical impedance z_{E2} of the external load, as depicted by the electrical circuit in the figure.

GENERATING SYSTEM, ELECTROMAGNETIC. In the simple generating system of the preceding entry both the steady magnetic flux and the change in flux, due to the deflection of the armature, flows through the armature. Consider a balanced armature type of generating system in which only the alternating flux flows longitudinally through the armature as shown in the figure.

Balanced armature electromagnetic generating system. In the mechanical circuit z_M is the total mechanical rectilinear impedance of the mechanical portion of the vibrating system actuated by f_M ; z_{ME} is the mechanical rectilinear impedance due to the electrical circuit. In the electrical circuit e is the internal electromotive force generated in the coil; z_{E1} is the damped electrical impedance of the coil; $z_{E1} = r_{E1} + j\omega L_1$. L_1 and r_{E1} are the damped inductance and electrical resistance of the coil. z_{E2} is the electrical impedance of the external load.

The electromotive force e , in abvolts, generated in the coil due to motion of the armature from Equation 2 of **driving system, electromagnetic** is

$$e = \frac{NMA}{a^2} \dot{x} \tag{1}$$

where N is the number of turns in the coil, M is the magnetomotive force, in gilberts, of the steady field, A is the area of a pole piece, in square centimeters, a is the spacing between the armature and pole, in centimeters, and \dot{x} is the velocity of the armature, in centimeters per second.

The velocity of the armature is governed by the mechanical driving force, the mechanical rectilinear impedance of the mechanical system, and the mechanical rectilinear impedance due to the electrical system. The vibrating system is shown in the figure. In the mechanical circuit z_M represents the mechanical rectilinear impedance in mechanical ohms, of the mechanical portion of the vibrating system including the mechanical rectilinear impedance of the armature. f_M represents the mechanomotive force, in dynes, on the armature. The mechanical rectilinear impedance z_{ME} , in mechanical ohms, due to the electrical system is, from Equation 6 of **driving system, electromagnetic**

$$z_{ME} = \frac{4N^2\phi M}{a^2 R_2 z_E} \tag{2}$$

where N is the number of turns in the coil, ϕ is the total flux in the air gap at one of the poles, in maxwells, M is the magnetomotive force, in gilberts, of the magnet, a is the spacing between armature and pole, in centimeters, R_2 is the reluctance, in oersteds, of the alternating magnetic circuit, $z_E = z_{E1} + z_{E2}$, z_{E1} is the electrical impedance of the coil, in abohms, and z_{E2} is the electrical impedance of the external load, in abohms.

The velocity of the armature, in centimeters per second, is

$$\dot{x} = \frac{f_M}{z_M + z_{ME}} \tag{3}$$

From Equations 1 and 3

$$e = \frac{NMA}{a^2} \dot{x} = \frac{NMAf_M}{a^2(z_M + z_{ME})} \tag{4}$$

The generated electromotive force is effectively in series with the electrical impedance z_{E1} of the coil and the electrical impedance z_{E2} of the external load, as depicted by the electrical circuit in the figure.

GENERATING SYSTEM, ELECTROSTATIC. A condenser or electrostatic generating system is a generating system in which

the electromotive force is developed by the relative motion between two plates carrying different electrostatic charges.

The current i_1 , in statamperes, generated by the motion of the movable plate of the condenser is, from Equation 2 of **driving system, electrostatic**

$$i_1 = \frac{e_0 A \dot{x}}{4\pi a^2} \quad (1)$$

where e_0 is the polarizing voltage, in statvolts, A is the area of the plate, in square centimeters, a is the spacing between the plates, in centimeters, and \dot{x} is the velocity of the movable plate, in centimeters per second.

The current i_2 , in statamperes, due to the electromotive force e across the electrical impedances z_{E1} and z_{E2} of the figure is

$$i_2 = -\frac{e}{z_E} \quad (2)$$

where e is the electromotive force, in statvolts,

$$z_E = \frac{z_{E1} z_{E2}}{z_{E1} + z_{E2}}$$

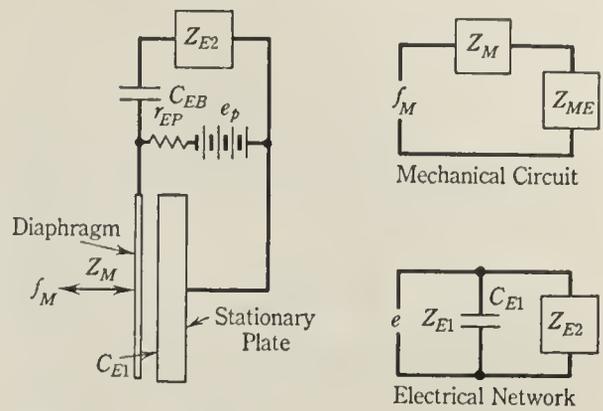

$$z_{E1} = \frac{1}{j\omega C_{E1}}$$

C_{E1} is the electrical capacitance of the condenser, in statfarads, and z_{E2} is the electrical impedance of the external load, in statohms.

Since there is no external current applied on the electrical side of the system the sum of the currents i_1 and i_2 is zero. From Equations 1 and 2 the generated electromotive force, e , in statvolts, across the electrical impedances z_{E1} and z_{E2} is

$$e = \frac{e_0 A \dot{x}}{4\pi a^2} z_E. \quad (3)$$

The velocity of the movable plate is governed by the mechanical driving force, the mechanical rectilinear impedance of the mechanical system and the mechanical rectilinear impedance due to the electrical system. The vibrating system is shown in the figure. In the mechanical circuit z_M represents the mechanical rectilinear impedance of the mechanical portion of the vibrating system actuated by f_M including the mechanical impedance of the movable plate. f_M represents the mechanomotive force at the movable plate. The me-

Electrostatic generating system. In the mechanical circuit z_M is the total mechanical rectilinear impedance of the mechanical portion of the vibrating system actuated by f_M ; z_{ME} is the mechanical rectilinear impedance due to the electrical circuit. In the electrical network e is the electromotive force generated across the condenser. z_{E1} , the damped electrical impedance of the condenser. $z_{E1} = 1/j\omega C_{E1}$. C_{E1} is the damped electrical capacitance of the condenser. Z_{E2} is the electrical impedance of the external load.

chanical rectilinear impedance z_{ME} , in mechanical ohms, due to the electrical system is, from Equation 4 of **driving system, electrostatic**

$$z_{ME} = \frac{e_0^2 A^2}{16\pi^2 a^4} z_E \quad (4)$$

$$\text{where } z_E = \frac{z_{E1} z_{E2}}{z_{E1} + z_{E2}}$$

$$z_{E1} = \frac{1}{j\omega C_{E1}}$$

C_{E1} is the capacity of the generator, in statfarads, z_{E2} is the electrical impedance of the external load, in statohms.

The velocity of the movable plate \dot{x} , in centimeters per second, is

$$\dot{x} = \frac{f_M}{z_M + z_{ME}}. \quad (5)$$

From Equations 3 and 5 the electromotive force e in abvolts, across z_{E1} and z_{E2} in parallel, depicted by the electrical network of the figure, is

$$e = \frac{e_0 A z_E f_M}{4\pi a^2 (z_M + z_{ME})}. \quad (6)$$

The electromotive force e_1 , in abvolts, in series with z_{E1} and z_{E2} which will produce the electromotive force e across z_{E2} is of interest in the design of generating systems.

Equation 3 may be written

$$e = \frac{e_0 A \dot{x}}{4\pi a^2} \left(\frac{z_{E1} z_{E2}}{z_{E1} + z_{E2}} \right). \quad (7)$$

The electrical capacitance of the condenser C_{E1} from Equation 4 is

$$C_{E1} = \frac{A}{4\pi a}. \quad (8)$$

The electrical impedance z_{E1} is

$$z_{E1} = \frac{1}{j\omega C_{E1}} = \frac{4\pi a}{j\omega A}. \quad (9)$$

Substituting Equation 9 in 8,

$$e = \frac{e_0 \dot{x}}{a j\omega} \left(\frac{z_{E2}}{z_{E1} + z_{E2}} \right). \quad (10)$$

The amplitude x in centimeters, in terms of the velocity is

$$x = \frac{\dot{x}}{j\omega}. \quad (11)$$

Substituting Equation 11 in 10,

$$e = \frac{e_0 x}{a} \left(\frac{z_{E2}}{z_{E1} + z_{E2}} \right). \quad (12)$$

The electromotive force e in terms of e_1 and the impedances z_{E1} and z_{E2} is

$$e = \frac{e_1 z_{E2}}{z_{E1} + z_{E2}}. \quad (13)$$

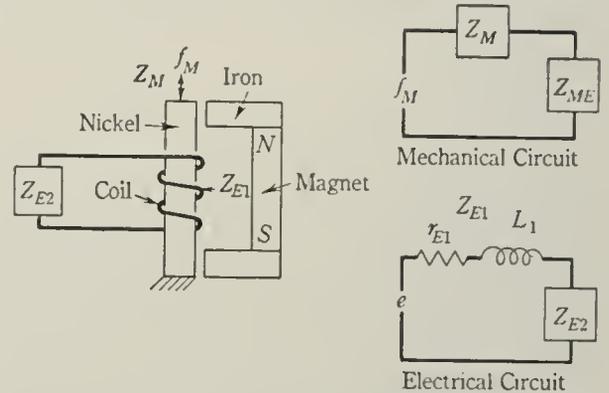

Comparing Equations 12 and 13,

$$e_1 = \frac{e_0 x}{a}. \quad (14)$$

The electrostatic generating system may be considered to consist of a generator having an internal or open circuit electromotive force e_1 as given by Equation 14 and an internal impedance z_{E1} . Equation 14 shows that this electromotive force is independent of the frequency if the amplitude is independent of the frequency. However, the voltage e across the load may vary with frequency depending upon the nature of load z_{E2} .

GENERATING SYSTEM, MAGNETOSTRICTION. A magnetostriction generating system is a generating system in which the electromotive force is developed in a stationary coil by a change in magnetic flux due to the deformation of a ferromagnetic material

having magnetostriction properties. The magnetostriction generator, shown in the figure, consists of a coil surrounding a magnetic circuit which includes a ferromagnetic material

Magnetostriction generating system. In the mechanical circuit z_M is the total mechanical rectilinear impedance of the mechanical portion of the vibrating system actuated by f_M ; z_{ME} is the mechanical rectilinear impedance due to the electrical circuit. In the electrical circuit e is the internal electromotive force generated in the coil; z_{E1} is the damped electrical impedance of the coil. $z_{E1} = r_{E1} + j\omega L_1$. L_1 and r_{E1} are the damped inductance and electrical resistance of the coil; z_{E2} is the electrical impedance of the external load.

having magnetostriction properties. The voltage e , in abvolts, developed in the coil due to deformation of the rod, from equation

$$e = \frac{4\pi N K}{R} \dot{x} \quad (1)$$

where N is the number of turns in the coil, R is the reluctance of the magnetic circuit, K is the constant representing the dynamical Villari magnetostriction effect, and \dot{x} is the velocity at the point of application of the driving force to the rod, in centimeters per second.

The velocity of the rod is governed by the mechanical driving force, the mechanical impedance of the mechanical system and the mechanical impedance due to the electrical system. The vibrating system is shown in the figure. In the mechanical circuit z_M represents the mechanical rectilinear impedance, in mechanical ohms, of the mechanical portion of the vibrating system actuated by f_M including the mechanical rectilinear impedance of the magnetostriction rod. f_M represents the mechanomotive force, in dynes, on the rod. It is assumed that the force f_M is the same at all points along the length of the rod and that the phase of the amplitude is constant along the rod. The mechanical recti-

lineal impedance due to the electrical system is, from Equation 8 of **driving system, magnetostriction**

$$z_{ME} = \frac{16\pi^2 N^2 K^2}{z_E R^2} \quad (2)$$

where $z_E = z_{E1} + z_{E2}$, z_{E1} is the electrical impedance of the coil, in abohms, and z_{E2} is the electrical impedance of the external circuit, in abohms.

The dimensions of the rod are assumed to be a small fraction of a wavelength. Under these conditions the rod is a compliance C_{M1} , in centimeters per dyne, given by

$$C_{M1} = \frac{l}{EA} \quad (3)$$

where A is the cross-sectional area of the rod, in square centimeters, l is the length of the rod, in centimeters, and E is Young's modulus.

The mechanical rectilinear impedance of the rod is

$$z_{M1} = \frac{1}{j\omega C_{M1}} \quad (4)$$

For the conditions under consideration the mechanical rectilinear impedance of the vibrating system is

$$z_M = z_{M1} + z_{M2} \quad (5)$$

where z_M is the total mechanical rectilinear impedance, in mechanical ohms, z_{M1} is the mechanical rectilinear impedance of the rod, in mechanical ohms, and z_{M2} is the mechanical rectilinear impedance of the load, in mechanical ohms.

The velocity of the rod, in centimeters per second, at the driving point is

$$\dot{x} = \frac{f_M}{z_M + z_{ME}} \quad (6)$$

From Equations 1 and 6 the generated electromotive force, in abvolts, is

$$e = \frac{4\pi N K f_M}{(z_M + z_{ME})R} \quad (7)$$

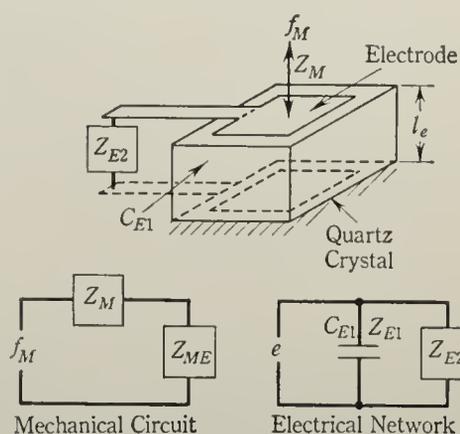

The generated electromotive force is effectively in series with the electrical impedance z_{E1} , in abohms, of the coil and the electrical impedance z_{E2} , in abohms, of the external load as depicted by the electrical circuit in the above figure.

In the above considerations the length of

the rod is assumed to be a small fraction of the wavelength. In general, magnetostriction generating systems are operated at resonance. The two most common systems are as follows: a rod fixed on one end and driven on the other and a rod free on one end and driven on the other.

GENERATING SYSTEM, PIEZOELECTRIC.

A piezoelectric generating system is a generating system in which the electromotive force is developed by the deformation of a crystal having converse piezoelectric properties. The crystal generating system, shown in the figure, consists of a suitably ground crystal

Piezoelectric generating system. In the electrical circuit z_M is the total mechanical rectilinear impedance of the mechanical portion of the vibrating system actuated by f_M ; z_{ME} is the mechanical rectilinear impedance due to the electrical network. In the electrical circuit e is the electromotive force generated across the crystal; z_{E1} is the damped electrical impedance of the crystal. $z_{E1} = 1/j\omega C_{E1}$. C_{E1} is the damped electrical capacitance of the crystal; z_{E2} is the electrical impedance of the external load.

having converse piezoelectric properties fitted with appropriate electrodes.

The current, in statamperes, generated by the motion of the crystal from Equation 4 of **driving system, piezoelectric**, is

$$i_1 = \frac{KEA}{l_e} \dot{x} \quad (1)$$

where K is a constant of the crystal, 6.4×10^{-8} for quartz, E is Young's modulus, l_e is the length of the crystal, in centimeters, A is the cross-sectional area of the crystal, in square centimeters, length of the crystal, in centimeters, and \dot{x} is the velocity of the crystal, in centimeters per second.

The current, in statamperes, due to the elec-

tromotive force e across the electrical impedances z_{E1} and z_{E2} is

$$i_2 = -\frac{e}{z_E} \quad (2)$$

where e is the electromotive force, in statvolts,

$$z_E = \frac{z_{E1}z_{E2}}{z_{E1} + z_{E2}}$$

$$z_{E1} = \frac{1}{j\omega C_{E1}}$$

C_{E1} is the electrical capacitance of the crystal, in statfarads, and z_{E2} is the electrical impedance of the external load, in statohms.

Since there is no external current applied to the electrodes of the crystal, the sum of the currents i_1 and i_2 is zero. From Equations 1 and 2 the generated electromotive force e , in statvolts, across the electrical impedance z_{E1} and z_{E2} is

$$e = \frac{KEA\dot{x}}{l_e} z_E \quad (3)$$

The velocity at the end of the crystal is governed by the mechanical driving force, the mechanical rectilinear impedance of the mechanical system and the mechanical rectilinear impedance due to the electrical system. The vibrating system is shown in the figure. In the mechanical circuit z_M represents the mechanical rectilinear impedance of the mechanical portion of the vibrating system actuated by f_M including the mechanical rectilinear impedance of the crystal. f_M represents the mechanomotive force at the end of the crystal. It is assumed that the force f_M is the same at all points along the length of the crystal and that the phase of the amplitude is constant along the crystal. The mechanical impedance z_{ME} , in mechanical ohms, due to the electrical system is

$$z_{ME} = \frac{K^2 E^2 A^2}{l_e^2} z_E \quad (4)$$

where $z_E = \frac{z_{E1}z_{E2}}{z_{E1} + z_{E2}}$

$$z_{E1} = \frac{1}{j\omega C_{E1}}$$

C_{E1} is the capacitance of the generator, in statfarads, z_{E2} is the electrical impedance of the external load, in statohms.

The dimensions of the crystal are assumed to be a small fraction of a wavelength. Under these conditions the crystal is a compliance given by

$$C_{M1} = \frac{l_e}{EA} \quad (5)$$

where A is the cross-sectional area of the crystal, in square centimeters, l_e is the length of the crystal, in centimeters, and E is Young's modulus.

The mechanical rectilinear impedance of the crystal is

$$z_{M1} = \frac{1}{j\omega C_{M1}} \quad (6)$$

For the conditions under consideration the mechanical rectilinear impedance of the vibrating system is

$$z_M = z_{M1} + z_{M2} \quad (7)$$

where z_M is the total mechanical rectilinear impedance, in mechanical ohms, z_{M1} is the mechanical rectilinear impedance of the crystal, in mechanical ohms, and z_{M2} is the mechanical rectilinear impedance of the load, in mechanical ohms.

The velocity at the end of crystal, in centimeters per second, is

$$\dot{x} = \frac{f_M}{z_M + z_{ME}} \quad (8)$$

From Equations 3 and 8 the electromotive force across z_{E1} and z_{E2} in parallel, depicted by the electrical network of the figure, is

$$e = \frac{KEA z_E f_M}{l_e (z_M + z_{ME})} \quad (9)$$

The electromotive force e_1 in series with z_{E1} and z_{E2} which will produce the electromotive force e across z_{E2} is of interest in the design of generating systems.

Equation 3 may be written

$$e = \frac{KEA\dot{x}}{l_e} \left(\frac{z_{E1}z_{E2}}{z_{E1} + z_{E2}} \right) \quad (10)$$

The electrical capacitance of the crystal is

$$C_{E1} = \frac{AD}{4\pi l_e} \quad (11)$$

where D is the dielectric constant of the crystal.

The electrical impedance z_{E1} is

$$z_{E1} = \frac{1}{j\omega C_{E1}} = \frac{4\pi l_e}{j\omega AD}. \quad (12)$$

Substituting 12 in 10,

$$e = \frac{4\pi KE\dot{x}}{j\omega D} \left(\frac{z_{E2}}{z_{E1} + z_{E2}} \right). \quad (13)$$

The amplitude x , in centimeters, in terms of the velocity is

$$x = \frac{\dot{x}}{j\omega}. \quad (14)$$

Substituting 14 in 13,

$$e = \frac{4\pi KE\dot{x}}{D} \left(\frac{z_{E2}}{z_{E1} + z_{E2}} \right). \quad (15)$$

The electromotive force e in terms of e_1 is

$$e = \frac{e_1 z_{E2}}{z_{E1} + z_{E2}}. \quad (16)$$

Comparing Equations 15 and 16,

$$e_1 = \frac{4\pi KE\dot{x}}{D}. \quad (17)$$

The piezoelectric generating system may be considered to consist of a generator having an internal or open circuit electromotive force e_1 as given by Equation 17 and an internal impedance z_{E1} . Equation 17 shows that this electromotive force is independent of the frequency if the amplitude is independent of the frequency. However, the voltage e across the load may vary with frequency depending upon the nature of the load z_{E2} .

In the above considerations the length of the crystal is assumed to be a small fraction of the wavelength. In general piezoelectric generating systems are operated at resonance. The two most common systems are as follows: a crystal fixed on one end and driven on the other and a crystal free on one end and driven on the other.

GENERATION RATE (IN A SEMICONDUCTOR). The time rate of creation of electron-hole pairs.

GENERATION TIME. In reactor theory, the time between the appearance of successive neutron generations, synonymous with neutron lifetime. (See **lifetime**, **neutron**.)

GENERATORS OF A SURFACE. See ruled surface.

GENERATORS OF ENVELOPE OF ONE-PARAMETER FAMILY OF PLANES. The characteristics of a one-parameter family of surfaces.

GENTILE STATISTICS. Gentile introduced the so-called intermediate statistics in which in a system of independent particles each single particle level can be occupied by up to l particles, where l is finite and larger than unity (compare $l = 1$ for **Fermi-Dirac statistics** and $l = \infty$ for **Bose-Einstein statistics**). These statistics have not found any application.

GEODESIC. See **geodesic line**.

GEODESIC CIRCLE ON A SURFACE. The locus of a point P on the surface such that geodesic distance (see **geodesic parallels**) r of P from a fixed point C on the surface is constant. This is an orthogonal trajectory of the geodesics drawn through C . C is the *center* of the geodesic circle and r its *radius*.

GEODESIC COORDINATES (PARAMETERS) FOR A SURFACE. Parameters u, v such that the curves $v = \text{constant}$ are a singly-infinite family of geodesics and the curves $u = \text{constant}$ are the **geodesic parallels** orthogonal to them.

GEODESIC CURVATURE (AT A POINT OF A CURVE ON A SURFACE). The curvature of the curve at the point relative to the geodesic which touches it at that point. Also called *tangential curvature* of the curve at the point.

GEODESIC DISTANCE (BETWEEN TWO GEODESIC PARALLELS). See **geodesic parallels**.

GEODESIC ELLIPSE ON A SURFACE. The curve $\frac{1}{2}(u + v) = \text{constant}$, where u and v are the geodesic distances of a point on the surface from two independent *geodesic parallels*, $u = 0$ and $v = 0$.

GEODESIC FORM FOR FIRST FUNDAMENTAL FORM. See **geodesic parallels**.

GEODESIC HYPERBOLA ON A SURFACE. The curve $\frac{1}{2}(u - v) = \text{constant}$, where u and v are the geodesic distances of a point on the

surface from two independent geodesic parallels, $u = 0$ and $v = 0$.

GEODESIC LINE ON A SURFACE (OR GEODESIC). The curve on a surface joining two points whose length between these points is less than that of any other curve on the surface joining them. A curve on the surface whose principal normal (see **normal, principal**) at each point coincides with the normal to the surface at that point.

GEODESIC, NULL. See **null-geodesic**.

GEODESIC PARALLELS ON A SURFACE. Consider a singly-infinite family of geodesics (see **geodesic line**) on a surface. The singly-infinite family of curves on the surface which cut these orthogonally at each point are called geodesic parallels. The distance between two geodesic parallels measured on the surface along any geodesic of the family is the same and is called the *geodesic distance* between the two geodesic parallels. If the geodesics are taken as the parametric curves $v = \text{constant}$ and their orthogonal trajectories are taken as the curves $u = \text{constant}$, then the first fundamental form for the surface takes the form

$$a(du)^2 + b(dv)^2$$

with a independent of v . In terms of the parameters \bar{u}, \bar{v} defined by

$$\bar{u} = \int \sqrt{a} du \quad \text{and} \quad \bar{v} = v,$$

the first fundamental form for the surface takes the form

$$(d\bar{u})^2 + b(d\bar{v})^2.$$

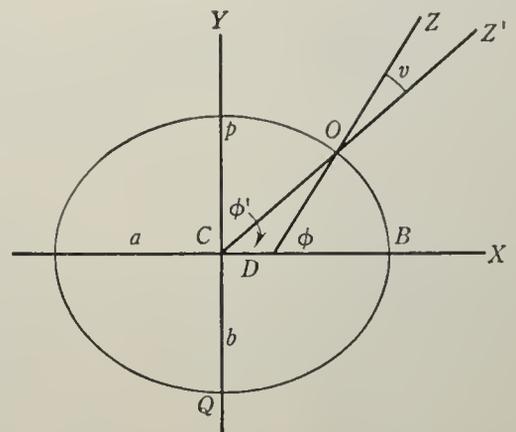

This is called the *geodesic form* for the first fundamental form.

GEODESIC POLAR COORDINATES FOR A SURFACE. Geodesic parameters u, v for the surface such that the curves $u = \text{constant}$ are geodesic circles of radius u on the surface having a common center, the pole of the coordinate system, and the curves $v = \text{constant}$ are geodesics joining the point u, v on the surface with the pole.

GEODESIC TANGENT (TO A CURVE ON A SURFACE AT A POINT). The geodesic (see **geodesic line**) on the surface which touches the curve on the surface at the point.

GEODESIC TRIANGLE ON A SURFACE. A curvilinear triangle on a surface bounded by geodesics (see **geodesic line**) on the surface.

GEOID. The shape of the surface of the rotating earth, as defined by the level of the ocean. For astronomical purposes it is sufficient to consider the geoid as a spheroid of revolution with the minor axis the line joining the poles of rotation. A plane containing the axis of rotation cuts the surface of the earth in a terrestrial meridian, which is elliptical. The major axis of the ellipse is in the plane of the equator and a , the length of the semi-major axis of the ellipse, is the equatorial

radius of the geoid (earth). Denoting the polar radius as b , and the eccentricity of the meridional ellipse as e , then $b^2 = a^2(1 - e^2)$. As is evident from the figure (axes CX and CY),

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1.$$

For an observer on the earth at O there are two types of latitude: The geocentric latitude represented by ϕ' and the astronomic latitude represented by ϕ .

The angle $\angle ZOZ'$ is known as the angle of the vertical and is represented by v . Now define a quantity m as $\frac{e^2}{(2 - e^2)}$ and thus

$$\phi - \phi' \equiv v = m \left(\frac{\sin 2\phi}{\sin 1''} \right)$$

$$- \frac{1}{2} \left(\frac{m^2 \sin 4\phi}{\sin 1''} \right) + \frac{1}{3} \left(\frac{m^3 \sin 6\phi}{\sin 1''} \right) \dots$$

For the sake of uniformity the so-called "International Geoid" is used by astronomers and its dimensions are:

a	equatorial radius.....	3963.339	statute miles
b	polar radius.....	3949.994	“ “
e	eccentricity.....	0.08199	
o	oblateness.....	$\frac{1}{297}$	
m		0.003373	

With this notation,

$$v \equiv \phi - \phi' = 695''.65 \sin 2\phi - 1''.17 \sin 4\phi.$$

In the various fields of science slightly different values for the dimensions of the geoid are used. However, the variations so caused in the various computed quantities are not significantly important.

GEOMAGNETIC COORDINATES. A system of **spherical coordinates** based on the best fit of a centered dipole to the actual magnetic field of the earth.

GEOMAGNETIC LATITUDE. (Or magnetic latitude.) A coordinate used in **geomagnetism** bearing the same relation to the geomagnetic equator as geographic latitude does to the geographic equator.

GEOMAGNETIC POLE. A pole of the system of **geomagnetic coordinates**; that is, an axis pole of the mathematical magnetic field of closest fit to the actual magnetic field of the earth. (Cf. **magnetic pole**.)

GEOMETRIC ASSOCIATION, PRINCIPLE OF. A principle used in forecasting the thickness of a layer between two given constant-pressure surfaces. In practical use of the principle, specific thicknesses are considered to be associated with **corresponding points** on the lower of the two constant-pressure surfaces (the upper one can also be used). A prognostic chart is prepared for the lower surface and the assumption is made that the thickness of the layer at the corresponding points is unchanged at the same corresponding points on the prognostic map. The prognostic **thickness chart** is then constructed from thickness values at the corresponding points.

GEOMETRIC(AL) BUCKLING. See **buckling**.

GEOMETRIC(AL) DISTORTION. Any monochromatic aberration which causes the reproduced image to be geometrically dissimilar to the perspective plane-projection of the object. If the image of a square in the object plane is a concave star-shaped region, the distortion is referred to as *pin cushion distortion*.

If, on the other hand, the image is convex, it is said to have *barrel distortion*.

GEOMETRIC(AL) ENERGY FLUX. If $L(u,v)$ is the optical differential invariant of a two-dimensional manifold of rays with parameters u,v and if S is a simply connected region in the (u,v) -plane bounded by a simple closed curve, then the integral invariant

$$\iint_S L(u,v) dS$$

is the geometrical energy flux through S .

GEOMETRIC MEAN. The geometric mean, G , of N positive **variates** is the N th root of the product of the N variates.

$$G = (x_1 x_2 x_3 \cdots x_N)^{\frac{1}{N}}.$$

It is found by use of logarithms.

$$\log G = \frac{1}{N} \sum_{j=1}^N \log x_j.$$

GEOMETRIC(AL) OPTICS. Visual phenomena are man's richest and most extensive contact with the physical world, so it is not surprising that geometrical optics as a systematic science antedates Euclid's *Catoptrics* of about 300 B.C. and includes such early monumental works as the 10-volume *Handbook on Optics* of Witela, about A.D. 1270.

Maxwell's discovery that the propagation of light is an electromagnetic phenomenon made optics a branch of electromagnetism. However, geometrical optics continues to be a useful description of many optical properties, always with the understanding that there is a limit to the physical accuracy of the results. Geometrical optics is always an extremely valuable intuitive tool. It is customary to use the name "physical optics" for the more complex and physically accurate theory based on electromagnetic theory.

A systematic development of geometrical optics can be carried out in a number of ways: (1) as a postulational system, (2) as derived from **Fermat's principle**, (3) as derived from **Huygens' principle**, (4) as a limiting form of physical optics (see **Kirchhoff's geometrical optics theorem**), or (5) by introducing the light rays as bicharacteristics of **Maxwell's equations**. (See **dynamical equations of light**

rays; paraxial ray tracing equations; direct method in geometrical optics.)

GEOMETRIC(AL) OPTICS, DIRECT METHOD. See **direct method in geometric optics.**

GEOMETRY. The subject-matter of geometry has become so general that it is difficult to give a definition suitable for the present day. In general, a geometry is the theory of properties of a set of points, lines, etc., which are invariant under a pre-assigned group of transformations. Classically, the methods of Euclid, who probably lived from 330–275 B.C., were used. These were based on a number of definitions, five postulates, and nine general axioms. The definitions included statements on point, line, solid, proposition, hypothesis, theorem, etc. The axioms were accepted without proof, the following being typical: if equals are added to or subtracted from equals the sums or remainders are equal; the whole is equal to the sum of all its parts and greater than any of its parts. Among the postulates, typical examples are: a straight line can be drawn from one point to another and can be produced indefinitely; a circumference can be described from any point as a center and with any given radius.

The development of mathematics and physical sciences gradually showed that there were logical deficiencies in the Euclidean definitions and postulates and, in 1899, the German mathematician David Hilbert resolved these difficulties with an improved set of geometric axioms. This work has been of profound significance in many branches of mathematics and science.

More specifically, non-Euclidean geometries discard one or more of the Euclidean axioms. The best-known of these are: hyperbolic geometry in which it is assumed that through any point there are two or more parallel lines which do not intersect a given line in the plane (it leads to the conclusion that the sum of three angles in a triangle is less than two right angles); elliptic geometry, in which the sum of the angles is greater than two right angles and all the lines through a given point intersect a given line in the plane so that no line has a parallel; parabolic geometry, namely that of Euclid. The names of mathematicians most prominently connected with these geometries are: hyperbolic, C. F. Gauss (1777–1855),

German; Wolfgang and John Bolyai, Hungarians, father and son; N. I. Lobatchewski, Russian (1793–1856); elliptic, G. Riemann (1826–1866), German.

There are several specialized branches of classical geometry or mathematical techniques related to it. Analytical geometry, developed by the French mathematician and philosopher, René Descartes (1596–1650) and Pierre Fermat (1601–1665), another Frenchman, is an application of algebraic results to geometry. It is also called coordinate geometry.

Descriptive and projective geometries developed from the interest of both painters and mathematicians in the problem of describing three-dimensional figures on a plane. Prior to the time of the Renaissance artists in general had been satisfied with symbolic representations of persons and objects but subsequently they became increasingly desirous of greater realism in their work. Albrecht Dürer, the German painter and engraver (1471–1528), is thought by some mathematical historians to be the inventor of descriptive geometry. Somewhat later, the French mathematician Gaspard Monge (1746–1818) placed the subject on a firm mathematical basis.

A more generalized development of geometric figures is projective geometry. Its founders include Gaspard Desargues, a French engineer (1593–1662); Blaise Pascal, French geometer and philosopher (1623–1662); Jean Victor Poncelet, French mathematician and general in the armies of Napoleon (1788–1867). One of its important objects is the study of properties invariant under projection and section.

Differential geometry is essentially the application of differential and integral calculus to the study of **curves** and surfaces. Methods of **tensor** calculus are frequently used and it is the chief mathematical apparatus of relativity theory.

Finally, mention should be made of **topology**, which is a study of one-to-one bicontinuous transformations. The usual description of topology as rubber-sheet geometry is sufficiently suggestive for two-dimensional space only, but the topological spaces of most importance in applied (or pure) mathematics, have an infinite number of dimensions; see, e.g., **Hilbert space**.

GEOMETRY FACTOR (RADIATION). The average solid angle at the source sub-

tended by the aperture or sensitive volume of the detector, divided by the complete solid angle (4π). Frequently used loosely to denote counting yield or **counter efficiency**.

GEOPOTENTIAL. The potential energy of a unit mass relative to sea level, numerically equal to the work that would be done in lifting the unit mass from sea level to the height at which the mass is located; commonly expressed in terms of **dynamic height** or **geopotential height**. The geopotential Φ at height z is given mathematically by the expression,

$$\Phi = \int_0^z g dz,$$

where g is the acceleration of **gravity**.

GEOPOTENTIAL HEIGHT. The height of a given point in the atmosphere in units proportional to the potential energy of unit mass (**geopotential**) at this height, relative to sea level. The relation, in the c.g.s. system, between the geopotential height Z and the geometric height z is

$$Z = \frac{1}{980} \int_0^z g dz,$$

where g is the acceleration of gravity, so that the two heights are numerically interchangeable for most meteorological purposes.

GEOPOTENTIAL SURFACE. (Also called **equigeopotential surface**, **level surface**.) A surface of constant **geopotential**, i.e., a surface along which a parcel of air could move without undergoing any changes in its **potential energy**. Geopotential surfaces almost coincide with surfaces of constant geometric height. Because of the poleward increase of the acceleration of **gravity** along a constant geometric-height surface, a given geopotential surface has a smaller geometric height over the poles than over the equator.

GEOSTROPHIC ACCELERATION. The acceleration experienced by a particle moving so that its velocity is always equal to the **geostrophic wind**. A term usually applied only in steady pressure fields.

If the wind is approximately geostrophic the geostrophic acceleration, which is roughly the convective rate of change of the geostrophic wind, is a measure of the ageostrophic wind, and

$$v_A = \frac{1}{f} v_G \cdot \text{grad } v_G$$

the direction being towards low pressure for an acceleration.

Alternatively, in a steady wind field

$$v_A \times \mathbf{f} = (v_G \cdot \text{grad}_H) v_G.$$

GEOSTROPHIC FORCE. Alternatively called the deviating force, or Coriolis force; the apparent force on particles moving relative to the earth when observed from the earth. For unit mass it is equal to $2\mathbf{v} \times \boldsymbol{\Omega}$ where \mathbf{v} is the velocity relative to the earth and $\boldsymbol{\Omega}$ is the earth's rotation vector. The vertical component is negligible compared with gravity and the horizontal component is equal to $\mathbf{v} \times \mathbf{f}$ where \mathbf{f} is twice the vertical component of the earth's rotation.

GEOSTROPHIC VORTICITY. The vorticity of the geostrophic wind, which is equal to $\frac{g}{f} \nabla_H^2 h$ if the variations of f with latitude are ignored, where ∇_H^2 is the two dimensional horizontal Laplacian operator, and h is the height of an isobaric surface.

The rate of change of geostrophic vorticity is a practical measure of the large scale horizontal convergence or divergence of the air which cannot be computed with comparable accuracy from wind measurements.

GEOSTROPHIC WIND. A measure of the horizontal pressure field in the atmosphere. If the isobars are at right angles to the x -axis the geostrophic wind v_G is given by

$$v_G = \frac{1}{\rho f} \frac{\partial p}{\partial x}$$

the direction being along the isobars in a cyclonic direction around low pressure centers, where ρ is the air density and $f = 2\Omega \sin \phi$, is twice the vertical component of the earth's rotation Ω , ϕ being the latitude.

Alternatively the geostrophic wind is given by

$$v_G = \frac{g}{f} \frac{\partial h}{\partial x}$$

where h is the height of an isobaric surface.

In vector form $v_G \times \mathbf{f} = \frac{1}{\rho} \text{grad}_H p$ where \mathbf{f} is a vertical vector and grad_H denotes the horizontal gradient.

The wind is approximately equal to the geostrophic wind when the acceleration is negligible and there is no exchange of momentum with the air above or below.

GERMS; KINETICS OF PHASE FORMATION. Consider a supersaturated vapor. The vapor is in metastable equilibrium with respect to the liquid phase (see **stability of phase**). This means that the **chemical potential** of the vapor is larger than that of the liquid considered as the bulk phase (see **chemical affinity**),

$$\mu^\alpha - \mu_\infty^\beta > 0 \quad (1)$$

where α denotes the vapor phase and β , the liquid phase, and the subscript ∞ indicates that the liquid phase is considered as a bulk phase. The chemical potential of a spherical drop increases when its radius r decreases (see **influence of curvature on chemical potential**). Therefore for sufficiently small drops

$$\mu^\alpha - \mu_r^\beta < 0 \quad (2)$$

where r is the radius of the drop. The vapor is therefore stable with respect to the formation of such drops. There exists a value of r such that

$$\mu^\alpha = \mu_r^\beta. \quad (3)$$

This relation defines a critical size for the drops. Drops of this size are called *condensation germs* (or *condensation nuclei*).

The critical size of the germ decreases rapidly when at constant temperature the vapor pressure is increased above the vapor tension, or when at a given pressure the temperature is decreased below the equilibrium coexistence value. Therefore at some point germs may be formed spontaneously as a consequence of statistical fluctuations. They then grow and the new phase appears. This mechanism explains why the kinetics of phase formation has a highly cooperative character. It also explains why it may be deeply influenced by the presence of impurities or walls. (See also **free energy of germ formation**.)

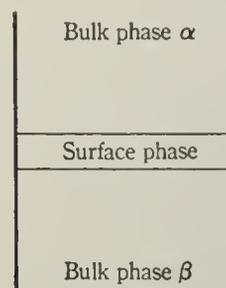

GEV. See **BEV**.

g-FACTOR. See **Landé g-factor**.

GIBBS-DALTON LAW. See **Dalton law**.

GIBBS DIVISION SURFACE. Consider a system consisting of two homogeneous bulk phases α and β separated by a surface phase.

The concentrations vary continuously through the surface phase from those of the interior of one phase to those of the interior of the other. In order to give a well-defined meaning to the thermodynamic functions of the surface phase, independently of the exact position of the boundaries of the surface layer, it is useful, following Gibbs, to replace the real surface phase by a geometrical surface. The bulk phases are considered to be homogeneous up to this geometrical surface, which is called the Gibbs division surface. (See figure.)

Gibbs division surface.

Call C_i^α , C_i^β the concentrations of component i in the bulk phases α , β and V' , V'' the volumes of the bulk phases in the description of the system in terms of the Gibbs division surface. The numbers of moles of component i in the phases prime and second prime will be defined by

$$n'_i = C_i^\alpha V'; \quad n''_i = C_i^\beta V''. \quad (1)$$

The number of moles of component i adsorbed at the surface is then defined by

$$n_i^a = n_i - n'_i - n''_i. \quad (2)$$

This number may be positive, zero or *negative*.

The adsorption of component i is defined as the ratio of n_i^a to the area of the Gibbs surface

$$\Gamma_i = \frac{n_i^a}{\Omega}. \quad (2)$$

An inconvenience of this definition is that the numerical value of the adsorption depends strongly on the exact position of the Gibbs surface. Therefore it is important to express the thermodynamic quantities in terms of *combinations* of Γ_i which are independent of this position. For example it can be shown that the *relative adsorption* of component i in respect to component 1

$$\Gamma_{i1} = \Gamma_i - \Gamma_1 \frac{C'_i - C''_i}{C'_1 - C''_1} \quad (3)$$

is independent of the position of the Gibbs surface. The adsorption of component i may alternatively be defined directly in terms of the molar content of the surface phase itself, by a formula similar to (2). Its numerical value then depends on the assumed position of the boundaries of the surface phase. Again, however, combinations of the adsorptions may be introduced which are independent of the exact specification of these boundaries.

GIBBS-DUHEM EQUATION. This equation expresses a connection between the increments of the **intensive variables** which characterize a thermodynamic system. It is

$$SdT - Vdp + \sum_i n_i d\mu_i = 0. \quad (1)$$

The variations occur in the intensive variables, absolute temperature T , pressure p , and **chemical potential** μ_i , while their coefficients are the extensive variables, entropy S , volume V , and number of moles n_i .

For changes taking place at constant temperature and pressure, Equation (1) reduces to

$$\sum_i n_i d\mu_i = 0. \quad (2)$$

This is simply a form of the **Euler theorem** for the chemical potentials, which are intensive variables.

GIBBS FORMULA FOR THE SURFACE TENSION. The total differential of the surface tension γ in the variables temperature T , and **chemical potentials** μ_i is

$$d\gamma = -s^a dT - \sum_i \Gamma_i d\mu_i \quad (1)$$

where s^a is the entropy per unit area of the surface phase (see **thermodynamic functions of surface phases**) and Γ_i the adsorption of component i (see **Gibbs division surface**).

This formula is the analog for a surface phase, of the **Gibbs-Duhem equation** for a bulk phase.

Another basic formula also due to Gibbs which relates the surface tension to the thermodynamic functions of the surface phase is

$$\gamma = A^a - \sum_i \Gamma_i \mu_i \quad (2)$$

where A^a is the Helmholtz free energy (**Helmholtz function**) per unit area of the surface phase. This expression is the analog of the

relation between the Gibbs free energy and the chemical potentials

$$G = \sum_i n_i \mu_i \quad (3)$$

valid for a bulk phase. Both relations (2) and (3) are related to the **Euler theorem**.

GIBBS FREE ENERGY. See **Gibbs function**.

GIBBS FUNCTION. The potential given by

$$G = H - TS = U + pV - TS$$

where $H = U + pV$ is the **enthalpy**; U is the internal energy; p is the pressure; V is the volume; T is the absolute temperature; and S is the entropy. Some authors use the graphic term free enthalpy, and some others call it free energy. Since the name **free energy** is also given to the **Helmholtz function**, confusion results and it is preferable to use the neutral term Gibbs function. (See also **thermodynamics, characteristic functions of**.)

GIBBS-HELMHOLTZ EQUATIONS. Equations relating the **Helmholtz function** A (or the **Gibbs function** G) to the total energy U (or the enthalpy H) (see **thermodynamics, characteristic functions of**).

$$\left(\frac{\partial \frac{A}{T}}{\partial T} \right)_{V, \xi} = - \frac{U}{T^2} \quad (1)$$

$$\left(\frac{\partial \frac{G}{T}}{\partial T} \right)_{p, \xi} = - \frac{H}{T^2} \quad (2)$$

where p is the pressure, T , the absolute temperature, V , the volume, ξ , the **extent of reaction**.

GIBBSIAN ENSEMBLE. See **ensemble (1)**.

GIBBS-KONOVALOV THEOREMS. Consider a binary system containing two phases (i.e., liquid and vapor). Both components can pass from one phase to another. The Gibbs-Konovalov theorems refer to the properties of the phase diagrams of such systems (see **azotropic systems**). The first theorem is: *At constant pressure, the temperature of coexistence passes through an extreme value (maximum, minimum or inflexion with a horizontal value) if the composition of the two phases is the same, and conversely at a point at which the*

temperature passes through an extreme value, the phases have the same composition. The second theorem is similar. It refers to the co-existence pressure at constant temperature. (See also **indifferent states**.)

GIBBS PARADOX. When two samples of the same gas at a given temperature and pressure are allowed to mingle by the removal of a separating partition, the entropy of the resulting system is equal to the sum of the entropies of the two original parts, and there is no extra term which arises when the two original systems are composed of different gases. This paradoxical absence is called the Gibbs paradox; it can be explained by using the theory of **grand canonical ensembles**.

GIBBS PHENOMENON. Behavior shown by a **function** with a discontinuity, when it is approximated by a finite number of terms in a **Fourier series**. As a simple example, consider $f(x) = 1$ for $0 > x > \pi$; $f(x) = -1$ for $\pi < x < 2\pi$. The sum of the first n terms in the Fourier series converges to ± 1 as $n \rightarrow \infty$, except at the discontinuity, $x = \pi/(2n + 1)$. There the sum approaches 1.179, overshooting the correct value by about 18%.

GILBERT. See **electromagnetic units**.

GINI MEAN DIFFERENCE. See **concentration**.

GIVENS METHOD. A method for computing **eigenvalues** of a **Hermitian matrix**.

GLADSTONE-DALE LAW. If the **refractive index** of a medium is a linear function of its **density**, then the medium satisfies the Gladstone-Dale law.

GLANCING ANGLE. (1) The angle between a ray and the tangent plane to a surface. The complement of the **angle of incidence**. (2) The term is often used as a modifier, to indicate the incidence of a beam at a very small angle with the surface.

GLASS COMPLIANCE. See **compliance, glass**.

GLASS MODULUS. See **modulus, glass**.

GLASS TRANSITION TEMPERATURE. See **glassy state**.

GLASSY STATE. Below the glass transition temperature of a polymer, local order is in-

creased and **viscoelastic** effects are less prominent.

GLIDE PLANE. (1) A **symmetry element** of a **space lattice**, such that the lattice remains unchanged after a **reflection** in the plane, followed by a **translation** parallel to the same plane. (2) Same as **slip plane** in theory of **dislocations**.

GLOBULAR CLUSTERS. See **star clusters**.

GOLDSCHMIDT LAW. The structure of a crystal is determined by the ratio of the numbers, the ratio of the sizes, and the properties of polarization of the atoms or ions from which it is formed.

Thus, there is a change from the face-centered to the body-centered lattice in the alkali chlorides as the cation radius increases. Similarly, there is a change from the rock-salt to the zincblende lattice in the series CdO, CdS, CdSe, CdTe, corresponding to the increasing size and polarizability of the anion.

GÖRTZEL-GREULING APPROXIMATION. In the theory of the slowing down of neutrons in matter, an approximate relationship between the **slowing-down density** q and neutron **flux** $\phi(E)$, first presented by G. Görtzel and E. Greuling, is:

$$q(E) = (\xi\Sigma_s + \gamma\Sigma_a)E\phi(E).$$

Here, Σ_s and Σ_a are macroscopic scattering and absorption cross sections, respectively, ξ is the average logarithmic energy loss for a neutron colliding with a nucleus of mass M , and

$$\gamma = 1 - \frac{\frac{1}{2}\alpha\epsilon^2}{1 - \alpha(1 + \epsilon)}; \quad \epsilon = \ln \frac{1}{\alpha}, \quad \alpha = \left(\frac{M - 1}{M + 1} \right)^2.$$

GÖRTZEL-SELENGUT METHOD. A method of analysis of the energy-dependent transport equation in **neutron transport theory**. A spherical harmonics expansion is made for the angular distribution of flux, and is cut off at the P_1 approximation. Then, in treating the collision integrals, those referring to scattering by hydrogen are treated exactly, while in those describing scattering by "heavy elements" the age approximation is used. (See **spherical harmonics method; age approximation**.)

GÖTHERT'S RULE. This rule is obtained from the linear equation of subsonic flow and applies to any body in a uniform subsonic stream, provided the perturbation velocities are small and the stream Mach number is not close to 1. The **Prandtl-Glauert rule**, which applies only to two-dimensional bodies, is a special case of the Göthert rule.

The Göthert rule relates the pressure coefficient C_p at a point on a given body A in a stream of Mach number M to the pressure coefficient C_{p_0} at the corresponding point on a related body B at zero Mach number. The body B is obtained by an **affine transformation** of the body A , in which all dimensions in directions perpendicular to the undisturbed stream are multiplied by $(1 - M^2)^{1/2}$. The relation between the pressure coefficients is then

$$\frac{C_{p_0}}{C_p} = 1 - M^2.$$

As is the case for the Prandtl-Glauert rule, the Göthert rule does not apply at Mach numbers above the critical Mach number.

GOUDSMIT AND UHLENBECK ASSUMPTION. To explain the **multiplet** structure of spectral lines and the anomalous **Zeeman effect** Goudsmit and Uhlenbeck made, at first independently of quantum mechanics, the assumption that the electron has an intrinsic angular momentum (rotation about its own axis) or **spin** s of magnitude $\frac{1}{2}h/2\pi$ with an associated magnetic moment of 1 **Bohr magneton**.

GOUDSMIT GAMMA-SUM RULE. See **gamma-value**.

g-PERMANENCE RULE. According to Pauli's **g-permanence rule** the sum of the **Landé g-factors** for the components of a given **multiplet** corresponding to a given value of M is independent of the field strength. For a weak field M is the quantum number corresponding to the component in the field direction of the resultant total electronic angular momentum J . For a moderately strong field $M = M_S + M_L$, where M_S and M_L are the quantum numbers of the components in the field direction of the resultant electronic orbital angular momentum L and electron spin S .

GRADE. For a continuous frequency distribution with **distribution** function $F(x)$ the

grade of a value is simply $F(x)$. It is a quantity analogous to that of **rank**, which cannot, of course, be defined for a continuous variable.

GRADIENT. (1) A vector denoting the maximum rate of change of a **scalar** ϕ and directed along the direction of the maximal change. Formally the vector obtained by the application of the vector differential operator **del** ∇ to a scalar point function. In rectangular coordinates it is

$$\text{grad } \phi = \nabla\phi = \mathbf{i} \frac{\partial\phi}{\partial x} + \mathbf{j} \frac{\partial\phi}{\partial y} + \mathbf{k} \frac{\partial\phi}{\partial z}$$

where \mathbf{i} , \mathbf{j} , \mathbf{k} are unit vectors along the X -, Y -, and Z -axes. At any point, P , it is normal to the surface $\phi(x,y,z) = \text{constant}$, which passes through P . (2) The **vector** gradient of a vector field \mathbf{V} is written $\text{grad} \cdot \mathbf{V}$. It is a **tensor** given by the **dyadic** multiplication of the del operator with the vector field \mathbf{V} .

GRADIENT COUPLING. Type of postulated coupling between nucleons and other particles (**mesons**, **β -particles** and **neutrinos**) in which the interaction energy depends explicitly on the first order derivatives of the wave functions with respect to position and time.

GRADIENT WIND. The wind v defined by

$$vf = \frac{1}{\rho} \frac{\partial p}{\partial x} \mp \frac{v^2}{R}$$

where the motion is steady, frictionless, and in circles of radius R , where the x -axis is taken locally towards high pressure. The motion is cyclonic around low pressure and anticyclonic around high pressure, the upper or lower sign being taken, respectively.

The deviating force and the cyclostrophic force balance the pressure gradient force if the air moves with the gradient wind velocity.

As a measure of the actual wind it is an improvement on the **geostrophic wind**, since it takes some account of the curvature of the path of the air, if R is taken as the local radius of curvature of the isobars.

GRADUATION. Another term for **smoothing**.

GRAEFFE METHOD. A **root-squaring method** for solving algebraic equations. Given the algebraic equation, separate odd and even powers of x on opposite sides of the equation:

$$x^n + a_2x^{n-2} + a_3x^{n-4} + \dots = a_1x^{n-1} + a_3x^{n-3} + \dots$$

If both sides are squared, all powers will be even, and x^2 can be replaced by y . Separate in the same way and repeat. After p such operations, let the equation be

$$z^n + c_2z^{n-2} + \dots = c_1z^{n-1} + \dots$$

Then the roots z_i of this equation, and the roots x_i of the first, are related by

$$z_i = x_i^p, \quad \nu = 2^p.$$

Then if

$$|x_1| > |x_2| \geq \dots,$$

it follows that, approximately,

$$c_1 \doteq x_1^p.$$

If

$$|x_1| \geq |x_2| > |x_3| \geq \dots,$$

then, approximately,

$$c_2 \doteq x_1^p x_2^p.$$

And, if

$$|x_1| = |x_2| > |x_3| \geq \dots,$$

then $z_1 = x_1^p$ and $z_2 = x_2^p$ satisfy, approximately,

$$z^2 - c_1z + c_2 \doteq 0.$$

When all roots are distinct,

$$x_2^p \doteq c_2/c_1, \quad x_3^p \doteq c_3/c_2, \quad x_4^p \doteq c_4/c_3, \dots$$

approximately. An enumeration of all possible contingencies resulting from the presence of conjugate pairs equal in modulus is out of the question, but generally speaking, a term that continues to oscillate rather than to increase after continued squaring marks the presence of a conjugate pair, and the pair z_i and z_{i+1} will satisfy approximately

$$c_{i-1}z^2 - c_i z + c_{i+1} = 0$$

(see **symmetric functions**). The method can be generalized to apply to a function expressible in the form

$$f(x) = 1 + a_1/x + a_2/x^2 + \dots$$

If the series converges for $|x| > R$, then all zeros of $f(x)$ exceeding R in modulus can be found. (See Alston S. Householder, *Principles of Numerical Analysis*, McGraw-Hill Book Company, 1953.)

GRAIN BOUNDARY. The surface separating two regions of a solid in which the crystal axes

are differently oriented. It has been shown that such a boundary may be thought of as built up of an array, or network of **dislocations**, whose spacing depends on the tilt θ of the axes across the surface. The energy (per unit area) of a grain boundary is given by

$$E/E_m = (\theta/\theta_m) \{1 - \ln(\theta/\theta_m)\}$$

where E_m and θ_m are parameters depending on the material.

GRAM-CHARLIER SERIES. The series, useful in statistics,

$$F(x) = \sum_{k=0}^{\infty} c_k e^{-x^2/2} H_k(x),$$

where the constants c_k depend on the frequency function (see **distribution**) represented over the interval $[-\infty, \infty]$ and the $H_k(x)$ are the **Hermite polynomials**. The Gram-Charlier series is similar to the **Edgeworth series**, and indeed the two are identical for infinite series; their difference arises in regard to the stoppage point when a finite number of terms only is taken as an approximation, in which case Edgeworth's form is probably preferable.

GRAM DETERMINANT. The Gram determinant of n functions (or vectors) f_1, f_2, \dots, f_n is the determinant of the $n \times n$ matrix whose general term is (f_i, f_j) , namely the scalar product of f_i and f_j . The vanishing of the Gram determinant is necessary and sufficient for linear dependence of the functions.

GRAM-SCHMIDT PROCESS. A method for converting a given set of vectors $\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_n$ into an orthonormal set $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n$. We begin with normalizing the vector \mathbf{u}_1 , by dividing it by its norm $\|\mathbf{u}_1\|$ and setting $\mathbf{v}_1 = \mathbf{u}_1/\|\mathbf{u}_1\|$. We then define a vector \mathbf{w}_2 , orthogonal to \mathbf{v}_1 by setting $\mathbf{w}_2 = \mathbf{u}_2 - (\mathbf{u}_2, \mathbf{v}_1)\mathbf{v}_1$. Next we normalize \mathbf{w}_2 by setting $\mathbf{v}_2 = \mathbf{w}_2/\|\mathbf{w}_2\|$. Again we define \mathbf{w}_3 orthogonal to \mathbf{v}_1 and \mathbf{v}_2 by setting $\mathbf{w}_3 = \mathbf{u}_3 - (\mathbf{u}_3, \mathbf{v}_1)\mathbf{v}_1 - (\mathbf{u}_3, \mathbf{v}_2)\mathbf{v}_2$ and then set $\mathbf{v}_3 = \mathbf{w}_3/\|\mathbf{w}_3\|$ and so forth. (See also **orthogonalization**.)

The process can be equally well applied to functions.

GRAND CANONICAL ENSEMBLE. A grand ensemble with a density ρ given by the equation

$$\rho = e^{-q + \nu n - \beta \epsilon},$$

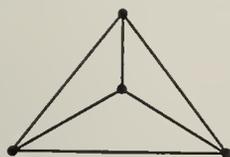

where q is a (normalizing) constant, $\beta = 1/kT$ (k , Boltzmann's constant; T , absolute temperature), ϵ , the energy of the system, $\nu = \beta g$ (g , the partial thermal potential), and n the number of particles of the system.

GRAND ENSEMBLE. See ensemble.

GRAND PARTITION FUNCTION. Same as density of a grand canonical ensemble.

GRAPH, AUTOMORPHISM. An isomorphism (see graph, isomorphic) of a graph with itself.

GRAPH, COMPLETE. A complete graph G is a linear graph in which every two distinct vertices are endpoints of an edge in G . The figure shown below is a complete graph with four vertices.

The total number N of distinct labeled trees in a complete graph containing v vertices is

$$N = v^{v-2},$$

a result due to Cayley. Thus, the above example has 16 trees. They are enumerated under tree.

GRAPH COMPONENT. A component of a graph G is a non-separable maximal connected subgraph. The decomposition of a graph into components is unique.

GRAPH, CONNECTED. A graph is connected if there exists a path between any two vertices. Stated differently, any two distinct vertices β_1 and β_2 are the terminal vertices of some path.

GRAPH CONNECTIVITY. The nullity of a graph G is also known as its connectivity.

GRAPH, DIRECTED. See digraph.

GRAPH, FINITE. Graphs containing only a finite number of line segments and vertices.

GRAPHICAL STATICS. The equilibrium of forces is often treated graphically in such practical problems as the stresses in the members of a framed structure. If three concurrent forces are in equilibrium, the three vectors drawn to a common scale to represent

them may be made to form a closed triangle (Figure 1); or if more than three, a closed

Fig. 1. Three forces in equilibrium.

polygon (Figure 2). The principle may be extended and is much used in the calculation of the forces in a truss by means of the so-called

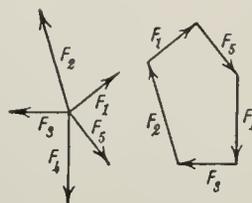

Fig. 2. Five forces in equilibrium.

stress diagram. A simple example is shown in Figure 3, which represents a small roof-truss with equal loads resting on it at the

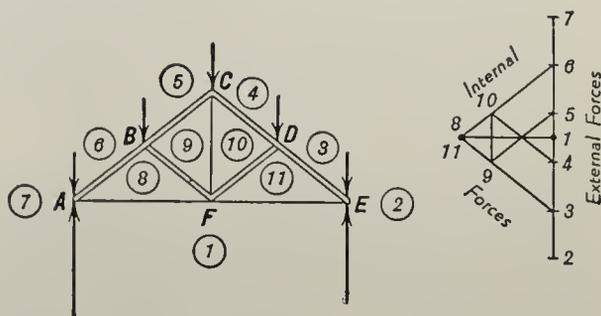

Fig. 3. Elevation of truss with corresponding phase diagram.

joints A, B, C, D, E , and supported by the upward reactions of the walls at A and E . The several compartments of the figure are numbered, and both the external forces and the forces acting along the members between these compartments are represented, both in magnitude and direction, by the lines joining the corresponding numbers in the stress diagram. For example, the compressive force in the strut BF is represented by the line 8-9, while the tension in the vertical rod CF is given by 9-10. The closed figure 5-4-10-9-5 in the stress diagram indicates the equilibrium of the forces acting at the joint C . This method of analysis is attributed to Maxwell.

In the graphical solution of some types of trusses it is found on reaching a particular joint that the arrangement of members is such that there are more than two unknowns. It

is then necessary to replace the unknowns by a substitute system which reduces the number of unknowns at the joint to two. The substitute system consists of a single member inserted in such a way that the truss remains stable and determinate. This member is called a substitute, fictitious or phantom member. When the solution reaches a joint where the stress in the members is unaffected by the substitution, the substitute arrangement is replaced by the original arrangement. The graphic procedure is reversed in direction to find the stress in the original members.

GRAPH, INFINITE. Graphs containing an infinite number of line segments and **vertices**. Such graphs have many interesting mathematical properties but have not as yet found practical application.

GRAPH, LINEAR. A collection of **edges** no two of which have a point in common that is not a **vertex**. The words linear-complex and 1-complex are frequently used alternatives.

As defined here a graph is an abstract graph devoid of any geometric significance whatsoever. It is true, however, that a graph can be interpreted as a **configuration** in 3-dimensional euclidean space.

GRAPH, NON-ORIENTED. A linear graph in which the **elements** have not been assigned an orientation is said to be non-oriented. (See **element, oriented**.) Such a graph is also called *ordinary*.

GRAPH, NON-SEPARABLE. A graph of which every **subgraph** has at least two **vertices** in common with its **complement**.

GRAPH, NULLITY. The nullity μ of a graph G possessing v **vertices**, e **edges** and P **maximal connected subgraphs** is

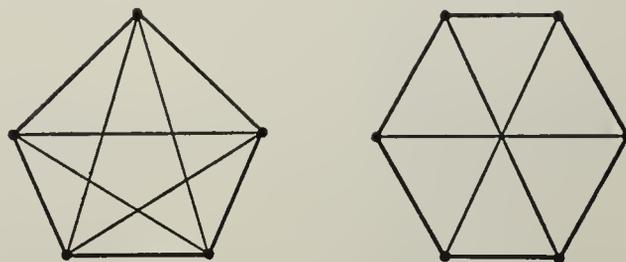

$$\mu = e - v + P \geq 0.$$

GRAPH, ORDINARY. See **graph, non-separable**.

GRAPH, ORIENTED. A linear graph is oriented when an orientation has been assigned to each of its elements (see **element, oriented**). By long-standing convention the phrase "oriented graph" is applied only to graphs which possess at most one directed segment between any two vertices. (For the more general case in which parallel edges are permitted see **digraph** or **graph, directed**.)

GRAPH, PLANAR. A linear graph G can be viewed from either a geometric or a topological standpoint. In the first it is considered to be a collection of **edges** no two of which have a point in common that is not a **vertex**. In the latter it is thought of as defining a set of points in three dimensions whose members are the points which make up the edges of the graph. This point set is the topological graph G^* corresponding to the linear graph G . G is said to be planar if G^* can be mapped on a plane by a one-to-one continuous transformation in such a way that no two image edges have a point in common that is not the image of a vertex in G .

It has been shown by Kuratowski that a linear graph is planar if and only if it does not contain either of the following two graphs as subgraphs:

GRAPH RANK. The rank of a graph G is $v - P$ where v is the number of **vertices** and P the number of **maximal connected subgraphs** of G .

GRAPHS, DUAL. The linear graph G_2 is the dual of the linear graph G_1 if the conditions enumerated below are satisfied:

(a) The **edges** of G_1 and G_2 are in one-to-one correspondence.

(b) If H_1 is any subgraph of G_1 and H_2 is the complement of the corresponding subgraph in G_2 ,

$$r_2 = R_2 - n_1,$$

where r_2 is the **rank** of H_2 , R_2 is the rank of G_2 and n_1 is the **nullity** of H_1 .

It follows easily from this definition that $\text{rank } G_1 = \text{nullity } G_2$ and $\text{rank } G_2 = \text{nullity } G_1$. Furthermore if G_2 is the dual of G_1 , G_1 is the dual of G_2 .

Two extremely useful and significant results are that the dual of a non-separable graph is non-separable and that a linear graph is planar if and only if it possesses a dual.

The usual geometric procedure for finding

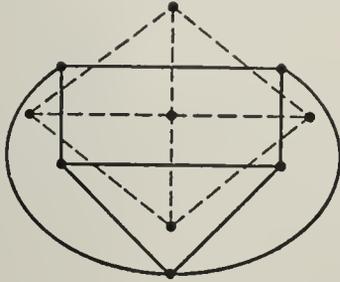

the dual of a planar graph G involves three steps:

(a) Choose a set of fundamental circuits. (See **circuit, fundamental**.)

(b) Put a **node** in each such circuit and a node outside the graph.

(c) Connect any two nodes which are on opposite sides of a branch by a line segment.

The resulting graph is the dual of G . These rules are illustrated in the accompanying diagram in which the dual appears dotted.

GRAPH, SEPARABLE. A connected graph is separable if it contains at least one **sub-graph** which has only one **vertex** in common with its complement. Otherwise the graph is non-separable.

GRAPHS, HOMEOMORPHIC. Two graphs G and G' are homeomorphic if there exists a one-to-one bicontinuous mapping between the two point-sets defined by G and G' . (See also **graph, planar**.)

GRAPHS, ISOMORPHIC. Two graphs G and G' are said to be isomorphic if there exists a one-to-one transformation which maps the **vertices** of G onto the vertices of G' and the **edges** of G onto the edges of G' in such a way as to preserve **incidence** relationships. In other words if vertex β and edge ϵ are incident in G , the respective images β' and ϵ' are incident in G' . The one-to-one transformation referred to above is an isomorphism of G with G' .

GRAPHS, THEORY OF. See various entries under **graph(s)**.

GRAPH, TOPOLOGICAL. See **graph, planar**.

GRASHOF NUMBER. A non-dimensional number G , relating buoyancy forces to viscous forces:

$$G = g\alpha \frac{\Delta T}{T} h \sqrt{\frac{h}{\nu^2}} = gBh^3/\nu^2$$

where B is the buoyancy force per unit mass. It is equal to (**Reynolds number** \div **Froude number**)² and to **Rayleigh number** \div **Prandtl number**.

GRAVITATIONAL CONSTANT. The law of universal gravitation, as stated by Newton, may be expressed as

$$F = G \frac{m_1 m_2}{d^2}$$

When m_1 and m_2 are unit masses and the distance between the centers of mass, d , is unit distance, $F = G$, which is defined as the constant of universal gravitation.

In the c.g.s. system of units $G = 6.670 \times 10^{-8}$. It follows that the attraction between two gram masses one centimeter apart is of the order of a 15-millionth of a dyne.

GRAVITATIONAL FIELD STRENGTH. The force per unit mass resulting from the gravitational attraction of other masses which produce a gravitational field.

GRAVITATIONAL FLATTENING. The constant

$$\frac{g_p - g_e}{g_e}$$

where g_p is the gravitational acceleration at the poles, and g_e is the gravitational acceleration at the equator. This constant occurs in the formula for finding the value of the **gravitational acceleration** at a given latitude.

GRAVITATIONAL POTENTIAL. For a point in a gravitational field (see **field, gravitational**), the amount of work which must be done on a particle of unit mass to move it from the point to infinity. It becomes equal to the potential energy per unit mass at the point in question if the potential energy is taken to be equal to zero at infinity, which is usually the case. If x, y, z are the coordinates of the attracted body of mass m and ξ, η, ζ are the coordinates of the attracting body and $\rho(\xi, \eta, \zeta)$ its density at that point, then the potential energy of m is

$$V^* = -Gm \iiint_B \frac{\rho d\xi d\eta d\zeta}{\sqrt{(\xi - x)^2 + (\eta - y)^2 + (\zeta - z)^2}}$$

the integration to be extended over the entire body. G is Newton's **gravitational constant**. The potential function is

$$\frac{V^*}{m} \equiv V = -G \iiint_B \frac{\rho d\xi d\eta d\zeta}{\sqrt{(\xi-x)^2 + (\eta-y)^2 + (\zeta-z)^2}}$$

V satisfies the Poisson equation:

$$\frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} + \frac{\partial^2 V}{\partial z^2} = 4\pi G\rho(x,y,z).$$

In empty space, this becomes Laplace's equation

$$\frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} + \frac{\partial^2 V}{\partial z^2} = 0.$$

The force on a point mass is located at the point (x,y,z) is

$$\mathbf{F} = -m \text{grad } V.$$

The solution of the two-dimensional Poisson equation

$$\frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} = 2\pi G\rho(x,y)$$

is

$$V = -G \iint \rho(\xi,\eta) \left| \ln \sqrt{(x-\xi)^2 + (y-\eta)^2} \right| d\xi d\eta.$$

The potential of a homogeneous spherical shell with inner radius b , outer radius a and density ρ is:

$$V = -G \cdot 2\pi\rho(a^2 - b^2) \quad \text{for } 0 \leq r \leq b$$

$$V = -G \cdot 4\pi\rho \left(\frac{a^2}{2} - \frac{b^3}{3r} - \frac{r^2}{6} \right) \quad \text{for } b \leq r \leq a$$

$$V = -G \cdot \frac{4\pi}{3} \rho \left(\frac{a^3 - b^3}{r} \right) \quad \text{for } a \leq r$$

the potential of an infinitely long, thin, homogeneous rod if density ρ (= mass per unit length)

$$V = -2G\rho |\ln r|$$

where r is the perpendicular distance from the rod.

GRAVITATIONAL RADIUS. The gravitational radius of a mass m is the length Gm/c^2 (G is the gravitational constant, c , the velocity of light in vacuo). For the sun this is 1.47 km, for the earth 5 mm.

GRAVITATIONAL SYSTEM OF UNITS. See mechanical units.

GRAVITATION, NEWTONIAN. See Newton law of universal gravitation.

GRAVITY, CENTER OF. See center of gravity.

GRAVITY WAVE. (Also called gravitational wave.) A wave disturbance in which buoyancy (or *reduced gravity*) acts as the restoring force on parcels displaced from **hydrostatic equilibrium**. There is a direct oscillatory conversion between potential and kinetic energy in the wave motion. Pure gravity waves are stable for fluid systems which have **static stability**. This static stability may be (a) concentrated in an interface or (b) continuously distributed along the axis of gravity.

GRAY BODY (NON-SELECTIVE RADIATOR). A gray body or a non-selective radiator (over the visible region of the spectrum) is a radiator whose spectral emissivity is independent of wavelength within this region.

GRAY SCALE. A series of achromatic tones ranging from black to white. A gray scale may be divided into three or more steps but 10 is a common number of divisions. A gray scale is sometimes included with the subject when making a color photograph so that measurements of its densities on the separation negatives or tripack will give the density range of that stage in the reproduction. A gray scale is helpful in controlling the processing stages in the analysis and synthesis of a color photograph.

GREAT CIRCLE CHART. (GREAT CIRCLE SAILING, COMPOSITE SAILING.) The great circle chart, on the gnomonic projection, is of considerable value to navigators in planning long voyages by sea or by air. The earth is presumed to be a sphere. The projection is perspective in character and corresponds to the picture of the spherical earth that would be received on a plane tangent to the surface of the earth by rays of light from the center.

Any plane through the center of the earth intersects the surface in a great circle. The trace of this plane on the tangent plane is a straight line. On the chart meridians of longitude are straight lines but not parallel, while parallels of latitude are curved. The graticule of latitude and longitude is printed on the chart, together with outlines of the land masses. Some directions relative to the use of the chart are also printed.

A straight line between any two points on the chart is the great circle track between the two points. This is neither the shortest distance nor the geodesic distance, but the difference between the two is a very small percentage of the total.

Any two points 180° apart on the great circle have the same latitude numerically, but with different signs, unless the great circle is the equator. The two points of greatest latitude along the great circle are called vertices. On either side of a vertex the latitude decreases until the equator is reached 90° from the longitude of the vertex.

Great circle sailing is employed when a ship wishes to take advantage of the shortest distance, rather than to follow the rhumb line of constant course. Because of distortion, the rhumb line appears to be shorter than the great circle, on the Mercator chart.

Composite track. When the great circle track between two points passes into regions unsuited for navigation (e.g., the great circle from north-western ports of the United States to Japan passes north of the Aleutian Islands) a composite track is used as the shortest available track. First, a limiting parallel is selected as being the highest latitude that should be used. Then great circles are computed from the point of departure and the point of destination that are parallel to the limiting parallel. The ship leaves and follows the great circle to the point of tangency. Then she steers east or west along the limiting parallel until the point where the great circle from destination is tangent to the limiting parallel. The ship now leaves the limiting parallel and follows the great circle to destination.

The problems relative to great circle and composite sailing may be solved on the great-circle chart. However, various methods have been devised for arriving at the same result by computation, and the results are far more accurate. Various methods for solving great circle and composite tracks are found in treatises on navigation such as *U.S. Hydrographic Office Publication #9*.

GREEN'S FORMULA. See Green's theorem.

GREEN'S FORMULA, FOUR DIMENSIONAL. See Minkowski world.

GREEN'S FUNCTION. A function $K(x, \xi)$ associated with a given boundary value prob-

lem $L[y] = \phi(x)$ that has the property that the solution is expressible in the form

$$y(x) = \int K(x, \xi) \phi(\xi) d\xi,$$

the integration extending over the interval on which the solution is to be defined. As an example, if $L[y] \equiv y''$, and the boundary conditions are $y(0) = y(1) = 0$, then

$$K(x, \xi) = \begin{cases} (1 - \xi)x & \text{for } x \leq \xi, \\ (1 - x)\xi & \text{for } x > \xi. \end{cases}$$

The limits of integration are then from 0 to 1. The notion can be generalized to spaces of higher dimensionality. For theoretical investigations the function is of fundamental importance, but for numerical computation it is seldom used.

GREEN'S IDENTITY. A class of integral identities useful in the study of **linear partial differential equations**. In particular, for a linear partial differential equation of the second order

$$L\phi = a\phi_{xx} + 2b\phi_{xy} + c\phi_{yy} + 2d\phi_x + 2e\phi_y + f\phi = g \quad (1)$$

where a, b, c, d, e, f, g are known functions of x and y , and (1) is a **hyperbolic equation** (i.e., such that $ac - b^2 < 0$), Green's identity is given by

$$\iint_R (\psi L\phi - \phi \bar{L}\psi) dx dy = \int_C \left[\sigma \left(\psi \frac{\partial \phi}{\partial x} - \phi \frac{\partial \psi}{\partial x} \right) + B\phi\psi \right] ds \quad (2)$$

where the adjoint operator \bar{L} is defined by

$$\bar{L}\psi = (a\psi)_{xx} + (2b\psi)_{xy} + (c\psi)_{yy} - (2d\psi)_x - (2e\psi)_y + f\psi, \quad (3)$$

R is a region with boundary curve C for which the exterior normal has direction cosines

$$\xi, \eta; \sigma = \sqrt{(a\xi + b\eta)^2 + (b\xi + c\eta)^2};$$

$$B = (2d - a_x - b_y)\xi + (2e - b_x - c_y)\eta;$$

and $\partial/\partial\nu$ is the directional derivative in the binormal direction, which is the direction with direction cosines

$$\xi' = \frac{a\xi + b\eta}{\sigma}, \quad \eta' = \frac{b\xi + c\eta}{\sigma},$$

i.e.,

$$\frac{\partial}{\partial v} = \xi' \frac{\partial}{\partial x} + \eta' \frac{\partial}{\partial y}.$$

This identity is useful in the **Riemann method** of solving the **Cauchy problem**.

GREEN'S THEOREM. Any one of several theorems relating an integral over a domain in n dimensions to an integral over a domain in $(n - 1)$ dimensions. In its most usual form it reads

$$\int_C \{P(x,y)dx + Q(x,y)dy\} = \int_A \left\{ \frac{\partial Q(x,y)}{\partial x} - \frac{\partial P(x,y)}{\partial y} \right\} dA,$$

where $P(x,y)$ and $Q(x,y)$ have continuous first partial derivatives in the domain A .

Green theorems for more than two dimensions are closely related to various theorems called by other names, e.g., Gauss theorem. For example, if u, v are scalar functions, S indicates a double and τ a triple integral, the Gauss theorem in vector form is

$$\int_{\tau} \nabla u \cdot \nabla v d\tau + \int_{\tau} u \nabla^2 v d\tau = \int_S u \nabla v \cdot dS,$$

and on exchanging u and v and subtracting the result from this equation, the Green theorem results

$$\int_{\tau} (u \nabla^2 v - v \nabla^2 u) d\tau = \int_S (u \nabla v - v \nabla u) \cdot dS.$$

In one dimension, the Green theorem runs

$$\int_a^b [vL(u) - u\bar{L}(v)] dx = [P(u,v)]_a^b$$

where \bar{L} is the operator adjoint to L (see **adjoint of an operator**) which in unintegrated form is also called *Lagrange's identity*. In general, Green theorems are equivalent to integration by parts.

GREGORY FORMULA (GREGORY-NEWTON FORMULA). A formula for numerical evaluation of an integral. It is obtained from the **Newton formula for interpolation** and may be written

$$\begin{aligned} \int_{x_0}^{x_r} f(x) dx &= h \left(\frac{1}{2} f_0 + f_1 + f_2 + \cdots + \frac{1}{2} f_r \right) \\ &- (\Delta f_{r-1} - \Delta f_0) / 12 - (\Delta^2 f_{r-2} + \Delta^2 f_0) / 24 \\ &- 19(\Delta^3 f_{r-3} - \Delta^3 f_0) / 720 \\ &- 3(\Delta^4 f_{r-4} + \Delta^4 f_0) / 160 + \cdots \end{aligned}$$

where h is the interval between equally-spaced values of the independent variable x and the quantities $\Delta^m f_k$ are **finite differences**.

GRID, AS MEANS OF GENERATING TURBULENCE. In many of the experiments that have been made on turbulence, a square-mesh grid of bars has been used in a wind tunnel to generate the turbulence. Until recently it was thought that the turbulence produced in this way, at a distance from the grid greater than about 20 mesh lengths, was very nearly homogeneous and isotropic. It has been shown recently, however, that there is a lack of isotropy in the large scale components of the turbulence and that even at large distances from the grid the variation of intensity across the stream is of order $\pm 10\%$.

GROSS CALORIFIC VALUE. See **combustion**.

GROSS SECTION. When a prismatic member contains holes or transverse slots or notches in a limited region, the cross-sectional area of the prism is called the gross area or gross section. A cross-sectional area from which material has been removed is called a *net area* or *net section*.

GROUND EFFECT (ON AIRPLANE). When an airplane is flying near the ground the air flow is modified by the presence of the ground. The effect may be calculated by considering the effect on the flow of an inverted image of the airplane below the ground, so that the condition of zero vertical velocity component at the ground is satisfied. Since the most important effects are caused by the trailing vortices of the image airplane, it is usually sufficiently accurate to represent the image airplane by a simple horse-shoe vortex, i.e., a uniformly loaded lifting line with trailing vortices springing from the tips.

The trailing vortices of the image airplane induce an upwash at the real airplane. This leads to a reduction of drag and incidence for a given value of the lift coefficient. An effect that is more important in practice is the reduction of downwash angle at the tail, which means that the upward elevator deflection required to maintain equilibrium at a given lift coefficient is increased.

GROUND FORMS OF A SURFACE. u^α ($\alpha = 1, 2$) are curvilinear coordinates on a

surface. The indicial notation and summation convention are used, repeated Greek indices denoting summation over the values 1, 2. \mathbf{r} denotes the vector from an origin to the point u^α on the surface; \mathbf{n} denotes the **unit normal** to the surface at that point.

First ground form: The quadratic differential form $a_{\alpha\beta}du^\alpha du^\beta$, where $a_{\alpha\beta}$ is the covariant **metric tensor** for the surface, or more loosely the metric tensor for the surface, defined by

$$a_{\alpha\beta} = \frac{\partial \mathbf{r}}{\partial u^\alpha} \cdot \frac{\partial \mathbf{r}}{\partial u^\beta}.$$

$a^{\alpha\beta}du^\alpha du^\beta$ is the square of the length of a linear element on the surface joining the points u^α and $u^\alpha + du^\alpha$. It is also called the *first fundamental form for the surface*. The quantities $a_{\alpha\beta}$ are also called the *fundamental magnitudes of the first order for the surface*. The contravariant **metric tensor** for the surface $a^{\alpha\beta}$ is defined by $a^{\alpha\beta}a_{\beta\gamma} = \delta_\gamma^\alpha$, where δ_γ^α is the **Kronecker delta**.

Second ground form: The quadratic differential form $b_{\alpha\beta}du^\alpha du^\beta$, where $b_{\alpha\beta}$ is defined by

$$b_{\alpha\beta} = -\frac{1}{2} \left(\frac{\partial \mathbf{n}}{\partial u^\alpha} \cdot \frac{\partial \mathbf{r}}{\partial u^\beta} + \frac{\partial \mathbf{n}}{\partial u^\beta} \cdot \frac{\partial \mathbf{r}}{\partial u^\alpha} \right),$$

and \mathbf{n} is the **unit normal** to the surface. Also called *second fundamental form for the surface*. The quantities $b_{\alpha\beta}$ are the *fundamental magnitudes of the second order for the surface*.

Third ground form: The quadratic differential form $c_{\alpha\beta}du^\alpha du^\beta$, where $c_{\alpha\beta}$ is defined by

$$c_{\alpha\beta} = a^{\sigma\tau} b_{\sigma\alpha} b_{\tau\beta}.$$

Also called *third fundamental form for the surface*.

GROUND STATE. The lowest energy state of a stationary quantum mechanical system, particularly of a nucleus.

GROUP. A set of elements, finite or infinite in number, satisfying the following conditions: (1) There is a defined operation by which to each ordered pair of elements A and B in the group \mathbf{G} there is associated an element C of \mathbf{G} , denoted by $C = AB$, and called the **product** of A and B . (2) For this operation the **associative** law holds: $(AB)C = A(BC) = ABC$ for any three elements A, B, C of \mathbf{G} . There exists: (3) a unit element E in \mathbf{G} such that $EA = A$ for every element A of \mathbf{G} , and (4) to

each element A of \mathbf{G} a **reciprocal** (or inverse) element A^{-1} of \mathbf{G} such that $A^{-1}A = E$.

It must be understood that product, as defined in (1), is a convenient word to use for the result of combining two or more elements in a group but the law of combination is not confined to multiplication. For example, let the group elements be the integers $0, \pm 1, \pm 2, \dots$ and let the combination law be addition, then the product of any two elements is their algebraic sum. These integers, regarded as elements of a group, will be seen to satisfy the requirements (1)–(4).

A finite group containing n elements is of order n . If $m \leq n$ elements satisfy the requirements of (1)–(4), they form a subgroup. Every group contains at least two subgroups: the unit element and the group itself.

If X is an element of a group \mathbf{G} and \mathbf{H} is a subgroup of \mathbf{G} , then the set of elements \mathbf{HX} consisting of all products HX with H in \mathbf{H} is called a right coset and $X\mathbf{H}$ is a left coset. In general, cosets are not groups because they do not contain E , the unit element. If A, B, X are three elements of a group, then $B = X^{-1}AX$ is the **transform** of A by X and A, B are conjugate to each other. The complete set of group elements conjugate among themselves is called a *conjugate class*, or merely a *class*, of the group.

If \mathbf{H} is a subgroup of the group \mathbf{G} and X is an element of \mathbf{G} , not necessarily contained in \mathbf{H} , then $X^{-1}\mathbf{H}X$ is also a subgroup of \mathbf{G} and is said to be conjugate to \mathbf{H} . A subgroup \mathbf{H} which is identical with every one of its conjugate subgroups is said to be *invariant*, or to be a *normal subgroup* or *normal divisor* of \mathbf{G} .

Suppose \mathbf{H} is an invariant subgroup of a group \mathbf{G} and that $\mathbf{HX}, \mathbf{HY}, \dots$ are its cosets. If the product of \mathbf{HX} and \mathbf{HY} is defined as the coset containing the product XY , then the set of cosets of \mathbf{H} is itself a group, called a *quotient* or *factor group* and denoted by \mathbf{G}/\mathbf{H} . For particular groups, permutation, symmetric, etc., see under the respective names. (For groups of linear, full linear, unitary transformations, etc., see under **Lie group**.)

GROUP, ALTERNATING. See **alternating group**.

GROUP DIFFUSION METHOD. See **neutron diffusion theory, multi-group**.

GROUP, LIE. See **Lie group**.

GROUP, NEUTRON. In neutron transport theory, the collection of all neutrons in a system whose energies lie within a specified band.

GROUP OF RESTRICTED HOMOGENEOUS LORENTZ TRANSFORMATIONS.

That subgroup of the **homogeneous Lorentz group** for which $\det \Lambda = +1$ and $\Lambda_0^0 \geq 1$. The following are some important facts about the restricted homogeneous Lorentz group: The group has both finite and infinite dimensional irreducible representations. However, the only *finite* dimensional irreducible representation is the one-dimensional trivial representation $\Lambda \rightarrow 1$. There exist a denumerable infinity of non-equivalent finite dimensional irreducible representations of the restricted homogeneous Lorentz group. (In general, these are non-unitary representations.) These finite dimensional irreducible representations can be labeled and characterized by two non-negative indices n, m , where $n, m = 0, \frac{1}{2}, 1, \frac{3}{2}, \dots$. The representation $\mathbf{D}(n, m)$ has the dimension $(2n + 1)(2m + 1)$; it is single valued if $n + m$ is integral and double valued otherwise. The basis vectors in the vector spaces, $V^{(n, m)}$ and $V^{(m, n)}$, on which the representations $\mathbf{D}(n, m)$ and $\mathbf{D}(m, n)$, respectively, act can be so chosen that the representation matrices for $\mathbf{D}(n, m)$ are the complex conjugates of those for $\mathbf{D}(m, n)$. A quantity which transforms under $\mathbf{D}(0, 0)$ is a scalar, one which transforms under $\mathbf{D}(\frac{1}{2}, \frac{1}{2})$ a 4-component vector, one which transforms under $\mathbf{D}(\frac{1}{2}, 0)$ a spinor, one which transforms under $\mathbf{D}(0, \frac{1}{2})$ a conjugate spinor, etc.

GROUP RELAXATION. A variant of the total-step iteration for solving a linear system (see **matrix inversion**) in which at each step two or more equations are satisfied simultaneously. Same as **block relaxation**.

GROUPS, TRANSFORMATION. See **transformation groups**.

GROUP VELOCITY. The velocity C of propagation of a group of waves formed by the superposition of wave trains of adjacent wavelength. If c is the phase velocity and C the group velocity,

$$C = c - \lambda \frac{\partial c}{\partial \lambda}$$

where λ is the wavelength. $C = c$ in a non-dispersive medium.

C is the velocity with which the wave energy is propagated. If a disturbance of finite duration is propagated and is dispersed into a series of waves, that part of the disturbance in which the oscillations are of wavelength λ travels with the corresponding group velocity, while the individual crests travel with their phase velocity, changing their length as they travel, and advancing or moving backwards relative to the disturbance (the group) according as $\frac{\partial c}{\partial \lambda} \geq 0$. In the former case the wave amplitude dies away as the waves approach the front of the group and new crests appear at the rear.

GROWTH CURVE. (1) A curve showing the general pattern of growth of a variable. (2) An **activity curve** in which the activity increases with time, or that portion of an activity curve showing such an increase. (3) A theoretical or experimental curve showing, as a function of time, the number of atoms, or the mass, or the activity of a nuclide being produced in a **radioactive transformation** or in an **induced nuclear reaction**.

GRÜNEISEN CONSTANT (OR GRÜNEISEN GAMMA). The constant γ occurring in the relation connecting the linear expansion coefficient β with the compressibility K and the specific heat C_V , i.e.,

$$\beta = K\gamma C_V / 3V$$

where V is the volume. This relation is reasonably well satisfied for cubic crystals. According to the theory by which it is deduced,

$$\gamma = - \frac{V d\Theta}{\Theta dV},$$

where Θ is the **Debye temperature**. (See **Mie-Grüneisen equation of state**.)

GRÜNEISEN FORMULA. An empirical formula for the variation of the **electrical resistivity** of a very pure metal with temperature, of the form

$$\rho \propto TG(\Theta/T)$$

where

$$G(x) = x^{-4} \int_0^x \frac{s^2 ds}{(e^s - 1)(1 - e^{-s})}.$$

There is good theoretical justification for a formula of this type, but the parameter Θ

should not be taken literally as a measure of the Debye temperature.

g-SUM RULE. (Pauli's g-sum rule.) In a weak magnetic field, for the group of atomic states arising from a given **electron configuration**, the sum of the Landé g-factors for all levels with the same value of J , the quantum number of resultant total electronic angular momentum, is a constant independent of the **coupling** conditions. In a stronger magnetic field where J is no longer defined, the rule applies to the levels with a given M , the quantum number of the component in the field direction of the resultant total electronic angular momentum.

In a field of intermediate strength M is to be taken as $M_S + M_L$, the sum of the quantum numbers of the components in the field direction of the resultant spin and resultant orbital angular momentum of the electrons. In a very strong field M stands for $\sum_i (m_{l_i} + m_{s_i})$, the sum of the quantum numbers of the components in the field direction of the spins and angular momenta of the individual electrons.

GUEST YIELD CONDITION. A linear version of the Mohr criterion:

$$\sigma_1 - \sigma_3 = c_1 + c_2(\sigma_1 + \sigma_3), \quad \sigma_1 \geq \sigma_2 \leq \sigma_3$$

where σ_1 , σ_2 and σ_3 are principal stresses.

GUIDED WAVE. A wave whose energy is concentrated near a boundary, or between substantially parallel boundaries, separating materials of different properties, and whose **direction of propagation** is effectively parallel to these boundaries.

GUIDING CENTER. The motion of a charged particle in a slowly varying (both spatially and temporally) electromagnetic field can be approximated by a rapid gyration around a moving point. This point is called the guiding center of the particle. This approximation is termed the guiding center theory.

GUIDING CENTER DRIFTS. In the **guiding center** approximation, the motion of the guiding center is described in terms of a drift velocity. An electric field \mathbf{E} produces a zeroth order drift velocity \mathbf{v} given by

$$\mathbf{v} = c\mathbf{E} \times \mathbf{B}/B^2,$$

where \mathbf{B} is the magnetic field and c is the velocity of light.

GULDBERG AND WAAGE LAW. See law of mass action.

GYROMAGNETIC RATIO. The ratio of the magnetic moment to the mechanical angular momentum of a system. In spectroscopy, as a rule, denoted by g and given in units $e/2mc$ (Bohr magneton divided by $h/2\pi$) or denoted by g_I and given in units $e/2m_p c$ (nuclear magneton divided by $h/2\pi$).

I. *Gyromagnetic ratio, electronic*

(a) Orbital motion of an electric point charge. An electron traveling around a circular orbit of radius r f times per second has a mechanical angular momentum of magnitude

$$p = 2\pi f m r^2$$

and generates a magnetic moment of magnitude

$$\mu = e f \pi r^2 / c = \frac{e}{2mc} p$$

(e and m are electronic charge and mass, c is velocity of light). The classical gyromagnetic ratio of an electron moving in an orbit is therefore

$$\mu/p = e/2mc \quad \text{or} \quad g = 1.$$

In an atom, for an orbital angular momentum \mathbf{L} of magnitude

$$p_L = \sqrt{L(L+1)} \frac{h}{2\pi}$$

the magnetic moment has the magnitude

$$\mu_L = \frac{e}{2mc} \frac{h}{2\pi} \sqrt{L(L+1)} = \mu_o \sqrt{L(L+1)}$$

(μ_o , Bohr magneton). The gyromagnetic ratio is, therefore as above,

$$\mu_o/p = \frac{e}{2mc} \quad \text{or} \quad g_o = 1.$$

(b) Electron spin. The magnetic moment associated with the intrinsic electronic angular momentum (spin) \mathbf{s} , of magnitude

$$p_s = \sqrt{s(s+1)} h/2\pi \quad (s = \frac{1}{2})$$

is given by

$$\mu_s = \sqrt{s(s+1)} \frac{e}{mc} \frac{h}{2\pi}.$$

The gyromagnetic ratio of the spinning electron is therefore

$$\mu_s/p_s = 2 \times \frac{e}{2mc} \quad \text{or} \quad g_s = 2.$$

(Actually, on account of the quantum electro-dynamical electron moment correction

$$g_s = 2 \times \left[1 + \frac{\alpha}{2\pi} - 2.973 \frac{\alpha^2}{\pi^2} \right] \\ = 2 \times 1.00114536.)$$

(c) Orbital motion of spinning electron. See **Landé g-factor**.

II. Magnetic ratio, nuclear

The magnetic moment associated with the intrinsic nuclear angular momentum (spin) \mathbf{I} , of magnitude

$$p_I = \sqrt{I(I+1)} h/2\pi$$

is given by

$$\mu_I = \frac{e}{2m_p c} \frac{h}{2\pi} \sqrt{I(I+1)}.$$

Here m_p is the mass of the proton and g_I the nuclear g-factor.

The nuclear gyromagnetic ratio depends in a complicated way on the structure of the nucleus concerned, and cannot be expressed by a simple formula.

For the proton the g-factor is

$$g_I = 5.5853 \quad (I = \frac{1}{2}).$$

(For further data on nuclear g-factors see H. Kopfermann, *Nuclear Moments*, Academic Press, Inc., New York, 1958.)

GYROSCOPE. A gyroscope is a rotating object with a very high angular momentum about a principal axis through its center of gravity. The spin does not diminish rapidly

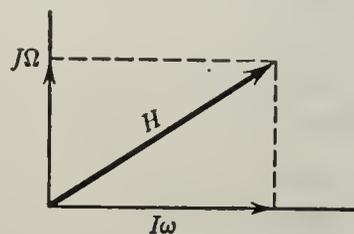

with time. When suspended freely, the moment about the center of gravity is zero and the spin axis remains fixed in space. The change in total angular momentum is then very closely the change in the spin momentum. It is denoted by:

$$\mathbf{M} = I\boldsymbol{\omega}$$

where \mathbf{M} is the angular momentum due to rotation, I is the moment of inertia and $\boldsymbol{\omega}$ is the spin. ($I = \frac{mk^2}{g}$, where m is the mass of the rotating element, g is the acceleration of gravity, and k is the radius of gyration.) Similarly, a gyroscope also has a precession momentum given by:

$$\mathbf{N} = J\boldsymbol{\Omega}$$

where \mathbf{N} is the precession momentum, J is moment of inertia of the gyroscope about the precession axis, and $\boldsymbol{\Omega}$ is the precession. The

vector sum of \mathbf{M} and \mathbf{N} is the total angular momentum, \mathbf{H} . That is,

$$\mathbf{H} = \mathbf{M} + \mathbf{N} = I\boldsymbol{\omega} + J\boldsymbol{\Omega}.$$

The time rate of change of the vector \mathbf{H} , ($d\mathbf{H}/dt$), is defined as the torque. Thus,

$$d\mathbf{H}/dt = \boldsymbol{\Omega} \times \mathbf{H}$$

$$\boldsymbol{\Omega} \times \mathbf{H} = \boldsymbol{\Omega} \times I\boldsymbol{\omega} + \boldsymbol{\Omega} \times J\boldsymbol{\Omega}$$

$$\boldsymbol{\Omega} \times \mathbf{H} = d\mathbf{H}/dt = \boldsymbol{\Omega} \times I\boldsymbol{\omega} \quad (\text{since } \boldsymbol{\Omega} \times J \rightarrow 0)$$

$$\mathbf{T} = \boldsymbol{\Omega} \times I\boldsymbol{\omega}.$$

H

HAAG'S THEOREM. The statement that any **relativistic quantum field theory** which has the following four properties: (a) relativistic transformation properties, (b) a unique, normalizable invariant vacuum state Ψ_0 and no negative energy states or states of space-like momenta, (c) canonical commutation rules at equal times, and (d) relation to the free field theory at a given time by a unitary transformation, is completely equivalent to a free non-interacting field theory.

HALF-LIFE. The half-life of a substance is the time required for one-half of it to undergo a disintegration or, in some cases, a reaction process. Thus, the half-life of a radioactive substance is the time required for disintegration of one-half the atoms of a sample of it. The relation of the half-life to the **disintegration constant** and the **mean life** is as follows:

$$t_{1/2} = \frac{\ln 2}{\lambda} = \frac{0.693}{\lambda} = 0.693\tau$$

where $t_{1/2}$ is the half-life, λ is the disintegration constant and τ is the mean life.

Again, the half-life of a free radical is the time required for one-half of those of a single kind present in the substance or system to undergo transformation. The biological half-life of a substance is the time in which a living tissue, organ or individual eliminates, through biological processes, one-half of a given amount of a substance which has been introduced into it. The effective half-life is a term usually applied to a radioactive substance in a biological organism. It is defined in terms of the half-life of the radioactive substance itself, and its biological half-life in the organism, by the following expression:

Effective half-life

$$= \frac{\text{Radioactive half-life} \times \text{Biological half-life}}{\text{Radioactive half-life} + \text{Biological half-life}}$$

HALF-PERIOD ELEMENT. The portion of a wave front contained between any two con-

centric spheres so that the difference of their radii equals one half wavelength. It is also called a *Fresnel zone* or a *Huygens' zone* of the **wave front**.

HALF-POWER WIDTH OF A RADIATION-LOBE. In a plane containing the direction of the maximum of the lobe, the full angle between the two directions in that plane about the maximum in which the radiation intensity is one-half the maximum value of the lobe.

HALF-SPACE PROBLEM. See **problem of Boussinesq and Cerruti**.

HALF-THICKNESS. The thickness of a particular absorber that will reduce the intensity of a beam of radiation to one-half its initial value. If the absorption is exponential, the half-thickness is related to the linear or mass **absorption coefficient** and the mean free path as follows:

$$d_{1/2} = \frac{\ln 2}{\mu} = \frac{0.693}{\mu} = 0.693l$$

where $d_{1/2}$ is the half-thickness, μ is the absorption coefficient and l is the mean free path.

HALF-WIDTH. If $y = f(x)$ is a function such that it has a maximum y_m at x_m and falls off rapidly on each side of this maximum, the half-width of the function is the difference $x_2 - x_1$ between the two values of x for which $y = y_m/2$; e.g., the half-width of the **error function** integrand e^{-y^2} is 1.67.

HALF-WIDTH OF A SPECTRAL LINE. A measure for the range in wavelength, or in units related to the wavelength, over which a spectral line has a measurable intensity. The definition of the term is essentially a matter of convenience for the purpose in hand. The term therefore occurs in the literature with several different denotations. For emission lines it may refer to (a) the distance from the center of the line to the point where the intensity has fallen to $1/2$ times its maximum value (also called "half-intensity-width"), or (b) the distance from the center of the line to the

point where the intensity has fallen to $1/e$ times its maximum value. For absorption lines it refers to the distance from the center of the line to the point where the **absorption coefficient** has fallen to $1/2$ times its maximum value. Twice the half-width is called "whole half-width," or simply "width" or "breadth" of the spectral line. For the limiting case of pure thermal broadening the half-width $\Delta\lambda$ for emission lines according to definition (a) and for absorption lines is given by

$$\Delta\lambda = \sqrt{\ln 2} (\Delta\lambda)_D$$

and for emission lines according to definition (b) by

$$\Delta\lambda = (\Delta\lambda)_D$$

where $(\Delta\lambda)_D$ is the **Doppler half-width** of the spectral line. For the limiting case of negligible thermal broadening the corresponding values are

$$\Delta\lambda = \frac{\gamma}{4\pi c} \lambda^2$$

and

$$\Delta\lambda = \frac{\gamma}{2\pi c} \lambda^2$$

where γ is a parameter depending on the gas pressure, and, in the presence of an external electric or magnetic field, the field strength.

The expression $\frac{\gamma}{2\pi c} \lambda^2$ sometimes is referred to as one half the "natural line width." However the latter term is more commonly used in the restricted sense given under the heading **natural line width**.

HALF-WIDTH OF RESONANT PEAK. See resonance, sharpness of.

HALL ANGLE. The ratio of the electric field E_y , developed across the current, to the field E_x , generating the current, in the magnetic field H_z , as a result of the Hall effect. (See **galvanometric and thermometric effects**.)

HALL COEFFICIENT (HALL EFFECT). See galvanometric and thermometric effects.

HALL MOBILITY. The mobility of electrons or holes in a semiconductor as measured by the Hall effect. (See **galvanometric and thermometric effects**.) It is given by

$$\mu_H = c\theta/H_z$$

where θ is the **Hall angle** in the magnetic field H_z , and c is the velocity of light.

HAMILTON-CAYLEY THEOREM. Every matrix satisfies its own characteristic equation.

HAMILTON CHARACTERISTIC. If $P(x,y,z)$ is a point in object space, and $P'(x',y',z')$ is a point in image space, then the optical path length $V(x,y,z,x',y',z')$ of the ray joining P and P' is the **characteristic function** of Hamilton, or the **cikonal** of Bruns, of an optical system. If n and n' are the refractive indices of object and image spaces then

$$\frac{\partial V}{\partial x} = p, \quad \frac{\partial V}{\partial y} = q, \quad \frac{\partial V}{\partial z} = r,$$

$$\frac{\partial V}{\partial x'} = -p', \quad \frac{\partial V}{\partial y'} = -q', \quad \frac{\partial V}{\partial z'} = -r',$$

where (p,q,r) and (p',q',r') are the optical direction cosines of the ray at the object and image points, respectively; thus V satisfies

$$\left(\frac{\partial V}{\partial x}\right)^2 + \left(\frac{\partial V}{\partial y}\right)^2 + \left(\frac{\partial V}{\partial z}\right)^2 = n^2,$$

$$\left(\frac{\partial V}{\partial x'}\right)^2 + \left(\frac{\partial V}{\partial y'}\right)^2 + \left(\frac{\partial V}{\partial z'}\right)^2 = (n')^2.$$

Any solution of this system of equations is a characteristic function. To distinguish V it is referred to as the *point characteristic*. Other commonly occurring characteristics are called the mixed characteristic, the angle characteristic, and the wave front characteristic.

A characteristic function forms the basis of the direct method in geometrical optics; all properties of the system can be derived from the characteristic. (See **Hamilton theorem**.)

HAMILTONIAN (HAMILTONIAN FUNCTION OF A SYSTEM). Generally denoted by the symbol H . It is defined by the equation

$$H(q_k, p_k, t) = -L(q_k, p_k, t) + \sum_{l=1}^{3n} p_l \dot{q}_l(q_k, p_k, t).$$

L is the **Lagrangian function** of the system, expressed as a function of the coordinates, momenta and time. \dot{q}_l stands for the generalized velocities, also expressed as functions of the coordinates, momenta and time, where q are the coordinates of position, p , those of momentum, and the dot means the derivative

with respect to time. n is the number of particles of the system. If the time does not occur explicitly, the system is called conservative and H is identical with the total energy of the system.

HAMILTONIAN DENSITY. See continuous systems, Lagrangian and Hamiltonian formalism for.

HAMILTONIAN FORMALISM FOR CONTINUOUS SYSTEMS. See continuous systems, Lagrangian and Hamiltonian formalism for.

HAMILTONIAN FUNCTION OF OPTICS. If the unit tangent vector of an optical path in a medium with refractive index $n = n(x, y, z)$ is $(\cos \alpha, \cos \beta, \cos \gamma)$ then the Hamiltonian function is

$$H(x, y, p, q) = -\sqrt{n^2 - p^2 - q^2} = -n \cos \gamma$$

where $p = n \cos \alpha$, $q = n \cos \beta$ are optical direction cosines. This leads to the canonical form of **Fermat's principle**: the optical paths are the curves $x = x(z)$, $y = y(z)$ for which

$$V = \int_{z_0}^{z_1} \left(p \frac{dx}{dz} + q \frac{dy}{dz} - H \right) dz$$

has an extreme value. (See **Hamilton theorem**.)

HAMILTONIAN OPERATOR. In quantum mechanics, an operator associated with the **Hamiltonian (Hamiltonian function of a system)** of classical physics. For a single particle the classical Hamiltonian function in rectangular Cartesian coordinates is given by

$$H = \frac{p_x^2 + p_y^2 + p_z^2}{2m} + V(x, y, z)$$

where p_x is the x -component of the momentum, etc., m is the mass and $V(x, y, z)$ is the potential energy of the particle. By the rules of Schrödinger wave mechanics for associating operators with dynamical variables (see **operators, quantum mechanical; momentum operator; and position operator**) the Hamiltonian operator in the Schrödinger representation becomes

$$H = -\frac{\hbar^2}{2m} \nabla^2 + V(x, y, z),$$

where ∇^2 is the Laplacian. Since the operator associated with the total energy of a system is $i\hbar \frac{\partial}{\partial t}$ one obtains, as the analogue to the equation $H = E$ in classical physics, the time-dependent Schrödinger equation (for one particle)

$$H\psi \equiv -\frac{\hbar^2}{2m} \nabla^2 \psi + V(x, y, z)\psi = i\hbar \frac{\partial \psi}{\partial t}.$$

HAMILTON-JACOBI PARTIAL DIFFERENTIAL EQUATION. A first order partial differential equation for the **action function**

$$S \left(q_k, \frac{dq_k}{dt}, t \right),$$

where q_k and $\frac{dq_k}{dt}$ are the generalized coordinates

and velocities of the system. The differential equation is

$$\frac{\partial S}{\partial t} + H \left(q_k, \frac{\partial S}{\partial q_k}, t \right) = 0.$$

H is the **Hamiltonian (Hamiltonian function of a system)** of the system, in which the momenta p_k are replaced by the expressions $\frac{\partial S}{\partial q_k}$.

HAMILTON PRINCIPLE. See **action principle**.

HAMILTON THEOREM. If V is the point characteristic of an optical system, i.e., V is the **optical path length** from an object to its Gaussian image point, if \mathbf{a} , \mathbf{a}' are position vectors of object and image points, and if \mathbf{s} , \mathbf{s}' are tangent vectors of length, n , n' of the object and image rays, then

$$\mathbf{s}' \frac{d\mathbf{a}'}{du} - \mathbf{s} \frac{d\mathbf{a}}{du} = \frac{dV}{du}$$

for any differentiable one-dimensional manifold of rays, with parameter u .

H AND D CURVE. See **exposure-density relationship**.

HANKEL FUNCTION. See **Bessel functions of the third kind**.

HANKEL TRANSFORM. Provided certain conditions are satisfied, $f(y)$ is the Hankel transform of $F(x)$ of order n if

$$f(y) = \int_0^{\infty} J_n(xy)F(x)xdx,$$

$$F(x) = \int_0^{\infty} J_n(xy)f(y)ydy,$$

where J_n is a Bessel function. (See also **integral transform**.)

HARDNESS (INDENTATION AND REBOUND). A measure of yield strength and work hardening which serves to identify, to control and to select materials and their treatment.

Brinell. The indenter is a 10-mm. diameter hardened steel ball. A sintered tungsten-carbide ball is also coming into use, especially for testing hard metals. The load applied is generally 500 kg. for soft metals and 3000 kg. for steels and hard metals. The Brinell hardness number is defined by the relation

$$\begin{aligned} BHN &= \frac{W}{\text{Area of indentation}} \\ &= \frac{2W}{\pi D[D - (D^2 - d^2)^{1/2}]} \end{aligned}$$

where W is the load, D is the diameter of the indenter, and d is the mean chordal diameter of the indentation. Tables are available for direct conversion to hardness from the diameter of the indentation as measured with a calibrated magnifier after removal of the piece from the testing machine.

Rockwell. Indenter is $\frac{1}{16}$ "-, $\frac{1}{8}$ "-, or $\frac{1}{4}$ "-diameter steel ball or a conical diamond having an apex angle of 120° and a slightly rounded point. The various scales used are designated by letters. Rockwell "B," for example, indicates a 100-kg load on a $\frac{1}{16}$ "-diameter ball. Rockwell "C" indicates a 150-kg load on the diamond indenter. Rockwell "30T" designates a load of 30 kg on a $\frac{1}{16}$ "-diameter ball. (An instrument of higher sensitivity known as the Rockwell Superficial Tester is used for loads of 15, 30, and 45 kg.) The size of the indentation is measured by a dial gauge as the final depth minus a small preliminary penetration produced by a minor preload of 10 kg. The Rockwell hardness values are arbitrary numbers having an inverse relationship to the depth of the indentation.

Vickers. Also known as Diamond Pyramid

Hardness. Indenter is a square-based diamond pyramid with included angle between faces of 136° . Loads may vary from 1 to 120 kg with 10, 30, and 50 kg in common use. Hardness is equal to load (kg) divided by surface area (sq mm) of the permanent indentation. It is determined directly from optical measurements of the diagonals of the indentation which appears square at the surface of the metal.

Tukon. A specially developed instrument for determining hardness under very light loads down to 25 grams. The small indentations are measured at high magnifications up to 1000 times. The indenter is a diamond pyramid that makes an elongated impression, one diagonal being 7 times the other in length.

Eberbach. Also used for very light loads. It consists of a spring-loaded, Vickers-type diamond pyramid indenter arranged for use on a metallurgical microscope.

Scleroscope. Values depend on the height of rebound of a diamond-tipped body falling under the force of gravity from a fixed height. The instrument is relatively small and is portable. One type reads directly on a graduated dial.

HARD SPHERE GAS. See **rigid sphere model**.

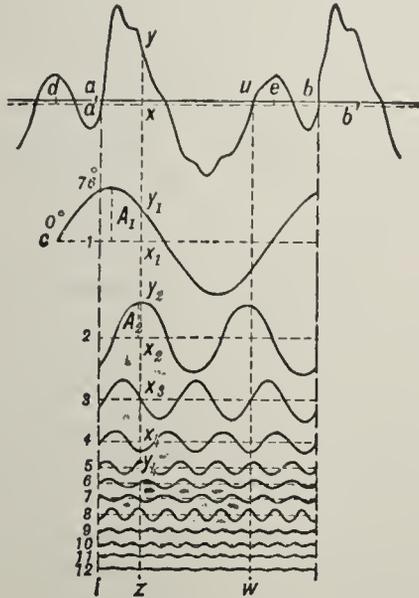

HARD SPHERE MODEL. See **rigid sphere model**.

HARMONIC ANALYSIS. Not only is it possible to combine two or more simple **harmonic motions** of different period, amplitude, and phase to form a complex motion, but there are also means of analyzing the resultant motion, when the latter is given, to find its component harmonics. Fourier showed that the analysis is possible for any periodic motion, however complicated. The equation, called the **Fourier series**, may be written

$$y = a \sin 2\pi nt + b \cos 2\pi nt + c \sin 4\pi nt + d \cos 4\pi nt + e \sin 6\pi nt + f \cos 6\pi nt + \dots,$$

in which y is the displacement of the vibrating particle and t is the time. The fundamental frequency n and the constants $a, b, c, d, \text{etc.}$, must be calculated from the given wave form or the data from which it is plotted. There is a type of instrument, called a "harmonic analyzer," which automatically computes the coefficients; or it may be done

mathematically, though the process is laborious and much aided by digital computer techniques. The accompanying figure shows the wave form and the twelve components of a complex tone.

Records of a complex sound and 12 of its components (after D. C. Miller).

HARMONIC FUNCTION. A function is harmonic within a given domain if it and its first derivative are continuous functions there and if it satisfies Laplace's equation. The most familiar ones are solid spherical harmonics which are homogeneous in the variables x, y, z . They must therefore also satisfy the equation of the Euler theorem for homogeneous functions. A spherical surface harmonic is the special set taken on the surface of a unit sphere and usually given in spherical polar coordinates. The angular dependent parts can be taken as

$$Y(\theta, \phi) = \begin{pmatrix} \cos m\phi \\ \sin m\phi \end{pmatrix} P_n^m(\cos \theta),$$

where P_n^m is the associated Legendre polynomial.

HARMONIC MEAN. Given the N positive numbers $x_1, x_2, x_3, \dots, x_N$, the harmonic mean, H , is defined as the reciprocal of the arithmetic mean of the reciprocals,

$$\frac{1}{H} = \frac{\frac{1}{x_1} + \frac{1}{x_2} + \dots + \frac{1}{x_N}}{N}.$$

The arithmetic mean of N unequal positive numbers is greater than the geometric mean which in turn is greater than the harmonic mean. The harmonic mean is used in time and rate problems.

HARMONIC MOTION. Simple harmonic motion is the to-and-fro motion of a body in a straight line, of such character that the displacement of the body from its equilibrium position (or mid-point of the motion) varies sinusoidally with time, i.e.,

$$x = a \cos(\omega t + \phi)$$

where x is the displacement and a and ϕ are constants. The frequency of the motion is $\omega/2\pi$. Such a motion occurs whenever a body moves on a straight line under the action of a restoring force proportional to the displacement, i.e., $f = -ks$, with no other forces acting. A mass suspended by a spring that obeys the Hooke law is the simplest example. The term is also applied to motions that approximate simple harmonic; for example, the motion of a pendulum bob approximates simple harmonic motion very closely for small amplitudes. Similarly, the addition of a small dissipative frictional force results in a motion which may be described as a simple harmonic motion with an amplitude that decreases with time.

The term harmonic motion (without the qualifier "simple") is used to describe rotary and other motions in which some variable, such as an angular displacement, varies sinusoidally with time.

Two simple harmonic motions of the same frequency, at right angles to each other, e.g.,

$$x = a \cos \omega t \quad \text{and} \quad y = b \cos(\omega t + \phi),$$

lead to an elliptical motion. Special cases occur for $\phi = 0$, when the ellipse degenerates to a straight line, and for $a = b$ and $\phi = 90^\circ$, when it degenerates to a circle. If the frequencies are unequal but commensurate, the motion is a Lissajou figure.

HARMONIC MOTION, DAMPED. The differential equation of a system which will oscillate with a harmonic motion is

$$M \frac{d^2x}{dt^2} + kx = F(t),$$

where M is the mass of the moving particle, k is the restoring force constant, x is the in-

stantaneous displacement and $F(t)$ is the external force applied to the mass. If frictional forces or other dissipative agencies act, the behavior of the system may often be approximated closely by the equation

$$M \frac{d^2x}{dt^2} + R \frac{dx}{dt} + kx = F(t)$$

where R is a constant, often called the resistance.

HARMONIC MOTION, PERIOD OF. The time for one complete oscillation, that is, the reciprocal of the frequency.

HARMONIC MOTION, SIMPLE ELLIPTIC. A compounded oscillatory motion consisting of (simple) harmonic motion in two fixed perpendicular directions with equal frequencies. The resultant trace of the motion is in general an ellipse, which depending on the relative phase and amplitudes of the two components may take the special form of a circle or straight line.

HARMONIC OSCILLATOR. See oscillator, harmonic.

HARMONIC OSCILLATOR, PARTITION FUNCTION OF. The function given by the equation

$$Z = \sum_n e^{-\beta h\nu(n+\frac{1}{2})} = e^{+\frac{1}{2}\beta h\nu} (e^{\beta h\nu} - 1)^{-1},$$

where $h\nu$ is the energy distance between successive oscillator levels, $\beta = 1/kT$ (k is Boltzmann's constant and T is absolute temperature), and Z is the partition function. Note that Planck's constant h is used in above formula, while the Dirac $\hbar = \frac{h}{2\pi}$, is used in the entry oscillator, harmonic.

HARMONIC PROGRESSION. The sequence a, b, c, \dots if their reciprocals $1/a, 1/b, 1/c, \dots$ form an arithmetic progression. The harmonic mean between two numbers is the middle term of a harmonic progression whose first and last terms are the given numbers. The harmonic mean between a and b is given by $H = 2ab/(a + b)$. If A, G , and H are respectively the arithmetic, geometric, and harmonic mean of two numbers then $G^2 = AH$.

HARMONIC SERIES OF SOUNDS. A series of sounds in which each basic frequency

in the series is an integral multiple of a fundamental frequency. (See harmonic analysis.)

HARTLEY. A unit of information content equal to the information content of a message, the *a priori* probability of which is one-tenth. If, in the definition of information content, the logarithm is taken to the base ten, the result will be expressed in hartleys.

HARTLEY FORMULA FOR TIME-FREQUENCY DUALITY. As implied by the Fourier transform, a time function cannot be confined within a small region on the time scale when the steady-state transmission characteristic is confined to a narrow range on the time scale. For example, it is well known that, if a telegraph dot is made narrower and narrower, its corresponding significant-frequency spectrum becomes broader and broader until, in the limit when the dot becomes an impulse, its significant-frequency spectrum is of infinite extent. Two mathematical equations which express this relationship are

$$g(t) = \int_{-\infty}^{\infty} c(f) \text{cas } 2\pi ftdf$$

$$c(f) = \int_{-\infty}^{\infty} g(t) \text{cas } 2\pi ftdt$$

where f is the cyclic frequency, t is time, and cas denotes cosine added to sine.

HARTLEY PRINCIPLES (WITH REGARD TO INFORMATION CAPACITY OF A TRANSMISSION CHANNEL). The amount of information that can be transmitted is proportional to the width of the frequency range, and the time it is available. Information content is equated to the total number of code elements, multiplied by the logarithm of the number of possible values a code element may assume. Information content is independent of how the code elements are grouped. By quantizing, the continuous magnitude-time function used in ordinary telephony may be transmitted by a succession of code symbols such as are employed in telegraphy. And, to obtain the maximum rate of transmission of information, the signal elements need to be spaced uniformly.

HARTMANN DISPERSION FORMULA. A very useful dispersion formula due to Hartmann which suggests the anomalous disper-

sion near an absorption band, but does not provide for more than one such band and hence can be used over only a limited range of wavelengths. It is of the form:

$$n = n_0 + \frac{c}{(\lambda - \lambda_0)^a},$$

where n_0 , c and λ_0 are constants to be determined from measurements. For best fit to empirical results $a = 1.2$, but for convenience $a = 1$ is often used.

HARTREE APPROXIMATION. A method used to determine energy levels of atomic systems. The wave function of the system is assumed to be the product of one-particle wave functions $\psi_k(x)$, each particle occupying a definite one-particle state. The anti-symmetry of the wave function is not taken into account. The expectation value of the energy in a state described by such a product wave function is then calculated and minimized with respect to variations of the functions $\psi_k(x)$. This gives equations to determine the one-particle wave functions $\psi_k(x)$. The potential appearing in these equations is determined by the states of the other particles. The particles move in a self-consistent field which determines their motion and which is determined by this motion.

HARTREE-FOCK METHOD. This is an improvement on the Hartree approximation for calculating energy levels of atomic systems. The wave function with respect to which the expectation value of the energy of the system is minimized is a Slater determinant, the anti-symmetrized product of one-particle wave functions $\psi_k(x)$. The equations determining these functions $\psi_k(x)$ include exchange effects due to the anti-symmetry of the wave function of the system.

HAUNCHED BEAM. See beam, haunched.

HAUSDORFF SPACE. See topological space.

HÄUÛY LAW. The fundamental law of crystallography stating that for a given crystal there exists a set of axial ratios such that the intercepts of every crystal plane on the crystal axes are expressible as rational fractions of these ratios. (See Miller indices.)

h-BAR OR \hbar . Symbol for Dirac- \hbar , the universal constant $h/2\pi$, where h is the Planck constant.

HEAT. The term has been used in two related, but distinctly different, senses. (1) According to best modern usage, heat is energy in the process of transfer between a system and its surroundings as a result of temperature differences. (2) According to the older (and still current) usage, heat is the energy contained in a sample of matter, including both potential energy resulting from interatomic forces and kinetic energy associated with the chaotic motion of the molecules of a substance. In the range of temperatures in which quantum effects are not of importance, the average kinetic energy per molecule is one-half of the Boltzmann constant times the Kelvin temperature for each degree of freedom, in accordance with the principle of the equipartition of energy. The average potential energy per molecule in monatomic solids, under the same conditions, is equal to the average kinetic energy; the Dulong and Petit law is explained by this fact.

In accordance with the second definition, terms such as heat content, specific heat, etc., are used as measures of the internal energy of matter.

Although we now recognize that heat is energy, it is still customary to express quantity of heat in the old water-temperature measure, by means of British thermal units or of calories; and whenever heat quantities so expressed are used in thermodynamic calculations, it is necessary to use the mechanical equivalent of heat as a conversion factor between these and the ordinary dynamic units of energy (foot-pounds, joules, or ergs).

HEAT BALANCE. A method of accounting for all heat units in a process or change during which heat is transferred. Examples of cases where heat balances might be undertaken are: (1) Determining the nature and the magnitude of the various losses which occur when coal is burned in a steam boiler furnace. (2) Accounting for all heat units during the operation of a prime mover such as a Diesel engine or a steam turbine. (3) Determining the distribution of heat in a static heating device such as a water heater supplied with steam.

Heat balance work is based upon the first

law of thermodynamics. (See **conservation of energy**.)

HEAT CAPACITIES, RELATION BETWEEN. (See **thermal coefficients**.) The molar heat capacity at constant pressure and the molar heat capacity at constant volume are related by

$$C_p = C_v + \frac{\alpha^2 TV}{\kappa}$$

where α is the **thermal expansion coefficient**, and κ , the **isothermal compressibility coefficient**.

HEAT CAPACITY. The amount of heat necessary to raise the temperature of a system, entity, or substance by one degree of temperature. It is most frequently expressed in calories per degree centigrade. If the mass of a substance is specified, then certain derived values of the heat capacity can be obtained, such as the atomic heat, molar heat, or specific heat. (See **thermal coefficients**.)

HEAT CAPACITY EQUATION. See **Einstein specific heat function**.

HEAT CAPACITY, QUANTUM THEORY OF. See **quantum theory of heat capacity**.

HEAT CARRIED AWAY. The **enthalpy** of combustion gases (in a chimney, stack, etc.) with reference to the enthalpy of the fuel and air entering the device; it is a measure of the energy lost through inability to cool the products of combustion to the temperature of the surrounding atmosphere. It is usually assumed that the atmosphere is at a standard temperature t_s (0°C or 60°F) and that the combustion gases are perfect. Hence

$$Q_c = \left\{ \frac{c}{12} [\bar{C}_p]_{t_s}^c \text{CO}_2 + \left(\frac{h}{2} + \frac{w}{18} \right) [\bar{C}_p]_{t_s}^c \text{H}_2\text{O} + 0.21(\lambda - 1) X_{min} [\bar{C}_p]_{t_s}^c \text{O}_2 + 0.79\lambda X_{min} [\bar{C}_p]_{t_s}^c \text{N}_2 \right\} t_c - [c]_{t_s}^f t_f - \lambda X_{min} [\bar{C}_p]_{t_s}^a t_a$$

for solid or liquid fuel, or

$$Q_c = t_c \sum_{\text{burnt gases}} x [\bar{C}_p]_{t_s}^c - t_f \sum_{\text{fuel gas}} x [\bar{C}_p]_{t_s}^f - \lambda X_{min} [\bar{C}_p]_{t_s}^a t_a$$

for a gaseous fuel.

Symbols: t_c is the temperature of burnt gases leaving the device; t_a is the temperature of air entering the device; t_f is the temperature of fuel entering the device; X_{min} is the stoichiometric quantity of air in volume units; λ is the **air ratio**; $[\bar{C}_p]_{t_1}^2$ is the **mean molar specific heat** between the temperatures indicated; x is the mole fraction and $c, h, \text{etc.}$, is the fuel composition in mass units of respective element per unit mass of fuel; w refers to moisture.

In a boiler or furnace the heat carried away is also known as the **stack loss**.

HEAT CONSUMPTION. See **specific heat consumption**.

HEAT CONTENT. See **enthalpy**.

HEAT DROP. See **enthalpy drop**.

HEAT EXCHANGER. A device for exchanging heat between two fluids. In a *heater* the temperature of the main fluid is raised; it is lowered in a *cooler*. The second fluid in a cooler is known as the *coolant*. The most widely used coolant is water (cooling water).

There are three principal types of heat exchanger, depending on the relative direction of the two fluids on the two sides of the heating surface: parallel flow, Figure 1, counter-flow or contra-flow, Figure 2, and cross-flow, Figure 3.

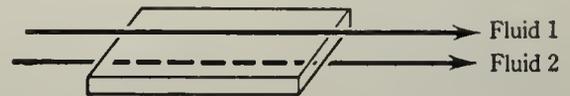

Fig. 1.

Fig. 2.

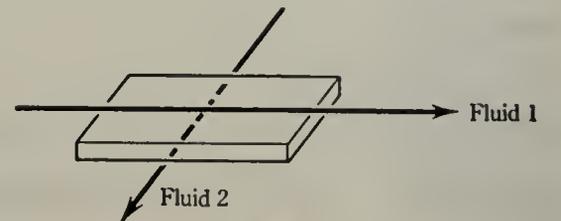

Fig. 3.

Practical heat exchangers are seldom strictly of one particular type and necessarily contains elements of each type. They are described by the designation which is related to the conditions prevailing over the greatest portion of the heating surface.

HEAT FLUX VECTOR. See *flux vector*.

HEAT FUNCTION. See *enthalpy*.

HEAT INDEX. As used by C. W. Thornthwaite in his 1948 *climatic classification*, a function of temperature designed to have low magnitude under cold conditions, increasing exponentially with increasing temperature. For a given station, it is numerically equal to the sum of the twelve monthly values of the expression

$$\left(\frac{t}{5}\right)^{1.514},$$

where t is the normal monthly temperature in °C.

HEATING SURFACE. The metal surface separating two fluids exchanging heat in a **heat exchanger**. In particular, the sum of the surfaces across which heat is added to the working fluid in a boiler.

HEATING VALUE. The heating, or caloric, value of a **fuel** is the quantity of heat produced by the combustion, under specified conditions, of unit weight or volume of the fuel. The heating value of a fuel may be calculated by a formula which may be derived for any fuel by multiplying the percentage of each chemical element present by its heating value per unit weight, and adding the products for all combustible elements in the fuel. Thus for coal, whose combustible elements consist of carbon, hydrogen, and sulfur, the heating value is:

$$14,540C + 62,000H + 4000S$$

(B.T.U. per lb of coal).

The numbers in the above formula are the heating values per lb respectively, of carbon, hydrogen, and sulfur. In the use of this formula, it is essential that only that portion of the element that is actually free to burn be employed. For example, all coal contains some moisture. Now the hydrogen present in this water is not free to burn (i.e., it is already combined with oxygen). Therefore the figure used for H in the foregoing formula should not include the hydrogen present as water.

Heating value by formula will not necessarily be the same as that obtained experimentally with the fuel calorimeter. The difference lies not in the accuracy of the experiment, nor of the calculation, but in the possible endo-

thermic or exothermic reactions which take place when a compound fuel, such as a hydrocarbon, is burned. The volatile matter of coal must be broken down into the elements of carbon and hydrogen by heat-absorbing action before they may reunite with the oxygen during combustion. For this reason, experimentally determined heating values are less than those which are computed by formulas, which contain no terms for such endothermic reactions. Approximate heating values of some of the common fuels are: coal, 13,000 B.T.U. per lb; natural gas, 1000 B.T.U. per cu ft; artificial gas, 300 B.T.U. per cu ft; gasoline, 19,000 B.T.U. per lb; wood, 5000 B.T.U. per lb.

Many thermodynamic analyses require the use of a "lower heating value" which may be obtained from the above values by subtracting an allowance for the latent heat of evaporation of the steam found in the products of combustion. (See also **combustion calculations in engineering**.)

HEAT, LATENT. The heat per unit mass or mole required to produce a change of phase at constant pressure and temperature; it is equal to the difference in the specific **enthalpies** of the substance at the two phases. Usually, latent heats are reckoned positive for the transition from a phase of lower to a phase of higher energy. (For example liquid → vapor.) Often an adjective is added to specify the type of transition involved, and the adjective "latent" may be omitted, e.g., (latent) heat of evaporation, (latent) heat of sublimation, (latent) heat of fusion, etc. Sometimes, particularly in the case of evaporation, the latent heat per unit mass

$$l = h_2 - h_1$$

is split up into two terms in view of the definition $H = U + pV$:

$$l = (u_2 - u_1) + p(v_2 - v_1) \quad (\text{since } p = \text{const}).$$

The first term, the change in internal energy

$$p = u_2 - u_1$$

is termed *internal (latent) heat* and the second term

$$\psi = p(v_2 - v_1)$$

which represents the work done at the boundaries of the system against the external pressure is called *external (latent) heat*.

HEAT, MECHANICAL EQUIVALENT OF.

The conversion factor between any unit commonly employed to express mechanical energy and a unit commonly employed to express thermal energy, e.g., 4.1840 joules/calorie.

HEAT, MOLECULAR. (Heat, Molar.) The product of the **gram-molecular weight** of a compound and its specific heat. (See **heat, specific.**) The result is the **heat capacity** per gram-molecular weight.

HEAT OF DILUTION. The *total* or *integral heat of dilution* is the difference in enthalpy between a solution and its components. The *differential heat of dilution* or of *mixing*, which is more commonly meant by the term heat of dilution, is the heat absorbed (change in partial molar enthalpy) when one mole of a specified component is dissolved in a large bulk of solution at constant temperature and pressure.

HEAT OF MIXING. See **excess functions.**

HEAT OF REACTION. See **thermal coefficients.**

HEAT OF TRANSFER. See **thermomolecular pressure.**

HEAT PROPAGATION IN CONDUCTING MEDIUM. A process governed by the general equation:

$$\nabla^2 T = \frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} = \frac{c\rho}{K} \frac{\partial T}{\partial t}$$

where T is the temperature, c , the specific heat, ρ , the density, K , the thermal conductivity, x, y, z , rectangular coordinates, and t , the time. For the case of radial heat flow (spherical coordinates), the equation is

$$\frac{\partial^2 T}{\partial r^2} + \frac{2}{r} \frac{\partial T}{\partial r} = \frac{\rho c}{K} \frac{\partial T}{\partial t}$$

where r is the radius.

For the case of radial heat flow in one plane (cylindrical coordinates), the equation is

$$\frac{\partial^2 T}{\partial r^2} + \frac{1}{r} \frac{\partial T}{\partial r} = \frac{\rho c}{K} \frac{\partial T}{\partial t}$$

HEAT REGENERATION. The process of exchanging heat internally between the working fluid at two different states in a particular cycle. Heat is best exchanged between two ranges of states in the same temperature range

and in a counter-flow **heat exchanger**. The process of heat regeneration results in an increase in efficiency. (For specific examples see **carnotization** and **Joule cycle**.)

HEAT, SPECIFIC. Also called the specific heat capacity. The quantity of heat required to raise the temperature of unit mass of a substance by one degree of temperature. The units commonly used for its expression are the unit mass of one gram, the unit quantity of heat in terms of the **caloric**. The unit mass of one **mole** is also used, although the preferred term for the quantity of heat is then the *molar heat* or *molecular heat*.

HEAT, SPECIFIC, AT CONSTANT PRESSURE. The amount of heat required to raise unit mass of a substance through one degree of temperature without change of pressure. Usually denoted by C_p , when the **mole** is the unit of mass, and c_p when the **gram** is the unit of mass.

HEAT, SPECIFIC, AT CONSTANT VOLUME. The amount of heat required to raise unit mass of a substance through one degree of temperature without change of volume. Usually denoted by C_v , when the **mole** is the unit of mass, and c_v when the **gram** is the unit of mass.

HEAT, SPECIFIC, OF SOLIDS. See **Dulong and Petit law**; **Debye theory of specific heat**; **Born-Einstein equation for heat capacity**; **Born-von Kármán theory of specific heat**.

HEAT THEOREM (NERNST HEAT THEOREM). An alternative name given to the third law of **thermodynamics**.

HEAT TONE. Latent heat associated with a change of phase, an allotropic transformation or a chemical reaction. The common feature of these processes is that they occur at $p = \text{constant}$ and $T = \text{constant}$ and that the overall system consists of a mixture of two systems 1 and 2 whose thermodynamic properties differ by finite amounts and whose relative masses change during the process. The heat tone refers to a complete transformation of a unit mass from 1 to 2.

HEAT TRANSFER. (1) The physical process whereby heat passes from one system to another. (2) The branch of science which describes the process of heat transfer, that is

also known as heat transmission. The central problem in heat transfer is to calculate the rate at which heat passes from one system to another under a variety of conditions. An auxiliary problem intimately connected with the preceding one is the calculation of the temperature field which exists in the system of interest while heat is being transferred.

Heat can be transferred by three essentially different physical mechanisms, known as *modes of heat transfer*. In *conduction* heat is transferred through a material medium at rest. It occurs in solid bodies and very thin layers of fluid. When the layers of fluid (liquid or gas) become extensive, the temperature field in the system which accompanies the transfer of heat causes the density to vary from point to point. A mass of fluid of varying density placed in the gravitational field of the earth will not be in equilibrium, unless the density stratification satisfies a definite relationship. Hence, the buoyancy forces acting on the fluid particles will give rise to a velocity field. In *convection* heat is transferred principally by virtue of the physical motion of the fluid. Convection is called *natural* when the velocity field in the fluid is caused predominantly by the interaction of the temperature field with the gravitational field of the earth. Convection is called *forced* when the velocity field is imposed on the fluid, e.g., by pressure gradients, etc. Convection does not occur in a solid, because in it, a temperature field causes varying degrees of *thermal expansion* which, in turn, may give rise to *thermal stresses*, but not to motion. Heat can also be transferred from one system to another without the intervention of a material body in between. It is then called *radiation*. Radiation is the transfer of energy by electromagnetic waves, and at the speed of light. We speak of *thermal radiation* when the bulk of the energy is carried in a particular range of wavelengths: 0.8 to 400 microns (visible light: 0.4 to 0.8 μ ; ultraviolet radiation: 0.02 to 0.4 μ ; X-rays: 10^{-6} to 0.02 μ).

Conduction. When a homogeneous system of arbitrary shape transfers heat by conduction, it is found that a (scalar) temperature field $T(x,y,z,t)$ is present throughout the system. The directed (vectorial) quantity $\dot{\mathbf{q}}$ which represents the rate of heat (energy) transfer per unit time and area at a point in the system is called *heat flux*. The principle of conservation

of energy, in the absence of heat sources, leads to the general equation of conduction

$$\rho c \frac{\partial T}{\partial t} + \text{div } \dot{\mathbf{q}} = 0 \quad (1)$$

(ρ is density; c is specific heat). The relation between the heat flux vector $\dot{\mathbf{q}}$ and the gradient of the temperature field is given by **Fourier's empirical law**:

$$\dot{\mathbf{q}} = -k \text{ grad } T. \quad (2)$$

In accordance with the second law of **thermodynamics**, the coefficient of proportionality $k(T)$, known as the *thermal conductivity* of the material, must always be positive

$$k > 0. \quad (2a)$$

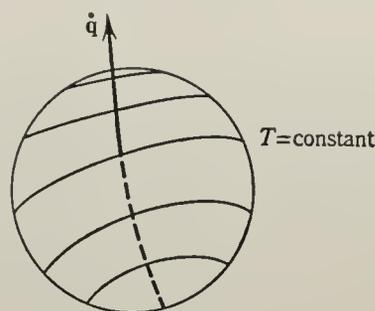

Fig. 1.

The thermal conductivity of known materials ranges from 0.003 for some gases to 300 Btu/hr ft F for some metals, i.e., over a ratio of 1:100,000.

Substitution of (2) into (1) leads to *Fourier's equation of heat conduction*

$$\rho c \frac{\partial T}{\partial t} = \text{div } \{k(T) \text{ grad } T\}. \quad (3)$$

In many applications, the thermal conductivity can be assumed constant, when Equation (3) simplifies to

$$a \frac{\partial T}{\partial t} = \nabla^2 T. \quad (4)$$

$$a = \frac{\rho c}{k} \quad (5)$$

is known as the *thermal diffusivity* of the material.

In the presence of heat sources, the source strength $Q'(x,y,z,t)$ must be added to the right-hand side of Equation (1); hence the term $Q'/\rho c$ will appear on the right-hand side of Equation (4). Fourier's equation, together with the ini-

tial and boundary conditions, determines the temperature field $T(x,y,z,t)$. Fourier's law then determines the heat flux $\dot{\mathbf{q}}$ at every point.

The instantaneous rate \dot{Q} at which heat is transferred across a solid body is found by integrating the heat flux $\dot{\mathbf{q}}$ over its surface, but *not* over its entire surface. It is necessary to integrate *separately* the portions with positive and negative heat fluxes. As a rule one part of the surface, Figure 2, will be in contact with

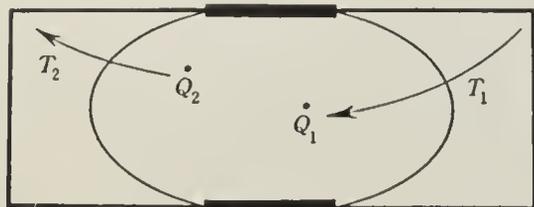

Fig. 2.

system 1 at T_1 and another part will be in contact with system 2 at T_2 , the remainder of the surface being adiabatic. The quantity of heat \dot{Q} transferred by conduction is measured separately for systems 1 and 2.

When the flow of heat is steady, the temperature field satisfies **Laplace's equation**

$$\nabla^2 T = 0 \quad (6)$$

in the absence of sources, and the function $T(x,y,z)$ is independent of the properties of the material, being a function of the geometrical arrangement only. It is easy to see that then in Figure 2 we have $\dot{Q}_1 = \dot{Q}_2$. The quantity is the rate at which heat is conducted through the solid body, because in the steady state the solid body neither stores nor discharges energy.

When the body is anisotropic (crystals), the vectors $\dot{\mathbf{q}}$ and $\text{grad } T$ are no longer collinear, but they remain proportional. Fourier's law (in Cartesian coordinates x_1, x_2, x_3) assumes the form

$$\begin{aligned} \dot{q}_1 &= -k_{11} \frac{\partial T}{\partial x_1} - k_{12} \frac{\partial T}{\partial x_2} - k_{13} \frac{\partial T}{\partial x_3} \\ \dot{q}_2 &= -k_{21} \frac{\partial T}{\partial x_1} - k_{22} \frac{\partial T}{\partial x_2} - k_{23} \frac{\partial T}{\partial x_3} \\ \dot{q}_3 &= -k_{31} \frac{\partial T}{\partial x_1} - k_{32} \frac{\partial T}{\partial x_2} - k_{33} \frac{\partial T}{\partial x_3}. \end{aligned} \quad (7)$$

The three fluxes $\dot{q}_1, \dot{q}_2, \dot{q}_3$ are seen to be coupled. It is a consequence of the second Law of thermodynamics and **Onsager's principle**

of **reciprocal relations** that the tensor k_{ij} is non-negative, definite and symmetrical

$$k_{ij} = k_{ji}. \quad (8)$$

The problem of calculating the transfer of heat by conduction has, therefore, been reduced to the purely mathematical problem of solving some form of Fourier's equation subject to appropriate boundary and initial conditions. Many particular problems have been solved and the reader will find an excellent compendium in *Conduction of Heat in Solids* by H. S. Carslaw and V. C. Jaeger, 2nd edition, Clarendon Press, 1959. The boundary conditions at the surface differ in accordance with the constraints imposed on it. Very seldom the surface temperature is prescribed by a function $T = f(x,y,z,t)$ on the surface. More frequently, the boundary condition is given in the form of a requirement on the heat flux $\dot{\mathbf{q}}$. When there is no heat flux (adiabatic surface) the condition is

$$\frac{\partial T}{\partial n} = 0, \text{ on surface} \quad (9)$$

(n is the normal to the surface). If forced or natural convection take place at the surface, the condition is written in the form of Newton's law of cooling (see below, *Convection*)

$$\dot{q}_{surf} = -k \frac{\partial T}{\partial n} = h(T_w - T_\infty). \quad (10)$$

Problems involving radiation at the surface occur seldom and are sometimes approximated by a condition identical with Equation (10).

Fourier's law and equation describe actual processes in an excellent manner, but the objection has been raised that Fourier's equation, being parabolic, admits of an infinite rate of propagation of temperature changes, contrary to physical reality. Proposed modifications of Fourier's law do not, however, materially alter the solution in practical cases, but necessarily lead to grave mathematical complications.

Convection. Since convection always involves a fluid in motion, it is possible to solve problems in convection from first principles only in the case of laminar motion. In most important applications, the accompanying motion is turbulent and it is necessary to rely to a large extent on empirical information. The fundamental empirical assumption, known as *Newton's law of cooling*, asserts that the rate of heat transfer per unit area \dot{q}'' is proportional to the difference between the temperature of the solid

surface, T_w , and that of the fluid at a large distance from the wall, T_∞ . Hence

$$\dot{q}'' = h(T_w - T_\infty) \quad (11)$$

where the coefficient h (Btu/ft² hr F), known as the *coefficient of heat transfer* or *film coefficient*, depends on the properties of the fluid and its state of motion. It is, therefore, a complicated function in any particular problem. Newton's law of cooling holds in the large majority of cases, but breaks down where the surface is not isothermal. In the case of compressible flows (at high Mach numbers), it is replaced by the relation

$$\dot{q}'' = h(T_w - T_a) \quad (12)$$

where T_a denotes the adiabatic wall temperature, i.e., the temperature which would be assumed by the fluid at the wall if the latter were non-conducting. This difference is due to the large amount of heat dissipated by the flow near a wall and is often referred to as the *thermal barrier* because, generally, it impedes the transfer of heat as $T_a = T_\infty + rU_\infty^2/2c_p$ (r is the recovery factor which depends on the flow; c_p is the specific heat at constant pressure).

Owing to the difficulties associated with the calculation of the coefficient of heat transfer, it is often necessary to confine oneself to a *dimensional analysis* of the problem. It is then found that for geometrically similar bodies in similar flow fields with similar boundary conditions, the relation between the coefficient of heat transfer h and the remaining parameters can be expressed in terms of various dimensionless groups (numbers). To show their relationships, certain of these numbers are given below in the dimensions used in the present discussion. They can, of course, be defined in numerically and dimensionally equivalent terms. For the definitions most commonly used, see the corresponding entries. They are:

the Nusselt number

$$Nu = \frac{hL}{k}$$

the Reynolds number

$$Re = \frac{\rho U_\infty L}{\mu} = \frac{U_\infty L}{\nu}$$

the Grashof number

$$Gr = \frac{g\beta(T_w - T_\infty)L^3}{\nu^2} \quad (13)$$

the Prandtl number

$$Pr = \frac{\nu}{a} = \frac{\mu c_p}{k}$$

the Eckert number

$$Ec = \frac{U_\infty^2}{c_p(T_w - T_\infty)}$$

(L is the characteristic length; μ is the dynamic viscosity; ν is the kinematic viscosity; U_∞ is the fluid velocity at large distance from surface; ρ is the density of fluid; β is the coefficient of thermal expansion of fluid; c_p is the specific heat of fluid at constant pressure.) The general relation is

$$Nu = f(Re, Gr, Pr, Ec). \quad (14)$$

The exact form of the function f must be determined, theoretically or empirically, for each class of dynamically similar problems. Equation (14) formulates the problem in terms of the minimum number of independent variables. Several specialized forms of Equation (14) are of importance. In general $(T_w - T_\infty) \ll U_\infty^2/c_p$ and the Eckert number can be omitted. In natural convection the Reynolds number can be omitted, when

$$Nu = f_1(Gr, Pr). \quad (\text{natural convection}) \quad (15)$$

When the natural motion is very slow,

$$Nu = f_2(Gr \times Pr) = f_2(Ra) \quad (16)$$

where Ra is known as the *Rayleigh number*. In forced convection, the Grashof number can be omitted, and we have

$$Nu = f_3(Re, Pr) \quad (\text{forced convection}) \quad (17)$$

when a more accurate analysis is performed, it is found that the turbulence intensity Tu of the free stream must be added to the independent variables in Equation (14). In particular, equation (17) must be rewritten to read

$$Nu = f_4(Re, Pr, Tu). \quad (18)$$

The Stanton number is $St = \frac{Nu}{Re \times Pr}$ (19)

In high-speed flow, the Eckert number cannot be omitted, and it or the

$$\text{Mach number } M = \frac{U_\infty}{c} = \frac{Ec}{\gamma - 1} \quad (20)$$

(c is the velocity of sound; γ is the ratio of specific heats) must be retained as an independent variable.

The velocity profile in a fluid near a wall, as well as the temperature distribution, are of the boundary layer type. Consequently, in many cases the relations for the Nusselt number (and hence for h) can be derived from boundary layer theory. In cases of laminar flow in the boundary layer, the problem is a mathematical one, because the boundary layer equations can then be written and analyzed. In cases when turbulent flow is involved, additional information of an empirical nature must be supplied.

Boundary layer theory leads to a general relation between the shearing stress τ (a characteristic of the velocity field) and the local heat flux \dot{q} (a characteristic of the temperature field) known as Reynolds' analogy. The analogy is usually expressed in the form of a relation between the dimensionless skin friction coefficient

$$c_f = \frac{\tau}{\frac{1}{2}\rho U_\infty^2} \quad (21)$$

and the Stanton number. In the simplest case of two-dimensional flow past a flat plate at zero incidence, and for $Pr = 1$, the analogy has the form

$$St = \frac{1}{2}c_f. \quad (22)$$

The relation is an expression of the fact that under those conditions the velocity and temperature profiles are identical functions of the coordinate perpendicular to the surface. For $Pr \neq 1$, the two are similar.

Boundary layer theory leads to the formulation of another important analogy, namely that between heat and mass transfer. The mechanism of the diffusion of a vapor into a flowing stream is basically identical with that of heat, and this reflects in the respective equations for laminar or turbulent flow. Hence a complete analogy can be established between the transfer of heat in forced convection and the transfer of mass into it.

Radiation. The transfer of heat by radiation is studied in terms of and in relation to the ideal case of black body radiation. Black body radiation constitutes an upper limit for the heat flux from any surface at the same temperature. The amount of heat emitted by a unit surface at temperature T is given by the **Stefan-Boltzmann law** $E = \sigma T^4$. Real surfaces are characterized by a coefficient $\epsilon < 1$, called its *emissivity* (equal to its absorptivity, see **Kirchhoff's law**). It is assumed that real surfaces are gray, i.e., that they have the same

spectral energy distribution as a black body. Hence for a gray surface

$$E = \epsilon\sigma T^4. \quad (23)$$

The quantity of heat exchanged between two surfaces at T_1 and T_2 , respectively, is obtained by considering that each one of them emits energy in accordance with Equation (23) and that, being gray, it reflects a fraction $1 - \epsilon$ of the energy emitted by the other surface. In this manner it can be calculated that the heat flux \dot{q}_{12} due to radiation between two infinite, parallel plane surfaces 1 and 2 is

$$\dot{q}_{12} = \frac{\sigma}{(1/\epsilon_1) + (1/\epsilon_2) - 1} (T_1^4 - T_2^4). \quad (24)$$

For two gray surfaces 1 and 2, Figure 3, we obtain

$$\dot{Q}_{12} = \frac{\epsilon_1 \epsilon_2}{\pi} \sigma (T_1^4 - T_2^4) \times \iint \frac{\cos \phi_1 \cos \phi_2}{r^2} dA_1 dA_2 \quad (25)$$

where the double integral constitutes a purely geometrical shape factor. The formula in Equation (25) is approximate only because it disregards the reflected quantities of energy. It is exact for two black surfaces $\epsilon_1 = \epsilon_2 = 1$.

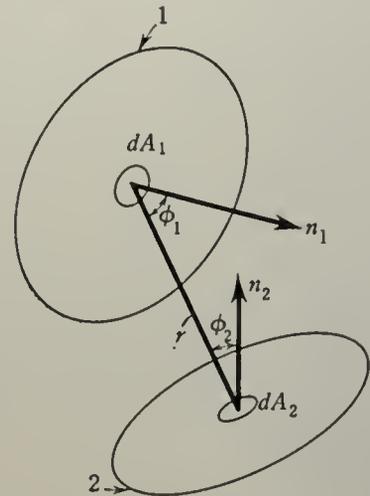

Fig. 3.

For concentric cylinders or spheres, the exact equation is

$$\dot{Q}_{12} = A_1 \frac{\sigma}{(1/\epsilon_1) + (A_1/A_2)\{(1/\epsilon_2) - 1\}} \times (T_1^4 - T_2^4). \quad (26)$$

(A_2 is the outer surface; A_1 is the inner surface.)

When the outer surface is very large, $A_2 \rightarrow \infty$, the rate of heat transferred becomes independent of its emissivity and depends only on the emissivity of the small surface.

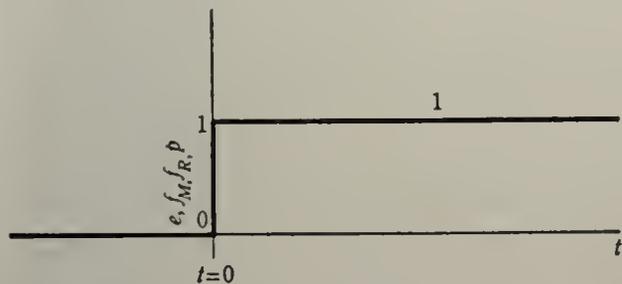

Radiation from flames poses special problems because gases are selective emitters (and absorbers) and emit (or absorb) energy in preferred wave bands. Consequently the relations become complex; they have not yet been fully explored.

HEAT, UNITS OF. See **thermal units**.

HEAVISIDE OPERATIONAL CALCULUS.

The behavior of a vibrating system may be analyzed by solving the differential equations of the dynamical system. In other words find the currents or velocities of the elements which when substituted in the differential equations will satisfy the initial and final conditions. The solution of the differential equation may be divided into the steady-state term and the transient term. The operational calculus is of great value in obtaining the transient response of an electrical, mechanical or acoustical system to a suddenly impressed voltage, force or pressure. The general analysis used by Heaviside is applicable to any type of vibrating system whether electrical, mechanical or acoustical. The response of a system to a unit force can be obtained with the Heaviside calculus.

Heaviside's unextended problem is as follows: given a linear dynamical system of n degrees of freedom in a state of equilibrium, find its response when a unit force is applied at any point. The unit function, **1**, depicted in the figure, is defined to be a force which is zero for $t < 0$ and unity for $t \geq 0$.

The unit function. The electromotive force, force, torque or pressure is zero before and unity after $t = 0$.

The response of a dynamical system to a unit force is called the indicial admittance of the system. It is denoted by $A(t)$. $A(t)$ represents the current, linear velocity, angular velocity, or volume current when a unit electromotive force, force, torque or pressure is

suddenly applied in a system which was initially at rest.

In the Heaviside calculus the differential equations are reduced to an algebraic form by replacing the operator d/dt by the operator p and the operation $\int dt$ by $1/p$. Tables of operational formulas have been compiled which serve for operational calculus the same purpose that tables of integrals serve the integral calculus. Operational formulas may be modified, divided or combined by various transformation schemes. This is similar to integration by parts or change of variable in the integral calculus.

The procedure in the Direct Heaviside Operational Method to be followed in obtaining an operational solution of an ordinary differential equation is as follows: Indicate differentiation with respect to the independent variable by means of the operator p . Indicate integration by means of $1/p$. Manipulate p algebraically and solve for the dependent variable in terms of p . Interpret and evaluate the solution in terms of known operators. (See **transient response of a dynamical system to an arbitrary force—Duhamel's integral**.)

HEAVISIDE UNIT FUNCTION. The function $f(x)$ defined by $f(x) = 0$ if x is negative, and $f(x) = 1$ if x is zero or positive.

HEINE-BOREL THEOREM. If an infinite set S of open intervals covers the finite closed interval $[a, b]$ in the sense that every point of $[a, b]$ is contained in at least one interval of S , then there exists a finite subset of S having the same property. The theorem is easily generalized in various ways.

HEINE FORMULA. An integral representation for **Legendre polynomials**:

$$P_n^m(x) = (n+1)(n+2)\cdots(n+m)(-1)^{m/2} \times \frac{1}{\pi} \int_0^\pi [x + \sqrt{x^2 - 1} \cos \phi]^n \cos m\phi d\phi.$$

HEISENBERG FORCE. A central force between two nucleons which is derivable from a potential containing an operator which exchanges both the spins and the positions of the two particles. Nuclear forces are known to have exchange properties of this general type.

HEISENBERG PICTURE. The description of the evolution in time of a quantum mechani-

cal system by the use of a time-independent state vector $|\Phi_H\rangle$

$$\partial_t |\Phi_H\rangle = 0 \quad (\text{a})$$

but by time-dependent operators, $F_H(t)$, corresponding to the observables of the system. The time dependence of $F_H(t)$ is given by

$$\partial_t F_H(t) = \frac{i}{\hbar} [H_H, F_H(t)] \quad (\text{b})$$

where H_H is the Hamiltonian of the system. The state vector, $|\Phi_H\rangle$, in the Heisenberg picture is the same for all time and describes the entire history of the system, i.e., the results of all possible experiments on the system throughout its history. However, if an actual experiment is performed on the system, the state vector will be changed. Although the Heisenberg state vector Φ_H does not depend on time, it may be specified by the results it predicts for some experiments at a given time. It can, for example, be specified as that state vector which corresponds to the **Schrödinger** picture state vector at time $t = 0$, i.e., $|\Phi_H\rangle = |\Psi_S(0)\rangle$. For a closed system, i.e., one for which the Hamiltonian H_S in the **Schrödinger picture** is time-independent, there exists a unitary transformation

$$V(t) = e^{iH_S t/\hbar} \quad (\text{c})$$

which effects the transition from the Schrödinger to the Heisenberg picture, with

$$|\Phi_H\rangle = V(t) |\Psi_S(t)\rangle \quad (\text{d})$$

$$F_H(t) = V(t) F_S V^{-1}(t) \quad (\text{e})$$

where it is assumed that the Schrödinger and Heisenberg pictures coincide at time $t = 0$. (It is to be noted that for a closed system $H_S = H_H = H$.) The Heisenberg picture is the one in which the investigation and expression of the **relativistic invariance** of the quantum mechanical equation of motion is usually made. The reason for this is principally that the Schrödinger picture deals only with experiments which are instantaneous in the **inertial frame** which it uses. Such experiments are difficult to express in terms of similar experiments in different inertial systems. Furthermore, in order to define an instantaneous state it must be possible to define a **complete set of commuting observables** which correspond to compatible experiments at a single instant of time. Since it is not at all clear that such a set exists for a relativistic (field) system one

cannot expect that instantaneous states can be defined for such systems. For this reason, as well as for the reason that relativistic covariance can be simply discussed in terms of Heisenberg states, the Heisenberg picture plays an important role in the formulation of relativistic quantum mechanics.

HEISENBERG THEORY OF FERROMAGNETISM. The exchange interaction (see discussion of **exchange energy**) between electrons in neighboring atoms can be shown to depend on the relative orientations of the electronic **spins**. If it should turn out that parallel spins are favored, there is a strong tendency for all the spins in the lattice to become aligned, the transition to the ordered state corresponding to the **Curie point**. The concept of localized spins (e.g., *d*-electrons in the transition metals) is confirmed by neutron diffraction, but the theory is incomplete at the stage of calculating the actual magnitude and sign of the interaction.

HEITLER - LONDON - SLATER - PAULING METHOD. See **valence bond method**.

HEITLER-LONDON THEORY OF VALENCE. Application of the Heitler-London method (see **hydrogen molecule, Heitler-London theory of; valence bond method**) to molecules formed from more complicated atoms for which, however, the calculations can be carried out less rigorously. In the case of molecular states of different multiplicities resulting from two atoms in *S* states, Heitler and London were able to show that the states with the lowest total spin **S** always lie lowest and that the others lie in the order of their multiplicities. In other words, the greater the number of electron pairs with antiparallel spins formed from the unpaired electrons of the separate atoms, the more stable the resulting molecular state will be. Within the limits to which this result can be generalized the valency of a **homopolar bond** is equal to the number of newly formed electron pairs and the valency of an atom equal to the number of unpaired electrons. The representation of the saturation of a homopolar bond as a saturation of electron spins by forming antiparallel pairs corresponds to the empirical concept of chemical bonding by electron pair formation.

HELE-SHAW CELL. A cell enclosing a thin layer of viscous fluid between parallel bound-

aries. If the layer is of uniform thickness and the viscosity large enough for the inertia forces to be negligible (i.e., **Stokes flow**, with low **Reynolds number**) the drag, which is in the opposite direction to the velocity and proportional to it, exactly balances the pressure gradient force and so

$$\mathbf{v} = -\kappa \text{grad } p.$$

The velocity profile across the layer is parabolic and so \mathbf{v} is a representative velocity. κ depends on how \mathbf{v} is defined, on the thickness of the layer, and on the fluid viscosity. The isobars are equipotentials if κ is a constant, and an analogy can be drawn with any two-dimensional problem requiring the solution of **Laplace's equation**, e.g., in magnetism, electrostatics, etc. The lines of flow which may be revealed by coloring the fluid and having glass walls to the cell are analogous with lines of force, etc., in problems with similar boundaries. Variable permeability, etc., may be represented by variable thickness of the cell.

HELICITY. The scalar product $\hat{\sigma} \cdot \hat{\mathbf{p}}$ where $\hat{\sigma}$ is a unit vector in the direction of the particle's spin and $\hat{\mathbf{p}}$ is a unit vector in the direction of the particle's momentum. (See **polarization**.)

HELIUM GAS. Because of its low atomic mass, helium has an appreciable vapor pressure even at low temperatures, its boiling point being 4.2°K. Because of this the **equation of state** of helium can only be obtained properly if one takes quantum effects into account.

HELIUM, LIGHT ISOTOPE OF. The most abundant helium atoms, He_4 , are **bosons**, but the He_3 atoms are **fermions**. This has as a consequence that liquid He_3 does not show superfluidity—a property very probably connected with the **Bose-Einstein statistics** obeyed by the He_4 atoms.

HELIUM, LIQUID. Because of its very large **zero-point energy** helium does not solidify under its own vapor pressure. At 2.2°K it undergoes a phase transition, the **lambda transition**. Below the lambda point it exhibits superfluidity and its viscosity behaves like that of a gas.

Liquid helium near the absolute zero is a quantum-liquid and can be approximately described as being a system of phonons and rotons.

HELIX. A curve traced on a cylindrical or conical surface in such a way that all elements of the surface are cut at a constant angle. A circular helix lies on a right circular cylindrical surface. In **parametric form**, its equation is

$$x = a \cos \theta, \quad y = a \sin \theta, \quad z = b\theta$$

where a, b are constants and θ is a parameter. The thread of a screw is often a circular helix.

HELMHOLTZ DERIVATIVE (Of a scalar $U(x,y,z,t)$ or a vector $\mathbf{A}(x,y,z,t)$.) (Also called Lorentz derivative.) The Helmholtz derivative is defined by the expressions

$$\frac{dU}{dt} = \frac{dU}{dt} + U \text{div } \mathbf{v}$$

and

$$\frac{d\mathbf{A}}{dt} = \frac{d\mathbf{A}}{dt} + \mathbf{A} \text{div } \mathbf{v} + (\mathbf{A} \cdot \nabla) \mathbf{v}.$$

$\frac{dU}{dt}$ and $\frac{d\mathbf{A}}{dt}$ are the total or substantial derivatives with respect to time, \mathbf{v} is the instantaneous velocity of a material particle, the carrier of the scalar property U or the vector property \mathbf{A} . If S is a moving material surface, then

$$\frac{d}{dt} \iint_S U dS = \iint_S \frac{dU}{dt} dS$$

and

$$\frac{d}{dt} \iint_S \mathbf{A} \cdot d\mathbf{S} = \iint_S \frac{d\mathbf{A}}{dt} \cdot d\mathbf{S}.$$

$$\frac{d}{dt} \int_C \mathbf{A} \cdot d\mathbf{r} = \int \left[\frac{\partial \mathbf{A}}{\partial t} + \left\{ (\text{curl } \mathbf{A}) \times \mathbf{v} \right\} \right] \cdot d\mathbf{r}$$

$$\frac{d}{dt} \iiint_V U dV = \iiint_V \left[\frac{\partial U}{\partial t} + \text{div} (U\mathbf{v}) \right] dV$$

HELMHOLTZ EQUATION (FOR OPTICAL MAGNIFICATION). An equation of the form

$$n_1 y_1 \tan \theta_1 = n_2 y_2 \tan \theta_2,$$

expressing the relation between the linear and the angular magnification at a spherical refracting interface. y_1, y_2 are linear dimensions of object and image, θ_1, θ_2 the angles made by focal rays and axis at object and image points and n_1, n_2 are refractive indices of object and image space. Also called

Lagrange-Helmholtz equation. (See, however, the **Abbe sine condition**.) A spherical surface cannot satisfy both these equations for finite angles. Hence a spherical surface can never make a perfect image. (See **Lagrange theorem**.)

HELMHOLTZ EQUATION FOR VORTICITY. An equation which describes the rate of change of vorticity ω in a homogeneous incompressible viscous fluid.

$$\begin{aligned} \frac{D\omega}{Dt} &= \frac{\partial\omega}{\partial t} + (\mathbf{v} \cdot \nabla)\omega \\ &= (\omega \cdot \nabla)\mathbf{v} + \nu \nabla^2 \omega. \end{aligned}$$

In the right-hand side the first term represents the change in vorticity due to stretching or shearing motion in the fluid, and the second term the conduction of vorticity by viscosity.

HELMHOLTZ FLOW. Flow with free streamlines or vortex sheets.

HELMHOLTZ FORMULATION OF HUYGENS PRINCIPLE. Solutions of the wave equation

$$\nabla^2 u = \frac{1}{c^2} \frac{\partial^2 u}{\partial t^2}$$

of the form $u = ve^{-ikct}$ where v is independent of t and solutions of $(\nabla^2 + k^2)v = 0$ are called monochromatic waves. Helmholtz is responsible for the theorem:

Suppose v is a solution of $(\nabla^2 + k^2)v = 0$ with first and second partial derivatives continuous outside and on a closed surface S , and such that $|rv|$ is bounded and

$$r \left(\frac{\partial v}{\partial r} - ikv \right) \rightarrow 0$$

uniformly with respect to θ and ϕ as $r \rightarrow \infty$. Let

$$I(P) = \iint_S \left\{ \frac{e^{ikr}}{r} \frac{\partial v}{\partial \nu} - v \frac{\partial}{\partial \nu} \left(\frac{e^{ikr}}{r} \right) \right\} dS$$

where r is the distance from a fixed point P and $\partial/\partial \nu$ denotes differentiation along the outward normal to S . The value of $I(P)$ is $-4\pi v(P)$ or zero according as P is outside or inside S .

HELMHOLTZ FREE ENERGY. See **Helmholtz function**.

HELMHOLTZ FUNCTION. The potential given by

$$A = U - TS$$

where U is the internal energy, T is the temperature, and S is the entropy. Some authors call this function **free energy** (or the work function). However, it is preferable to use the neutral term **Helmholtz function** because other authors use the term **free energy** to denote the **Gibbs function**, with resulting confusion. (See also **thermodynamics, characteristic functions of**.)

HELMHOLTZ INSTABILITY. (Also called shearing instability.) The hydrodynamic **instability** arising from a shear, or discontinuity, in current speed at the interface between two fluids in two-dimensional motion. The perturbation gains kinetic energy at the expense of that of the basic currents.

According to the theory of **small perturbations**, waves of all wavelengths on such an interface are unstable, their rate of growth being $\exp \mu t$ with μ given by

$$\mu = \frac{\pi}{\lambda} |U - U'|,$$

where λ is the wavelength and U and U' the current speeds of the two fluids. Such waves are called **Helmholtz waves** or *shear waves*, and move with a phase speed c equal to the mean of the current speeds

$$c = \frac{1}{2}(U + U').$$

HELMHOLTZ-KETTELER FORMULA. The dispersion formula:

$$n^2 = 1 + \sum \frac{D'\lambda^2}{\lambda^2 - \lambda_s^2 + G\lambda^2}$$

where D' is a constant, $G\lambda^2$ is the term representing the frictional force, λ is the wavelength and the sum is taken over s , the λ_s being the resonant wavelengths of the medium.

HELMHOLTZ-LAGRANGE FORMULA. See the **Lagrange theorem** and **Helmholtz' equation (for optical magnification)**.

HELMHOLTZ THEOREM. The statement that if \mathbf{F} is a vector field satisfying certain quite general mathematical conditions, then \mathbf{F} is the sum of two vectors, one of which is **irrotational** (has no vorticity), the other **solenoidal** (has no divergence).

HELMHOLTZ WAVES. Unstable waves at a discontinuity of velocity in a fluid, i.e., at a **vortex sheet**. In the simplest case the discontinuity is horizontal and the density above (ρ_1) is less than below (ρ_2) so that the surface is statically stable; then waves of length $2\pi/k$ given by

$$\frac{g}{k} < \frac{\rho_1 \rho_2}{\rho_2 - \rho_1} (U_1 - U_2)^2$$

are unstable when the amplitude is small, where U_1 and U_2 are the velocities of the upper and lower streams, and the streams are deep compared with the wavelength.

Helmholtz waves have been invoked by some authors to explain the flapping of flags, the ruffling of a water surface by wind, and the formation of some forms of billow clouds.

HENCKY-PRANDTL NET. Net of orthogonal systems of slip lines in plane plastic flow of a perfectly plastic material. (See **slip line** for their properties.)

HENNEBERG METHOD. A method of analyzing statically determinate complex trusses by substituting for one of the bars to arrive at a simple truss. This substitute truss first is analyzed under the given loads and next under the action of equal and opposite forces along the bar which was removed. The magnitude and sign of the pair of forces is adjusted to make the total force in the substitute bar equal to zero.

HENRY. See **electromagnetic units**.

HENRY LAW. See **vapor pressure of ideal solutions**.

HEREDITARY MATERIAL. See **viscoelasticity**.

HERMANN-MANGUIN SYMBOLS. A notation sometimes used to describe the **symmetry classes** of crystals. Two-, three-, four- and six-fold **rotation axes** are represented by the numbers 2, 3, 4 and 6. Three-, four- and six-fold **inversion axes** have symbols $\bar{3}$, $\bar{4}$, $\bar{6}$. Asymmetry has the symbol 1. A center of **symmetry** has the symbol $\bar{1}$. A plane of **symmetry** is represented by m (mirror). The first number denotes the **principal axis**. If a plane of symmetry is perpendicular to an axis, this is represented by n/m (e.g., $2/m$, $4/m$, $6/m$). Then follow the symbols for the sec-

ondary axes, if any, and then any other symmetry planes.

HERMITE EQUATION. A second-order differential equation

$$y'' - 2xy' + 2ny = 0$$

where n is a constant. (See **Hermite polynomials**.)

HERMITE INTERPOLATION FORMULA. An **interpolation** formula which makes use of the polynomial of degree $2n + 1$ with prescribed value and prescribed slope at each of the $n + 1$ abscissae

$$x_0, x_1, \dots, x_n,$$

assumed distinct. The polynomial* is

$$H(x) = \sum_0^n [f_i v_i(x) + f'_i w_i(x)] L_i^2(x),$$

where f_i and f'_i are the prescribed values and slopes; where

$$v_i(x) = x - x_i,$$

$$w_i(x) = 1 - w_i(x)\omega''(x_i)/\omega'(x);$$

and where the $L_i(x)$ and $\omega(x)$ occur in the **Lagrange interpolation formula**. More generally, higher derivatives may also be prescribed.

HERMITE POLYNOMIALS. The class of **special functions** obtained by orthogonalizing over the interval $[-\infty, \infty]$ the sequence of powers $1, x, x^2, \dots$, with the weighting function $w(x) = e^{-x^2}$. (Sometimes the weighting function is taken to be $e^{-x^2/2}$, and notations also differ by a factor of $(-1)^n$ or $n!$.) They satisfy the (Hermite) differential equation,

$$y''(x) - 2xy' + 2ny = 0, \quad n = 0, 1, 2, \dots$$

Explicitly they are given by (the normalizing factor is $2^n n! \sqrt{\pi}$)

$$H_0(x) = 1, \quad H_1(x) = 2x,$$

$$H_2(x) = 4x^2 - 2, \quad H_3(x) = 8x^3 - 12x, \dots,$$

$$H_n(x) = (2x)^n - \frac{n(n-1)}{1!} (2x)^{n-2} + \frac{n(n-1)(n-2)(n-3)}{2!} (2x)^{n-4} + \dots$$

Their generating function is $e^{x^2} e^{-(t-x)^2}$. They satisfy the recursion formula

$$H_{n+1}(x) - 2xH_n(x) + 2nH_{n-1}(x) = 0, \quad n \geq 1.$$

Their Rodrigues formula is:

$$H_n(x) = (-1)^n e^{x^2} \frac{d^n e^{-x^2}}{dx^n}.$$

They are useful, e.g., in the problem of the linear oscillator in quantum mechanics. (For a closely associated series much used in statistics, see **Gram-Charlier series**.)

HERMITIAN CONJUGATE. (1) See **Hermitian matrix**; **Hermitian operator**; **representation theory**, **quantum mechanical**.

HERMITIAN MATRIX. A matrix **A** such that $A^* = A$. Its **eigenvalues** (proper values) are all real and it can always be diagonalized. In fact, there exists a unitary matrix **V** such that

$$A = V\Lambda V^*$$

where Λ is diagonal. The computation of the **eigenvalues and eigenvectors** is much simpler, therefore, than in the more general case.

One of the most successful methods is that of *Givens*, which will be described for the symmetric (real) case: Let R_{23} be a matrix that differs from the identity only in the elements (2, 2), (3, 3), (2, 3), and (3, 2), and let

$$\rho_{22} = \cos \phi = \rho_{33}; \quad \rho_{23} = -\rho_{32} = \sin \phi.$$

Then R_{23} is orthogonal, and ϕ can be chosen so that in

$$R_{23}^T A R_{23}$$

the elements in positions (1, 3) and (3, 1) vanish. If a matrix R_{24} is formed analogously, the elements in (1, 4) and (4, 1) can be annihilated without disturbing the zeros previously created. By continuing this process, the final matrix will be tridiagonal in form:

$$T = \begin{pmatrix} \alpha_1 & \beta_1 & 0 & 0 & \cdots \\ \beta_1 & \alpha_2 & \beta_2 & 0 & \cdots \\ 0 & \beta_2 & \alpha_3 & \beta_3 & \cdots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{pmatrix}.$$

The characteristic polynomial can be obtained by means of a very simple recursion:

$$\begin{aligned} \phi_0(\lambda) &= 1, \\ \phi_1(\lambda) &= \lambda - \alpha_1, \\ \phi_2(\lambda) &= (\lambda - \alpha_2)\phi_1(\lambda) - \beta_1^2\phi_0(\lambda), \\ \phi_3(\lambda) &= (\lambda - \alpha_3)\phi_2(\lambda) - \beta_2^2\phi_1(\lambda), \\ &\dots \end{aligned}$$

$\phi_n(\lambda)$ being the required polynomial. However, if every $\beta_i \neq 0$ the polynomials $\phi_i(\lambda)$ form a Sturm sequence, possessing all the properties required for satisfying the **Sturm theorem**.

Consequently, for any μ , by counting the variations in sign of the sequence of values $\phi_i(\mu)$ one can ascertain the precise number of eigenvalues exceeding and exceeded by μ . It is therefore advantageous not to expand the polynomial $\phi(\lambda)$ explicitly, but to proceed as follows for solving the equation: Having found an interval on which one or more roots are known to lie, take consecutive midpoints, evaluating the terms of the sequence for each by means of the recursion.

If the vectors are required, it will be necessary to form the product **R** of all the rotations applied. Then

$$AR = RT,$$

and if **t** is an eigenvector of **T** belonging to λ :

$$Tt = \lambda t,$$

then

$$ARt = RTt = \lambda Rt$$

so that **Rt** is an eigenvector of **A** belonging to λ . (See also **Lanzos method of biorthogonalization**.)

Another method, often called the *Jacobi method*, for computing eigenvalues is iterative in character, and makes use of the fact that the matrix **A** can be transformed to the diagonal form Λ as the limit of an infinite sequence of plane rotations. The rotation matrices R_{ij} are of the same form as before, but the angle ϕ is chosen so that in the matrix

$$R_{ij}^T A R_{ij}$$

the elements vanish in the positions (i, j) and (j, i) . Zeros are not preserved, in general, but the sum of the squares of the diagonal elements is increased by the squares of the annihilated elements at each step. Optimally one should, at each step, annihilate the pair of largest off-diagonal elements, but to reduce the searching one can go through the elements above the diagonal in some sequential order, annihilating all elements greater than some specified magnitude. With successive cycles the level should be decreased. In the limit the product of all the rotation matrices R_{ij} is the matrix **V** of eigenvectors. This method has

been described in detail by von Neumann, Goldstine, and Murray.

HERMITIAN OPERATOR. An operator P , operating in a complex **Hilbert space**, is Hermitian if, for all elements u, v in the space, the following relation holds for scalar products $(Pv, u) = (v, Pu)$. Thus, if (u, v) is defined by

$$(u, v) = \int_a^b u^* P v dx,$$

where u^* is the complex function conjugate to u , then P is Hermitian if

$$\int_a^b u^* \cdot (Pv) dx = \int_a^b v \cdot (Pu)^* dx.$$

All operators of interest in quantum mechanics have this property.

HERMITIAN SCALAR PRODUCT. See **vector space**.

HERMITIAN SPACE. See **vector space**.

HERPOLHODE. The curve along which the cone traced out by the **angular velocity vector** intersects the invariable plane tangent to the momental ellipsoid (see **ellipsoid, momental**) and perpendicular to the angular momentum vector, in the case of a rotating rigid body not subject to any external torque. (See **polhode**.)

HERSCHEL CONDITION. To obtain **Abbe's sine condition** the change in aberration due to a transverse displacement of the object point is investigated and this change is zero if the sine condition is satisfied. Similarly, Herschel's condition is sufficient for the vanishing of the change in aberration due to a longitudinal displacement of the object point. The condition for an axially symmetric optical system is

$$\frac{\sin \frac{1}{2}\theta}{u} = \frac{\sin \frac{1}{2}\theta'}{u'}$$

where u, u' are the angles from the optical axis made by a paraxial ray between the paraxial foci O, O' , and θ, θ' are the angles with the optical axis made by any ray from O to O' . If the object and image are at infinity, i.e., the system is telescopic, the Herschel condition becomes

$$\frac{\rho}{y} = \frac{\rho'}{y'}$$

where ρ, ρ' are the incident heights of a paraxial ray at finite aperture in the plane of the entrance and exit pupils, respectively, and y, y' are the incident heights of the ray in object and image spaces, respectively.

Herschel's condition and Abbe's sine condition cannot simultaneously hold, except for telescopic systems or systems with transverse magnification ± 1 . In these cases the two conditions are equivalent.

HERTZ. A unit of frequency equal to one cycle per second.

HERTZ VECTOR. The integration of Maxwell's equations can be reduced to the determination of a vector potential \mathbf{A} and a scalar potential Φ which in a homogeneous medium satisfy the wave equations

$$\nabla^2 \mathbf{A} - \frac{1}{c^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} = 0$$

$$\nabla^2 \phi - \frac{1}{c^2} \frac{\partial^2 \phi}{\partial t^2} = 0$$

and the Lorentz gauge condition

$$\nabla \cdot \mathbf{A} + \frac{1}{c} \frac{\partial \Phi}{\partial t} = 0.$$

(Whenever the operator ∇^2 precedes a vector quantity it is to be understood that the vector is expressed in Cartesian coordinates.)

Heinrich Hertz has shown that it is possible under ordinary conditions to define the electromagnetic field in terms of a single vector function \mathbf{F} , viz.

$$\mathbf{A} = \frac{1}{c^2} \frac{\partial \mathbf{F}}{\partial t}$$

$$\Phi = \text{div } \mathbf{F}$$

and

$$\mathbf{H} = \frac{1}{c^2} \text{curl } \frac{\partial \mathbf{F}}{\partial t}; \quad \mathbf{E} = -\text{grad } \text{div } \mathbf{F} - \frac{1}{c^2} \frac{\partial^2 \mathbf{F}}{\partial t^2}$$

$$\nabla^2 \mathbf{F} - \frac{1}{c^2} \frac{\partial^2 \mathbf{F}}{\partial t^2} = 0.$$

\mathbf{F} is the Hertz vector.

If the field is generated by a charge distribution $\rho = \rho(\xi, \eta, \zeta, t)$ and a velocity distribution $\mathbf{v} = \mathbf{v}(\xi, \eta, \zeta, t)$ and if

$$\mathbf{p} = \int_0^t \rho \mathbf{v} dt,$$

then

$$F(x,y,z,t) = \iiint \frac{dx dy dz}{r} \mathbf{p}_{t-r/c}$$

where $r = \sqrt{(x - \xi)^2 + (y - \eta)^2 + (z - \zeta)^2}$ and the subscript $t - \frac{r}{c}$ signifies that \mathbf{p} is to be evaluated at the retarded time $\frac{t - r}{c}$. If the charge is concentrated in one point and is oscillating about a fixed point in a fixed direction, the quantity \mathbf{p} represents the dipole moment with respect to this fixed point. If the fixed point is chosen as the origin of the coordinate system ($\xi = \eta = \zeta = 0$) and the fixed direction as the z -axis, then

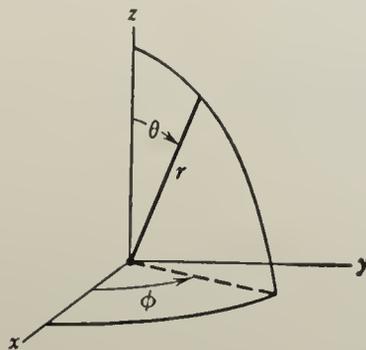

$$p_x = p_y = 0$$

$$p_z = p(t)$$

and

$$\mathbf{F} = \mathbf{k} \frac{p(t - r/c)}{r}$$

In this case it is best to use polar coordinates:

The potentials are given by

$$A_r = \left(\frac{\dot{p}}{cr} \cos \theta \right)_{t-r/c}$$

$$A_\theta = - \left(\frac{\dot{p}}{cr} \sin \theta \right)_{t-r/c}$$

$$A_\phi = 0$$

$$\Phi = \left\{ \frac{\dot{p}}{cr} + \frac{p}{r^2} \right\}_{t-r/c} \cos \theta$$

$$H_r = H_\theta = 0; \quad H_\phi = \frac{\sin \theta}{r} \left\{ \frac{\ddot{p}}{c^2} + \frac{\dot{p}}{cr} \right\}_{t-r/c}$$

$$E_\phi = 0; \quad E_r = 2 \cos \theta \left\{ \frac{\dot{p}}{cr^2} + \frac{p}{r^3} \right\}_{t-r/c}$$

$$E_\theta = \left[\frac{\dot{p}}{c^2 r} \sin \theta + \left(\frac{\dot{p}}{cr^2} + \frac{p}{r^3} \right) \sin \theta \right]_{t-r/c}$$

A dot means partial derivative with respect to time. The field in the "near-zone" is given by

$$H_\phi = \frac{\dot{p}}{cr^2} \sin \theta$$

$$E_r = \frac{2p}{r^3} \cos \theta; \quad E_\theta = \frac{p}{r^3} \sin \theta.$$

It is understood that unretarded values are used in this case. This is the field of a current \dot{p} and a static dipole p . The field in the "far-zone" or "wave-zone" is given by

$$H_r = H_\theta = 0; \quad E_r = 0; \quad E_\phi = 0;$$

$$H_\phi = \left\{ \frac{\ddot{p}}{rc^2} \sin \theta \right\}_{t-r/c}; \quad E_\theta = \left\{ \frac{\ddot{p}}{rc^2} \sin \theta \right\}_{t-r/c}.$$

The total radiation per unit time is given by

$$S = \frac{2}{3c^3} (\ddot{p})^2_{t-r/c}.$$

An accelerated charge emits not only radiation but also angular momentum. The amount of angular momentum radiated per unit time is

$$\mathbf{M} = \frac{2}{3c^3} \left[\mathbf{p} \times \dot{\mathbf{p}} \right]_{t-r/c}$$

HERZBERGER DISPERSION FORMULA.

The dispersion formula for the index of refraction

$$n = \mu_0 + \mu_1 \lambda^2 + \mu_2 (\lambda^2 - 0.035)^{-1} + \mu_3 (\lambda^2 - 0.035)^{-2}$$

is due to Herzberger. The μ_i are empirical constants.

HESSEBERG METHOD. See **eigenvalues and eigenvectors.**

HESSE NORMAL FORM.

Most of the standard forms, $y = mx + b$; $Ax + By + C = 0$, etc., of equation for the straight line in analytic geometry suffer from the defect that they fail to represent certain lines ($y = mx + b$ does not represent a vertical line) or else that many different equations (e.g., $Ax + By + C = 0$ and $2Ax + 2By + 2C = 0$) represent the same straight line. Hesse's normal form is constructed with the purpose that exactly one such equation shall correspond to each straight line; it is obtained from $Ax + By + C = 0$ in the following way. By division, if necessary, by -1 it is arranged that: if

$C \neq 0$, then $C > 0$; if $C = 0$, $B \neq 0$, then $B > 0$; if $C = B = 0$, then $A > 0$; and the equation is then divided by the normalizer factor $\sqrt{A^2 + B^2}$. Hesse's normal form is of considerable practical importance in the problem of finding the distance from a point to a line.

HESSIAN. The Hessian of a function $F(x_1, x_2, \dots, x_n)$ of n variables is the functional determinant,

$$\begin{vmatrix} F_{1,1} & F_{1,2} & \cdots & F_{1,n} \\ F_{2,1} & F_{2,2} & \cdots & F_{2,n} \\ \vdots & \vdots & & \vdots \\ F_{n,1} & F_{n,2} & \cdots & F_{n,n} \end{vmatrix}$$

where $F_{ij} = \partial^2 F / \partial x_i \partial x_j$. It is to be noted that the Hessian of F is the **Jacobian** of the n functions $\partial F / \partial x_1, \partial F / \partial x_2, \dots, \partial F / \partial x_n$.

HESS LAW. The heats of reaction may be added in the same way as the equations for chemical reactions. This fact is of use when the heat of a particular reaction is difficult to measure experimentally, but the reaction can be split into other reactions whose heats are more easily determined.

HETEROPOLAR BOND. (Also called ionic bond or electrovalent bond.) The chemical bond between two ions of opposite charge, produced by the classical electrostatic attraction. For two pointlike ions of charge ϵ ($= 4.8024 \times 10^{-10}$ esu) at distance r from each other, the potential energy, according to Coulomb's law, is

$$V = -\frac{\epsilon^2}{r} = -\frac{11.615}{r} \times 10^4,$$

where the numerical factor gives V in cm^{-1} if r is substituted in Angstrom units. As a result of the finite extent of the actual ions, a deviation from the simple Coulomb law takes place at small internuclear distances. The deviation is always in the sense of a repulsion and can be represented by an exponential term, so that

$$V = -\frac{\epsilon^2}{r} + Be^{-r/\rho},$$

where B and ρ are constants. ρ is a measure of the sum of the radii of the ions under consideration. (For more detail see G. Herzberg,

Molecular Spectra and Molecular Structure, I, Spectra of Diatomic Molecules, 2d ed., D. Van Nostrand Co., Inc., Princeton, 1950.)

HEXAGONAL CLOSE-PACKED STRUCTURE. A crystal structure obtained by packing together equal spheres as follows: A layer is made by placing each sphere in contact with six others. A second layer is added by placing each sphere in contact with three spheres of the bottom layer. In the third layer, the spheres go directly above those in the first layer—and so on. (See also **close-packed structure**.)

HEXAGONAL SYSTEM. One of the seven crystal systems. In this system, three equal axes are coplanar at 60° , fourth axis is at right angles to the other three.

HICKS FORMULA. A formula developed from the original Rydberg formula for a more accurate representation of the observed wave numbers ν_n in atomic line series. Hicks' formula is:

$$\nu_n = \nu_\infty - \frac{R}{\left[n + \mu + \frac{a}{n} + \frac{b}{n^2} + \frac{c}{n^3} + \cdots \right]^2}$$

where a, b, c, \dots are constants. (For the meaning of the other symbols, see **Rydberg equation**.)

HIDDEN COORDINATES. (See derivation of **Hamilton-Jacobi partial differential equation**.) It may happen that some of the coordinates $q_1 q_2 \dots$ are not explicitly contained in the **Lagrangian**, although the velocities $\frac{dq_1}{dt}, \frac{dq_2}{dt}, \dots$ are so contained. Such coordinates are called *hidden, ignorable* or *cyclic*. Their corresponding conjugate momenta are constants of motion: Example: the angular position of a particle rotating along a circle with uniform angular velocity. The angle does not occur in the Lagrangian.

HIGH ELASTICITY. See **elasticity, high**.

HIGHER IGNITION LIMIT. See **ignition limit**.

HIGHEST COMMON FACTOR. The highest common factor of two polynomials, P_0 and P_1 , is the polynomial of greatest degree that divides both. In case this is a constant, the polynomials are said to be relatively prime.

It can be found by applying the Euclidean algorithm: Supposing the degree of P_1 not exceeding that of P_0 , divide P_1 into P_0 and let $-P_2$ represent the remainder; divide P_2 into P_1 with $-P_3$ the remainder; \dots ; then if $P_i \neq 0$, $P_{i+1} = 0$, P_i is the highest common factor. This is represented

$$\begin{aligned} P_0 &= Q_1 P_1 - P_2, \\ P_1 &= Q_2 P_2 - P_3, \\ &\dots \dots \dots \\ P_{i-1} &= Q_i P_i. \end{aligned}$$

HILBERT SPACE. A space which is linear, metric and complete. (See under Euclidean space, and under complete.) Usually a Hilbert space is also taken to be infinite-dimensional; that is, for any integer n there exist n linearly independent points (or vectors) in the space; and also separable, that is, there exists a sequence of points which is everywhere dense in the space. The most important realizations of a Hilbert space are the set of all sequences $(x_1, x_2, \dots, x_n, \dots)$ such that $(x_1^2 + x_2^2 + \dots + x_n^2 + \dots)$ is convergent, and the set of measurable functions f integrable in square over a fundamental interval; that is, such that $\int_a^b f^2(x) dx$ is integrable in the sense of Lebesgue.

HILBERT TRANSFORM. The integral transform defined by

$$\begin{aligned} f(x) &= \frac{1}{2\pi} \int_{-\pi}^{\pi} \left[1 + \cot \frac{(x-y)}{2} \right] \phi(y) dy \\ \phi(y) &= \frac{1}{2\pi} \int_{-\pi}^{\pi} \left[1 + \cot \frac{(x-y)}{2} \right] f(x) dx. \end{aligned}$$

(See also integral transform.)

HINDERED ROTATION AROUND A SINGLE BOND. According to elementary theories, the σ C—C single bond in ethane, propane, acetaldehyde, etc., should be axially symmetrical. One observes, however, that the relative rotation of the two groups around this bond is not free, but hindered by a potential barrier of the order of 1–3 kcal, which must be crossed over whenever the mutual orientation of the groups is changed by about 20° .

HINGE. A support or junction point in a structure at which there is no restraint against rotation. The bending moment or end moment is zero at a hinge, but shear and axial

force generally can be transmitted across a hinge.

HINGED ARCH. See arch.

HINGE, PLASTIC. When the limit moment is reached in a beam of perfectly plastic material, rotation can take place under constant moment. At such a plastic hinge, no additional moment is required to produce rotation, while at an actual hinge no moment at all is needed. (See mechanism; method of analysis of frames.)

HITCHCOCK METHOD. A method for finding complex roots of an algebraic equation. (See Bairstow method.)

HITCHCOCK TRANSPORTATION PROBLEM. See transportation problem.

H-L-S-P (HEITLER-LONDON-SLATER-PAULING) METHOD. See valence bond method.

H-M-H (HUND-MULLIKEN-HÜCKEL) METHOD. See molecular orbitals method.

HODOGRAPH. The curve formed by the ends of the velocity vectors of a moving particle, when all the vectors are drawn from a common point.

HODOGRAPH EQUATIONS, TRANSONIC. See transonic hodograph equations.

HODOGRAPH TRANSFORMATION. A transformation of the x, y -plane into the u, v -plane where x, y are the independent, and u, v the dependent variables in the differential equations of gas dynamics. In certain gases, it transforms the equations into linear ones.

HOFF CONVERGENCE METHOD. The stability of a rigid-jointed truss under a given set of loads is checked by applying an arbitrary moment at any joint and determining the end moments everywhere by moment distribution. Stiffness and carry-over factors are computed, taking axial force into account. If the moment distribution process converges and the answer is unique, the truss is stable. Uniqueness can be checked by changing the order of balancing of joints.

HOHLRAUM. See black body.

HÖLDER CONDITION. A function $f(x)$ satisfies a Hölder condition at a point a if

there exist constants c and k such that $|f(x) - f(a)| < c|x - a|^k$ for all x in some neighborhood of a . (Compare **Lipschitz condition**.)

HÖLDER INEQUALITY. A generalization of the **Schwarz inequality**; thus for real numbers,

$$|a_1b_1 + \cdots + a_nb_n| \leq \{ |a_1|^p + \cdots + |a_n|^p \}^{1/p} \{ |b_1|^q + \cdots + |b_n|^q \}^{1/q},$$

and for real functions,

$$\left| \int_a^b f(x)g(x)dx \right| \leq \left\{ \int |f(x)|^p dx \right\}^{1/p} \cdot \left\{ \int |g(x)|^q dx \right\}^{1/q}$$

with

$$\frac{1}{p} + \frac{1}{q} = 1.$$

These formulas give the **Schwarz inequality** for the case $p = q = 2$.

“HOLE.” In general, a state or **energy level** not occupied by a particle, particularly when adjacent levels are filled. The term is applied particularly to the case of electrons in a metal, or **semiconductor**, where it is more convenient to describe an **energy band** as containing just a few holes, rather than as nearly full of electrons. This usage is reinforced by the circumstance that the electrons in such states, near the top of a band, have anomalous properties, such as negative **effective mass**, whereas the holes, representing the absence of such anomalous electrons, are mobile, and behave otherwise as if they were normal particles (although, of course, of opposite electric charge).

For the application of the term in particle theory, see entry following.

HOLE THEORY. The theory proposed by Dirac in 1930 to resolve the difficulty associated with the negative energy solutions of the **Dirac equation**. The latter admits both positive and negative energy solutions. The meaning of a negative energy particle is, however, not clear. A negative energy particle if it existed, would have a negative rest mass, and it would be accelerated in a direction opposite to that of the external force. No such particles are known to exist in nature. In the presence of an external field the Dirac equa-

tion predicts a finite probability for a transition from a positive energy state to a negative energy one. Furthermore, in order to guarantee energy conservation, such transitions (from a positive to a negative energy state) would be to have to release an amount of energy of the order of $2mc^2$, where m is the mass of the particle. Such transitions are never observed. To resolve this difficulty Dirac advanced the **hole theory** in which he assumed that all the negative energy states are occupied with one particle in each state in accordance with the **Pauli exclusion principle**. If this is so, the exclusion principle also makes it impossible for positive energy particles to make transitions to negative energy states (since they are all occupied), unless they are first emptied by some means. Such an unoccupied negative energy state will now appear as something with positive energy, since to make it disappear, i.e., to fill the unoccupied state up, we would have to add to it a negative energy particle. Similarly, the charge of the “hole” (i.e., of the unoccupied negative energy state) would be opposite of that of the positive energy particle.

In his original formulation, which identified the electron as the positive energy particle, Dirac envisaged an electron distribution of negative density everywhere in the world, with a perfect vacuum having all states of negative energy occupied, and all states of positive energy unoccupied. One difficulty encountered with this assumption involves the enormous charge density contributed by the negative energy states. In the modern version of the theory, as developed by Heisenberg, Kramers and others, this difficulty is overcome and there exists a complete symmetry between particles and **anti-particles** (“hole”).

Dirac’s hole theory predicts the possibility of “pair creation” (i.e., the simultaneous creation of a particle anti-particle pair) if enough energy is supplied by a γ -ray (or otherwise) to lift an electron from a negative energy state to a positive energy state, i.e., if the energy of the γ -ray is greater than $2mc^2$. The hole theory, in fact, predicts electromagnetic effects even if the energy is less than $2mc^2$ because the electromagnetic field will cause redistribution of charge and thus give rise to a “**polarization of the vacuum**.”

The correctness of the hole theoretic interpretation of the spin $\frac{1}{2}$ Dirac equation as

applied to electrons, neutrinos, μ -mesons, protons, neutrons, Λ and Σ particles has been established experimentally by the verification of the existence of positrons (the anti-particle in the case of electrons), anti-neutrons, μ -particles, anti-protons, anti-neutrons, anti- Λ and anti- Σ particles. The existence of electronic vacuum polarization effects has also been established experimentally, particularly through a contribution to the **Lamb shift**, by the fine structure of the positronium ground state and by the level shifts of mesic atoms.

HOLLOW BOX. See **black body**.

HOLOMORPHIC FUNCTION. A function is said to be holomorphic (or regular) in a region S of the complex plane if it has a derivative at every point of S .

HOLONOMIC MOTION. Motion is holonomic when the differential equations of constraint are integrable, *non-holonomic* if they are not.

HOLTE METHOD. In the theory of the slowing down of neutrons at large distances from a source, this method is the most powerful and general of the analytical methods. It is based upon analytical continuation in the plane of the energy-transform variable, and unlike the methods of **Bethe** and of **Wick** may be extended to the case of a medium having energy-dependent cross sections.

HOMEOMORPHIC GRAPHS. See **graphs**, **homeomorphic**.

HOMOCENTRIC. A pencil of rays is homocentric or *stigmatic* if the rays are concurrent in a point other than the **object point**.

HOMOGENEOUS. A function $f(x_1, x_2, \dots, x_n)$ is homogeneous in all of its variables if, for any parameter t , $f(tx_1, tx_2, \dots, tx_n) = t^n f(x_1, x_2, \dots, x_n)$. The exponent n is the order of the function. The Euler theorem on homogeneous functions states that for such a function

$$x_1 \frac{\partial f}{\partial x_1} + \dots + x_n \frac{\partial f}{\partial x_n} = nf.$$

The term is used with two meanings for a differential equation: (1) A first-order equation, $y' = M(x,y)/N(x,y)$ is a homogeneous equation if M, N are homogeneous functions of the same degree. (2) The general equation,

$f(x,y,y',y'',\dots) = 0$ is homogeneous and linear if f is a homogeneous linear function of y and all its derivatives. If the right-hand side equals a function of x , the independent variable, it is still linear but now inhomogeneous.

An **integral equation**, a **boundary condition**, or a system of simultaneous linear algebraic equations can also be homogeneous or inhomogeneous in a similar way.

HOMOGENEOUS AFFINE TRANSFORMATION. See **affine transformation**.

HOMOGENEOUS DEFORMATION. A deformation in which a particle initially at X_i in a rectangular Cartesian reference system x moves to x_i in the same system, where

$$x_i = b_i + a_{ij}X_j$$

where b_i and a_{ij} are constants and the **indicial notation** and **summation convention** are used.

HOMOGENEOUS FUNCTIONS IN THERMODYNAMICS. See **Euler theorem**.

HOMOGENEOUS LORENTZ TRANSFORMATION. The linear transformation which relates the space-time coordinates $x^\mu = \{x^0 = ct, x^1, x^2, x^3\}$ of an event as seen by an observer S to the space-time coordinates x'^μ of the same event as seen by an observer S' . The most general homogeneous Lorentz transformation is the linear transformation

$$x'^\mu = \sum_{\nu=0}^3 \Lambda^\mu{}_\nu x^\nu \quad (a)$$

(where $x^\mu = \{x^0 = ct, x^1, x^2, x^3\}$) which leaves the quadratic form

$$\begin{aligned} x^2 &= \sum_{\mu=0}^3 x^\mu x_\mu = (x^0)^2 - \mathbf{x}^2 \\ &= (x^0)^2 - (x^1)^2 - (x^2)^2 - (x^3)^2 \end{aligned} \quad (b)$$

invariant, i.e., for which $x^2 = x'^2$. The requirement that $x'^2 = x^2$ is the mathematical statement of the fact that light propagates with the same speed, c , with respect to both 0 and $0'$. In (a) the transformation coefficients Λ_μ^ν are all real. The condition that the quadratic form x^2 be invariant requires that

$$\sum_{\mu,\rho=0}^3 \Lambda_\nu{}^\mu g_{\mu\rho} \Lambda_\sigma{}^\rho = g_{\nu\sigma} \quad (c)$$

or in matrix form

$$\Lambda^T g \Lambda = g \quad (d)$$

where $g_{\mu\nu}$ is the **metric tensor** with components

$$g_{00} = -g_{11} = -g_{22} = -g_{33} = +1$$

$$g_{\mu\nu} = 0 \quad \text{for } \mu \neq \nu. \quad (e)$$

It follows from Equation (d) that $\det \Lambda = \pm 1$ and therefore for every homogeneous Lorentz transformation there exists an inverse transformation Λ^{-1} such that $\Lambda^{-1}\Lambda = 1$, the identity transformation corresponding to $S = S'$. The product of two homogeneous Lorentz transformations is again a homogeneous Lorentz transformation so that the set of all homogeneous Lorentz transformations form a **group**: the **homogeneous Lorentz group**.

By setting $\sigma = \nu = 0$ in Equation (c) one obtains

$$(\Lambda_0^0)^2 = 1 + \sum_{i=1}^3 (\Lambda_0^i)^2$$

$$\geq 1$$

so that $\Lambda_0^0 \geq 1$ or $\Lambda_0^0 \leq -1$. A Lorentz transformation for which $\Lambda_0^0 \geq 1$ is called an **orthochronous homogeneous Lorentz transformation**.

The set of all Λ can be divided into four subsets according to whether $\det \Lambda$ equals plus or minus one and Λ_0^0 is greater than +1 or less than -1. The subset with $\det \Lambda = +1$ and $\Lambda_0^0 \geq 1$ is called the group of restricted homogeneous Lorentz transformations and is a 6-parameter continuous group. The other subsets can be obtained by adjoining to the restricted homogeneous Lorentz group the following three (discrete) transformations:

(a) Space Inversion: $x_0 \rightarrow x'_0 = x_0$; $\mathbf{x} \rightarrow \mathbf{x}' = -\mathbf{x}$

$$\Lambda(i_s) = \begin{pmatrix} 1 & & & \\ & -1 & & \\ & & -1 & \\ & & & -1 \end{pmatrix}$$

$$\det \Lambda(i_s) = -1 \quad \Lambda_0^0 \geq 1$$

(b) Time Inversion: $x_0 \rightarrow x'_0 = -x_0$; $\mathbf{x} \rightarrow \mathbf{x}' = \mathbf{x}$

$$\Lambda(i_t) = \begin{pmatrix} -1 & & & \\ & 1 & & \\ & & 1 & \\ & & & 1 \end{pmatrix}$$

$$\det \Lambda(i_t) = -1 \quad \Lambda_0^0 \leq -1$$

(c) Space-Time Inversion: $x' = -x$

$$\Lambda(i_{st}) = \Lambda(i_s)\Lambda(i_t)$$

$$= \begin{pmatrix} -1 & & & \\ & -1 & & \\ & & -1 & \\ & & & -1 \end{pmatrix}$$

$$\det \Lambda(i_{st}) = +1 \quad \Lambda_0^0 = -1$$

These subsets are disjoint and are not continuously connected.

HOMOGENEOUS PROCESS. A **stochastic process** $\{x(t)\}$ is homogeneous in t if the probability of transition from state $x(t_1)$ to $x(t_2)$ depends only on the difference $t_2 - t_1$.

HOMOGRAPHIC TRANSFORMATION. A homographic (also called linear or linear fractional) transformation of a complex variable z is a transformation of the form

$$w = \frac{az + b}{cz + d}$$

with constants a, b, c, d such that $ad - bc \neq 0$. Any three points α, β, γ may be transformed by a (uniquely determined) homographic transformation into any three others α', β', γ' . (See also **homogeneous Lorentz transformation**.)

HOMOMETRIC PAIRS. Two **crystal structures** having the same X-ray diffraction pattern. This is possible because, basically, a diffraction pattern depends only on the relative vector distances between the atoms in the lattice, not on their absolute positions in space.

HOMOMORPHISM. A mapping of a group G onto a group G' such that products are mapped onto products, i.e., such that, if $a \rightarrow a'$ and $b \rightarrow b'$, then $ab \rightarrow a'b'$. If the mapping is one-to-one it is called an *isomorphism*. A homomorphism (isomorphism) of a group into itself is called an *endomorphism* (*automorphism*).

HOMOPOLAR BOND. See **atomic bond**.

HOMOTOPIC. See **deformation**.

HOOKE'S LAW. The concept of the proportionality of stress to strain as a suitable description of the behavior of most materials in

the elastic range. (See Hooke's law, generalized; elastic constants.)

HOOKE'S LAW, GENERALIZED. Each of the six components of stress at a point of a body is a linear function of the six components of (infinitesimal) strain at that point. The law is valid for a large number of hard materials over a range of strain of practical interest. For isotropic materials the law takes the following form in a rectangular Cartesian coordinate system:

$$\sigma_{ij} = 2\mu e_{ij} + \lambda e_{kk} \delta_{ij},$$

where σ_{ij} and e_{ij} are the components of stress and strain respectively in the system, δ_{ij} is the **Kronecker delta** and the **summation convention** is used. λ and μ are then physical constants for the particular material to which the equation applies and are called the Lamé constants. μ is also known as the *rigidity modulus*, *rigidity*, or *sheer modulus* for the material.

HOOP STRESS. See stress, circumferential.

HORIZONTAL SHEAR. See shear, horizontal.

HORN EQUATION, FUNDAMENTAL. A horn is a passive acoustical transducer consisting of a tube of varying sectional area. The fundamental wave equation for axial motion in tube of varying section is

$$\ddot{\phi} - c^2 \frac{\partial \phi}{\partial x} \frac{\partial}{\partial x} (\log S) - c^2 \frac{\partial^2 \phi}{\partial x^2} = 0$$

where ϕ is the velocity potential, c is the velocity of sound, in centimeters per second, S is the cross-sectional area at a point x along the axis, in square centimeters, and x is the distance along the axis of the horn, in centimeters.

HORNER METHOD (FOR OBTAINING IRRATIONAL ROOTS OF AN ALGEBRAIC EQUATION). Given that a particular root is located between consecutive integers n_0 and $n_0 + 1$, reduce the roots by n_0 . Then locate the root between consecutive tenths, say $n_1/10$ and $(n_1 + 1)/10$, $0 \leq n_1 \leq 9$, and reduce by $n_1/10$. By continuing, the root can be determined as

$$n_0 + n_1 10^{-1} + n_2 10^{-2} + \dots$$

to as many decimals as desired (see **synthetic division**). For hand computation the method

is not to be recommended, but with a binary machine the method takes the form of successive bisection of an interval on which a root is known to lie, in order to obtain successive binary digits, and the method is often very effective. (See **algebraic equations**.)

HORN, FINITE CONICAL. The acoustical impedance at the throat of a finite conical horn may be obtained in a manner similar to the procedure for the finite cylindrical horn in the following entry by employing the equations for the pressure and velocity in an infinite conical horn and applying the proper boundary conditions. The expression for the acoustical impedance, z_{A1} , at the throat in terms of the dimensions of the horn and the acoustical impedance, z_{A2} , at the mouth is

$$z_{A1} = \frac{\rho c}{S_1} \left[\frac{jz_{A2} \frac{\sin k(l - \theta_2)}{\sin k\theta_2} + \frac{\rho c}{S_2} \sin kl}{\left\{ \begin{array}{l} z_{A2} \frac{\sin k(l + \theta_1 - \theta_2)}{\sin k\theta_1 \sin k\theta_2} \\ - \frac{j\rho c \sin k(l + \theta_1)}{S_2 \sin k\theta_1} \end{array} \right\}} \right] \quad (1)$$

where z_{A1} is acoustical impedance at the throat, in acoustical ohms, S_1 is the area of the throat, in square centimeters, S_2 is the area of the mouth, in square centimeters, l is the length of the horn, in centimeters, $k\theta_1$ is $\tan^{-1} kx_1$, $k\theta_2$ is $\tan^{-1} kx_2$, x_1 is the distance from the apex to the throat, in centimeters, x_2 is the distance from the apex to the mouth, in centimeters, k is $2\pi/\lambda$, λ is the wavelength, in centimeters, c is the velocity of sound, in centimeters per second, ρ is the density of air in grams per cubic centimeter, z_{A2} is the acoustical impedance at the mouth, in acoustical ohms.

The acoustical impedance at the mouth of the horn is usually assumed to be the same as that of a piston in an infinite baffle. In this case the mouth acoustical impedance, z_{A2} , is given by Equation 5 of **mechanical and acoustical impedance load upon a vibrating piston**.

HORN, FINITE CYLINDRICAL. The acoustical impedance at the throat of the finite cylindrical horn is

$$z_{A1} = \frac{p_1}{U_1} \quad (1)$$

where z_{A1} is the acoustical impedance, in acoustical ohms, p_1 is the pressure at the throat, in dynes per square centimeter, and U_1 is the volume current, in cubic centimeters per second.

The acoustical impedance, at the mouth of a cylindrical horn is

$$z_{A2} = \frac{p_2}{U_2} \quad (2)$$

where z_{A2} is the acoustical impedance, in acoustical ohms, p_2 is the pressure at the mouth, in dynes per square centimeter, and U_2 is the volume current, in cubic centimeters per second.

From Equations 4 and 5 of **horn, infinite cylindrical** the expressions for the pressures and volume currents at the throat and mouth are given by

$$\text{At } x = 0, \quad p_1 = kc\rho A e^{jkt} \quad (3)$$

$$U_1 = S_1 k A e^{jkt} \quad (4)$$

$$\text{At } x = l, \quad p_2 = kc\rho A e^{jk(ct-l)} \quad (5)$$

$$U_2 = S_1 k A e^{jk(ct-l)}. \quad (6)$$

From Equations 1, 2, 3, 4, 5 and 6 the expression for the acoustical impedance, z_{A1} , at the throat in terms of the length and cross-sectional area of the horn and the acoustical impedance, z_{A2} , at the mouth is

$$z_{A1} = \frac{\rho c}{S_1} \left(\frac{S_1 z_{A2} \cos(kl) + j\rho c \sin(kl)}{jS_1 z_{A2} \sin(kl) + \rho c \cos(kl)} \right) \quad (7)$$

where ρ is the density of the medium, in grams per cubic centimeter, k is $2\pi/\lambda$, λ is the wavelength, in centimeters, c is the velocity of sound, in centimeters per second, S_1 is the cross-sectional area of the pipe, in square centimeters, l is the length of the pipe, in centimeters, and z_{A2} is the acoustical impedance at the mouth, in acoustical ohms.

The acoustical impedance at the mouth of the horn is usually assumed to be the same as that of a piston in an infinite baffle. In this case the mouth acoustical impedance, z_{A2} , is given by Equation 5 of **mechanical and acoustical impedance load upon a vibrating piston**.

HORN, FINITE EXPONENTIAL. The acoustical impedance at the throat of a finite exponential horn may be obtained in a manner similar to the procedure for the finite cylindrical horn in the preceding entry by employing the equations for the pressure and

velocity in an infinite exponential horn and applying the proper boundary conditions. The expression for the acoustical impedance, z_{A1} , at the throat in terms of the length and flare constant of the horn and the acoustical impedance, z_{A2} , at the mouth is

$$z_{A1} = \frac{\rho c}{S_1} \left[\frac{S_2 z_{A2} [\cos(bl + \theta)] + j\rho c [\sin(bl)]}{jS_2 z_{A2} [\sin(bl)] + \rho c [\cos(bl - \theta)]} \right] \quad (1)$$

where z_{A1} is the acoustical impedance at throat, in acoustical ohms, S_1 is the area of the throat, in square centimeters, S_2 is the area of the mouth, in square centimeters, l is the length of the horn, in centimeters, z_{A2} is the acoustical impedance of the mouth, in acoustical ohms, θ is $\tan^{-1} a/b$, a is $m/2$, and b is $\frac{1}{2}\sqrt{4k^2 - m^2}$.

For $b = 0$, Equation 1 is indeterminate. To evaluate, take the derivative of the numerator and denominator with respect to b and set $b = 0$. Then the expression for the throat acoustical impedance becomes

$$z_{A1} = \frac{\rho c}{S_1} \left[\frac{z_{A2} \left(1 - \frac{ml}{2}\right) + j \frac{\rho c}{S_2} \frac{lm}{2}}{jz_{A2} \frac{lm}{2} + \frac{\rho c}{S_2} \left(1 + \frac{ml}{2}\right)} \right] \quad (2)$$

Below the frequency range corresponding to $b_1 = 0$, b_1 is imaginary. For evaluating this portion of the frequency range the following relations are useful:

$$\begin{aligned} \tan^{-1} jA &= j \tanh^{-1} A \\ &= \frac{1}{2}j[\log \epsilon(1 + A) - \log \epsilon(1 - A)] \end{aligned} \quad (3)$$

$$\begin{aligned} \log \epsilon(-1) &= \pm j\pi(2K + 1), \\ K &= \text{any integer} \end{aligned} \quad (4)$$

$$\cos(A \pm jB) = \cos A \cosh B \mp j \sin A \sinh B \quad (5)$$

$$\sin jA = j \sinh A \quad (6)$$

The acoustical impedance at the mouth of the horn is usually assumed to be the same as that of a piston in an infinite baffle. In this case the mouth acoustical impedance, z_{A2} , is given by Equation 5 of **mechanical and acoustical impedance load upon a vibrating piston**.

HORN, INFINITE CONICAL. The equation expressing the cross-sectional area as a function of the distance along the axis is

$$S = S_1 x^2 \tag{1}$$

where S is the cross-sectional area at x , in square centimeters, x is the distance along the horn axis, in centimeters, and S_1 is the cross-sectional area at x_1 , in square centimeters.

The general horn equation for the conical horn from Equation 1 and the fundamental horn equation (see **horn equation, fundamental**) is

$$\ddot{\phi} - \frac{2c^2}{x} \frac{\partial \phi}{\partial x} - c^2 \frac{\partial^2 \phi}{\partial x^2} = 0. \tag{2}$$

The velocity potential, pressure, and volume current are

$$\phi = \frac{A}{x} \epsilon^{j(\omega t - kx)} \tag{3}$$

$$p = -\frac{j\omega\rho A}{x} \epsilon^{j(\omega t - kx)} \tag{4}$$

$$U = -\frac{AS(1 + jkx)\epsilon^{j(\omega t - kx)}}{x^2} \tag{5}$$

where ϕ is the velocity potential, A is the amplitude of ϕ , p is the sound pressure, in dynes per square centimeter, U is the volume current, in cubic centimeters per second, ρ is the density of the medium, in grams per cubic centimeter, ω is $2\pi f$, f is the frequency, in cycles per second, t is the time, in seconds, k is $2\pi/\lambda$, λ is the wavelength, in centimeters, c is the velocity of sound, in centimeters per second.

The real and imaginary components of the acoustical impedance, in acoustical ohms, at the throat are

$$r_A = \frac{\rho c}{S_1} \frac{k^2 x_1^2}{1 + k^2 x_1^2} \tag{6}$$

$$x_A = \frac{\rho c}{S_1} \frac{kx_1}{1 + k^2 x_1^2} \tag{7}$$

where r_A is the acoustical resistance, in acoustical ohms, x_A is the acoustical reactance, in acoustical ohms, S_1 is the area at x_1 , in square centimeters, x_1 is the distance of throat from $x = 0$, in centimeters.

HORN, INFINITE CYLINDRICAL (INFINITE PIPE). The equation expressing the cross-sectional area as a function of the distance along the axis is

$$S = S_1 \tag{1}$$

where S_1 is the cross section of the pipe, in square centimeters.

The general horn equation for the infinite pipe from Equation 1 and the fundamental horn equation is

$$\ddot{\phi} - c^2 \frac{\partial^2 \phi}{\partial x^2} = 0. \tag{2}$$

The velocity potential, pressure, and volume current are

$$\phi = A \epsilon^{jk(ct-x)} \tag{3}$$

$$p = kc\rho A \epsilon^{jk(ct-x)} \tag{4}$$

$$U = S_1 k A \epsilon^{jk(ct-x)} \tag{5}$$

where ϕ is the velocity potential, A is the amplitude of ϕ , x is the distance along the axis, in centimeters, p is the sound pressure, in dynes per square centimeter, U is the volume current, in cubic centimeters per second, t is time, in seconds, k is $2\pi/\lambda$, λ is the wavelength, in centimeters, ρ is the density of the medium, in grams per cubic centimeter and c is the velocity of sound, in centimeters per second.

The real and imaginary components of the acoustical impedance at the throat or input end of the pipe are

$$r_A = \frac{\rho c}{S_1} \tag{6}$$

$$x_A = 0 \tag{7}$$

where r_A is the acoustical resistance, in acoustical ohms, and x_A is acoustical reactance, in acoustical ohms.

HORN, INFINITE EXPONENTIAL. The equation expressing the cross-sectional area as a function of the distance along the axis

$$S = S_1 \epsilon^{mx} \tag{1}$$

where S is the cross-sectional area at x , in square centimeters, x is the distance along the axis, in centimeters, S_1 is the cross-sectional area at the throat, that is, $x = 0$, in square centimeters, and m is the flaring constant.

The general horn equation for the exponential horn from Equation 1 and the fundamental horn equation is

$$\ddot{\phi} - c^2 m \frac{\partial \phi}{\partial x} - c^2 \frac{\partial^2 \phi}{\partial x^2} = 0. \tag{2}$$

The velocity potential, pressure, and volume current are

$$\phi = \epsilon^{-(m/2)x} \left[A \epsilon^{-j \frac{\sqrt{4k^2 - m^2}}{2} x} \right] \epsilon^{j\omega t} \tag{3}$$

$$p = -j\omega\rho\epsilon^{-(m/2)x} \left[A\epsilon^{-j\frac{\sqrt{4k^2-m^2}}{2}x} \right] \epsilon^{j\omega t} \quad (4)$$

$$U = -AS \left[\frac{m}{2} + j\frac{\sqrt{4k^2-m^2}}{2} \right] \left[\epsilon^{-\frac{m}{2}x-j\frac{\sqrt{4k^2-m^2}}{2}x+j\omega t} \right] \quad (5)$$

where ϕ is the velocity potential, A is the amplitude of ϕ , p is the sound pressure, in dynes per square centimeter, U is the volume current, in cubic centimeters per second, ω is $2\pi f$, f is the frequency, in cycles per second, t is the time, in seconds, k is $2\pi/\lambda$, λ is the wavelength, in centimeters, c is the velocity of sound in centimeters per second and ρ is the density of the medium, in grams per cubic centimeter.

The real and imaginary components of the acoustical impedance, in acoustical ohms, at the throat are

$$r_A = \frac{\rho c}{S_1} \sqrt{1 - \frac{m^2}{4k^2}} \quad (6)$$

$$x_A = \frac{\rho c}{S_1} \frac{m}{2k} \quad (7)$$

where r_A is the acoustical resistance, in acoustical ohms and x_A is the acoustical reactance, in acoustical ohms.

When $m = 2k$ or $4\pi f = mc$ the acoustical resistance is zero. This is termed the cutoff frequency of the exponential horn.

Below the cutoff frequency the acoustical impedance is entirely reactive and

$$x_A = \frac{\rho c}{S_1} \left(\frac{m}{2k} - \sqrt{1 - \frac{m^2}{4k^2}} \right). \quad (8)$$

HORN, INFINITE PARABOLIC. The equation expressing the cross-sectional area as a function of the distance along the axis is

$$S = S_1 x \quad (1)$$

where S is the cross-sectional area at x , in square centimeters, x is the distance along the horn axis, in centimeters and S_1 is the cross-sectional area at x_1 , in square centimeters.

The general horn equation for the parabolic horn from Equation 1 and the fundamental horn equation (see **horn equation, fundamental**) is

$$\ddot{\phi} - \frac{c^2}{x} \frac{\partial \phi}{\partial x} - c^2 \frac{\partial^2 \phi}{\partial x^2} = 0. \quad (2)$$

The velocity potential, pressure, and volume current are

$$\phi = A[J_0(kx) - jY_0(kx)]\epsilon^{j\omega t} \quad (3)$$

$$p = -j\omega\rho A[J_0(kx) - jY_0(kx)]\epsilon^{j\omega t} \quad (4)$$

$$U = ASk[-J'_0(kx) + jY'_0(kx)]\epsilon^{j\omega t} \quad (5)$$

where ϕ is the velocity potential, A is the amplitude of ϕ , p is the sound pressure, in dynes per square centimeter, U is the volume current, in cubic centimeters per second, ω is $2\pi f$, f is the frequency, in cycles per second, t is the time, in seconds, k is $2\pi/\lambda$, λ is the wavelength, in centimeters, J_0 , J_1 are **Bessel functions** of the first kind of order zero and one, and Y_0 , Y_1 are Bessel functions of the second kind of order zero and one.

The real and imaginary components of the acoustical impedance, in acoustical ohms, at the throat are

$$r_A = \frac{\rho c}{S_1} \frac{2}{\pi k x_1 [J_1^2(kx_1) + Y_1^2(kx_1)]} \quad (6)$$

$$x_A = \frac{\rho c}{S_1} \frac{J_0(kx_1)J_1(kx_1) + Y_0(kx_1)Y_1(kx_1)}{J_1^2(kx_1) + Y_1^2(kx_1)} \quad (7)$$

where r_A is the acoustical resistance, in acoustical ohms, and x_A is the acoustical reactance, in acoustical ohms, ρ is the density of the medium, in grams per cubic centimeter, c is the velocity of sound, in centimeters, S_1 is the area at x_1 , in square centimeters, x_1 is the distance of the throat from $x = 0$, in centimeters, k is $2\pi/\lambda$, and λ is the wavelength, in centimeters.

HOROPTER. (1) A horopter, or *frontal horopter*, is a **geodesic** in the **Luneburg geometry** of visual space that is apparently perpendicular to the median.

(2) The *horopter of single vision* is defined for a given point of fixation and attitude of the eyes as the set of points in the binocular field of view whose retinal images lie on corresponding points of curves on the two retinas.

HOSPITAL RULE. See under **L'Hospital**.

HOTELLING'S T. A generalization to the multivariate case by H. Hotelling (1931) of the statistic t known as "**Student's distribution**." It tests simultaneously a set of means of variates which may be interdependent.

HOUR ANGLE (LHA) (SHA). The hour angle of a celestial object (*LHA*) is the angle measured along the celestial equator from the

observer's celestial meridian to the point of intersection of the hour circle through the object with the celestial equator. Hour angle is usually measured to the west (in the direction of apparent rotation of the celestial sphere) from the local meridian to the hour circle through the object. If the hour angle is measured toward the east it *must* be carefully labeled.

Sidereal hour angle (SHA) is the hour angle of a celestial object measured from the vernal equinox toward the west.

HOUR CIRCLE. Any great circle on the celestial sphere that passes through the poles of rotation is perpendicular to the celestial equator and is known as an hour circle.

H THEOREM. The *H function* has been introduced by Boltzmann:

$$H = \int f \log f d\mathbf{v}$$

where f is the molecular distribution function, and \mathbf{v} the velocity. For uniform systems (f independent of the position) and in the absence of external forces, it can be shown from the Boltzmann equation that:

$$\frac{dH}{dt} = -\frac{\pi}{2} \sum_{ij} \iiint \ln \frac{f'_i f'_j}{f_i f_j} (f'_i f'_j - f_i f_j) \mathbf{g}_{ij} b db d\mathbf{v}_i d\mathbf{v}_j \quad (1)$$

where \mathbf{g}_{ij} is the relative velocity and b the impact parameter.

Whether $f'_i f'_j$ be larger or smaller than $f_i f_j$, each term of the sum on the right hand side of (1) is always positive or 0. Therefore, one has the fundamental relationship:

$$\frac{dH}{dt} \leq 0.$$

The irreversible behavior of H can be paralleled with that of the entropy. The demonstration of the H theorem was the first "proof" of irreversible behavior from microscopic arguments, but the demonstration rested on the validity of the Boltzmann equation, which, at the time, was based on intuitive probabilistic arguments.

HUBBLE CONSTANT. The reciprocal of T in the equation $d = vT$, where v is the velocity

of recession of a galaxy which is at a distance d . $T \doteq 8 \times 10^9$ years is sometimes called the age of the universe, although there is no evidence that the term should be taken literally.

HUME-ROTHERY RULES. (See **crystal phases**.) The ratio of the number of valence electrons to the total number of atoms in an alloy is characteristic of a given crystal phase. Thus CuZn, AgCd, Cu₃Al, are all in the β -phase with ratio 3:2, while Cu₅Zn₈, Cu₉Al₄, are in the γ -phase with ratio 21:13.

HUMIDITY. (1) Absolute. The mass of water vapor present in unit volume of gas, usually expressed in grams of water vapor per cubic meter. (2) Mixing ratio. The ratio of the mass of water vapor to the mass of other gas in a mixture, expressed in meteorology in grams of water vapor per kilogram of dry air. (3) Relative. The percentage of the saturation mixing ratio of water vapor actually present in a gas mixture.

HUND COUPLING CASES. A set of relatively simple coupling cases proposed by F. Hund, representing limiting cases of the various possible coupling conditions in diatomic and linear polyatomic molecules (see also **coupling in atomic and molecular structure**). Of most practical importance are Hund's cases (a) and (b). In case (a) the resultant electronic angular momentum \mathbf{L} and the resultant electron spin \mathbf{S} are strongly coupled to the internuclear axis with components Λ and Σ respectively, so that the total electronic angular momentum in the direction of the internuclear axis $\Omega = \Lambda + \Sigma$ is well defined. In case (b) the vector \mathbf{L} has a well-defined component Λ in the direction of the internuclear axis. However \mathbf{S} is no longer coupled to the internuclear axis, but to the resultant \mathbf{N} of Λ and the molecular rotation. (For more detail see G. Herzberg, *Molecular Spectra and Molecular Structure, I. Spectra of Diatomic Molecules*, 2d ed., D. Van Nostrand Co., Inc., Princeton, 1950, p. 219 ff.)

HUND-MULLIKEN-HÜCKEL METHOD. See **molecular orbitals method**.

HUND RULES FOR ATOMIC MULTIPLETS. (1) Of the atomic terms resulting from **equivalent electrons**, those with greatest **multiplicity** $2S + 1$ (S , quantum number of resultant electron spin) lie lowest, and of these the lowest is the one with the highest value of

L (L , quantum number of resultant orbital electronic angular momentum).

(2) Multiplets formed from equivalent electrons are regular when less than half the shell is occupied, but inverted when more than half the shell is occupied. (See **electron shells in an atom**.)

HURWITZ CRITERION. See **stability (of system)**.

HURWITZ POLYNOMIAL. A polynomial of order n in some variable s having real coefficients,

$$H(s) = \sum_{r=0}^n a_r s^r$$

is known as a Hurwitz polynomial if the n roots of the equation

$$H(s) = 0$$

all have negative real parts. The constraints on the coefficients required for this to be true are discussed under **stability**, algebraic criteria.

An interesting property of Hurwitz polynomials is that the component polynomials consisting of the odd and even terms in $H(s)$, namely,

$$H_1(s) = a_0 + a_2 s^2 + a_4 s^4 + \dots$$

and

$$H_2(s) = s(a_1 + a_3 s^2 + a_5 s^4 + \dots)$$

have zeros which all lie on the imaginary axis of s , the zeros of H_1 and H_2 interlacing.

HUYGENS' PENDULUM. See **tantochrone**.

HUYGENS' PRINCIPLE. Hadamard has analyzed Huygens' principle in the syllogism:

(Major premise.) To determine the effect at time t_1 of a luminous phenomenon caused by a given disturbance at time $t_0 < t_1$ we may find the state at time t^1 , $t_0 < t^1 < t_1$, and from that deduce the state at t_1 .

(Minor premise.) If during $t_0 - \epsilon \leq t \leq t_0$ a luminous disturbance is localized in the immediate neighborhood of a point O , the effect at the subsequent time t^1 is localized in a very thin spherical shell with center O and radius $c(t^1 - t_0)$, where c is the velocity of light.

(Conclusion.) The effect at time t_1 due to a luminous disturbance localized at O at time t_0 is determined when the initial disturbance is replaced by a suitable system of luminous disturbances taking place at time t^1 , $t_0 < t^1 < t_1$,

and distributed over the surface of the sphere with center O and radius $c(t^1 - t_0)$.

Huygens' principle gives a satisfactory account of the laws of reflection and of refraction but is not sufficient for the explanation of diffraction phenomena though it provides a good approximation in some cases. Fresnel extended Huygens' principle, by adjoining assumptions concerning the amplitude of the secondary disturbances, and thereby explained some diffraction phenomena. Helmholtz, for monochromatic wave functions, and Kirchhoff in the general case, showed that these special assumptions were satisfied by all sufficiently well-behaved solutions of the wave equation. (See **Helmholtz formulation of Huygens' principle** and **Kirchhoff's formulation of Huygens' principle**.)

HUYGENS' WAVELETS. The secondary disturbances in **Huygens' principle** are referred to as Huygens' wavelets. If $V(x, y, z, u, v)$ is **Hamilton's point characteristic**, where u, v are curvilinear coordinates on the surface of a primary disturbance, then Huygens' wavelets are given by

$$V(x, y, z, a, b) = ct$$

where c is the velocity of light and t is time.

If the wave fronts of the primary disturbance are

$$\phi(x, y, z) - ct = 0$$

then

$$\phi_x^2 + \phi_y^2 + \phi_z^2 = n^2$$

but $V(x, y, z, u, v)$ is also an integral of this differential equation, depending on two parameters, and it follows that the envelope of the wavelets also is a solution of this equation. That is, both the wavelets and their envelope are **wave fronts**.

HUYGENS' ZONE. See **half-period element**.

HYBRIDIZATION OF EIGENFUNCTIONS.

Strictly speaking, this term means any linear combination of the **eigenfunctions** of one problem used to represent an eigenfunction of another problem. It is applied to problems of electronic **bonding**, where the true **bonding orbitals** may be hybrids of, for example, both s and p type **atomic orbitals**. (See next entry.)

HYBRIDIZATION OF ELECTRON ORBITALS. Some atoms, such as boron and carbon, have 3 or 4 singlet electrons in their

maximum valency state. From elementary considerations, one of these should be in the $2s$, and the others in the $2p$ states. One would then observe a marked difference between the properties of the bonds formed by these different electrons. The fact that the three BH bonds in the BH_3 molecule, or the four CH bonds of methane are found to be equivalent can be understood when one takes into account the possible hybridization of the wave functions of the three or four electrons of these atoms. Each of the $2s$ and $2p$ wave functions is itself a solution of the wave equation for the maximum valency state (5S for carbon); a linear combination of these is therefore also a solution. Pauling has shown that such hybrid orbitals can be constructed, and that they lead to the formation of equivalent bonds and to the observed valency angles.

HYBRID ORBITALS. See hybridization of electron orbitals.

HYDRAULIC JUMP, OR BORE. A transition at which the mass transport of a stream moving under gravity is unchanged but the horizontal momentum flux is decreased by a rise in pressure due to an increase in depth of the stream. There is a loss of total head at the jump so that the transition is irreversible: energy is dissipated at the jump in a breaking wave.

For a jump to be possible the flow must be super-undal, i.e., the **Froude number**

$$F = U/(gh)^{1/2}$$

must exceed unity. If u_1 , u_2 and h_1 , h_2 are the speeds and depths of the stream moving on a horizontal bed, the bore being stationary, then

$$u_2^2 = \frac{g}{2} \frac{h_1}{h_2} (h_1 + h_2).$$

If $H_1 = h_1 + u_1^2/2g$ is the total head of the oncoming stream, the loss of head at the jump is

$$H_1 - H_2 = (h_2 - h_1)^3/4h_1h_2.$$

By impressing on the system a velocity $-u_1$ it is seen that a bore invades still water with speed u_1 where

$$u_1^2 = \frac{g}{2} \frac{h_2}{h_1} (h_1 + h_2).$$

HYDRODYNAMIC ANALOGY (FOR THE TORSION PROBLEM IN CLASSICAL ELASTICITY THEORY). A hydrodynamic problem the solution to which is determined by differential equations and boundary conditions equivalent to those of the **torsion** problem. For example, the differential equations and boundary conditions determining the torsion function ϕ and conjugate torsion function ψ are those determining the **velocity potential** and **stream function**, respectively, for the irrotational motion of an incompressible inviscid fluid, contained in a vessel of the same shape as the cylinder which undergoes torsion and rotated with uniform angular velocity (vorticity) about the line corresponding to the axis of torsion. Again, the differential equation and boundary condition determining $\psi - \frac{1}{2}(x^2 + y^2)$ are the same as those determining the velocity distribution in a **Newtonian fluid** which flows under a constant pressure head through a straight pipe, the cross section of which is the same as that of the cylinder which undergoes torsion.

HYDRODYNAMICS. The science of the dynamics of fluid motion, especially the steady motions of an incompressible, inviscid fluid.

HYDRODYNAMICS, RELATIVISTIC. See relativistic hydrodynamics.

HYDROGEN BOND. The hydrogen atoms in such groups as HF, HO, HN and sometimes HC tend to be shared between the electronegative atom or group to which they are attached and similar groups on other molecules. These hydrogen bonds increase the intermolecular forces and the boiling points of HF, H_2O , NH_3 (to a certain extent), as well as those of organic alcohols and acids, etc.

The formation of these hydrogen bridges is usually explained by the fact that the H atom, attached to an electronegative atom or group, becomes more or less positively charged. It tends to acquire a coordination number 2 instead of 1, and to share an electron doublet with an O, N, or F atom of another molecule. It is only when the C atom is linked to strongly electronegative atoms such as Cl or F that the CH bond is sufficiently polarized to form hydrogen bonds with other molecules.

HYDROGEN FINE STRUCTURE. If in the Bohr-Sommerfeld model of the hydrogen atom and the hydrogen-like ions relativity effects

are taken into account, the elliptical electron orbits (see **electron orbits in an atom**) are found to describe a rosette motion (Sommerfeld). The energy corresponding to the different orbits depends in this case on both the principal quantum number n and the azimuthal quantum number k , and is given by

$$E_{n,k} = -\mu c^2 \left[1 + \frac{\alpha^2 Z^2}{(n-k + \sqrt{k^2 - \alpha^2 Z^2})^2} \right]^{-1/2} - \mu c^2$$

or, in series expansion,

$$E_{n,k} = -\frac{2\pi^2 \mu e^4 Z^2}{h^2 n^2} \left[1 + \frac{\alpha^2 Z^2}{n} \left(\frac{1}{k} - \frac{3}{4n} \right) \right] = -\frac{RZ^2}{n^2} hc - \frac{R\alpha^2 Z^4}{n^4} \left[\frac{n}{k} - \frac{3}{4} \right] - \dots$$

Here h stands for Planck's constant, c for the velocity of light, Z for the atomic number, μ for the reduced mass

$$\mu = \frac{mM}{m+M}$$

(m and M , for masses of electron and nucleus respectively), α , for Sommerfeld's fine structure constant

$$\alpha = \frac{2\pi e^2}{hc} = 7.29729 \times 10^{-3}$$

(e , electronic charge, and R for the **Rydberg constant**). Since the fine structure constant α is small, higher terms in Z in the above expansion can, as a rule, be neglected. They are, however, important in the x-ray spectra of hydrogen-like ions of high atomic number Z . (For the higher terms see H. E. White, *Introduction to Atomic Spectra*, McGraw-Hill, Inc., New York, 1934, p. 134.) The first term of the expansion formula gives the main part of the energy which is the same as that of the circular Bohr orbit.

Dirac's formula for the hydrogen fine structure is the same as Sommerfeld's if k is replaced by $j + \frac{1}{2}$ ($j + \frac{1}{2} = k = 1, 2, \dots, n$). To each value of j , except for the j value corresponding to $k = n$, there are two possible values of the orbital quantum number $l = j + \frac{1}{2}$ and $l = j - \frac{1}{2}$. Therefore to each level with the quantum number n and the quantum number $k \neq n$ in Sommerfeld's the-

ory, there corresponds, in Dirac's theory, a pair of levels with the quantum numbers n and $j \pm \frac{1}{2}$. However the energy of these two levels, e.g., $2^2S_{1/2}$ and $2^2P_{1/2}$ (for notation see **energy levels of atoms**) is strictly the same. (For removal of this degeneracy see **Lamb shift**.)

HYDROGEN MOLECULE, HEITLER-LONDON THEORY OF. Solution of the wave equation for the H_2 molecule using the state of the separated atoms as zero approximation and then introducing the interaction of the two atoms as a perturbation.

The potential energy of two electrons 1 and 2 in the field of two protons A and B is given by

$$V = \frac{e^2}{R} - \frac{e^2}{r_{1A}} - \frac{e^2}{r_{2A}} - \frac{e^2}{r_{1B}} - \frac{e^2}{r_{2B}} + \frac{e^2}{r_{12}}$$

where R, r_{1A}, \dots are defined as in Figure 1. If a first order perturbation calculation is carried

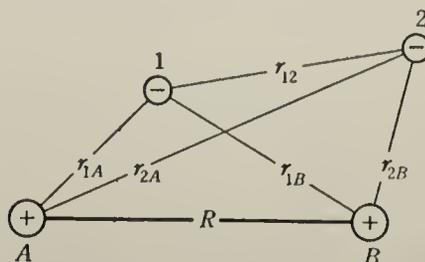

Fig. 1. Designations for the H_2 molecule. (From G. Herzberg, *Molecular Spectra and Molecular Structure. I. Spectra of Diatomic Molecules*, 1950, D. Van Nostrand Company, Inc., Princeton.)

out using as perturbation function W , the deviation from the potential energy for large R

$$W = +\frac{e^2}{R} + \frac{e^2}{r_{12}} - \frac{e^2}{r_{1B}} - \frac{e^2}{r_{2A}}$$

one obtains two energy levels E_s and E_a with eigenfunctions ψ_s and ψ_a given by

$$\psi_s = N_s[\phi_A(1)\phi_B(2) + \phi_A(2)\phi_B(1)]$$

$$\psi_a = N_a[\phi_A(1)\phi_B(2) - \phi_A(2)\phi_B(1)].$$

Here $\phi_A(1), \phi_B(1), \phi_A(2), \phi_B(2)$ are the hydrogen eigenfunctions for each of the electrons moving in the field of nuclei A and B , respectively, and N_s and N_a are normalization factors. The eigenfunction ψ_s is symmetric, that is, remains unchanged for an exchange of the electrons. ψ_a is antisymmetric, that is, it changes sign for such an exchange.

For the energies one finds

$$E_s = 2E_H + \frac{K + J}{1 + S}$$

$$E_a = 2E_H + \frac{K - J}{1 - S}$$

Here E_H is the energy of the ground state of the H atom, and

$$S = \int \phi_A(1)\phi_B(1)\phi_A(2)\phi_B(2)d\tau_1d\tau_2$$

$$K = \int \phi_A(1)\phi_B(2)W\phi_A(1)\phi_B(2)d\tau_1d\tau_2$$

$$J = \int \phi_A(1)\phi_B(2)W\phi_A(2)\phi_B(1)d\tau_1d\tau_2.$$

All three integrals, K , J , and S , occurring in the energy expressions, depend on the value of the internuclear distance R . Actual evaluation of these integrals gives the lower broken-line curve in Figure 2 for E_s and the upper for

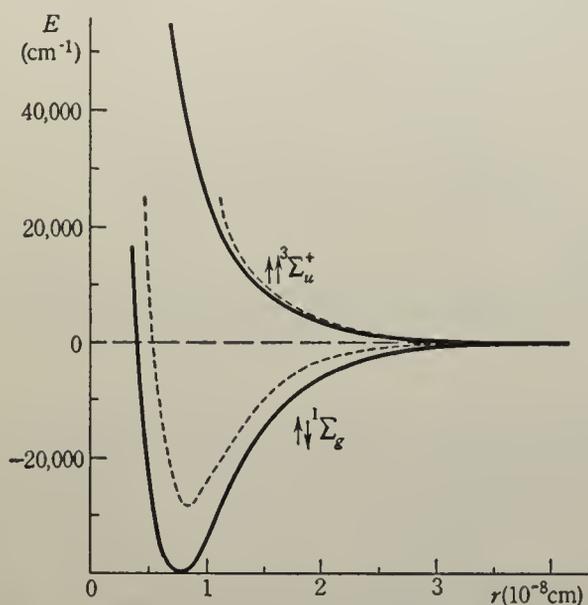

Fig. 2. Potential curves of the two lowest states of the H_2 molecule. (From G. Herzberg, *Molecular Spectra and Molecular Structure. I. Spectra of Diatomic Molecules*, 1950. D. Van Nostrand Company, Inc., Princeton.)

E_a (omitting the constant term $2E_H$), that is for the state characterized by the symmetric eigenfunction ψ_s a potential minimum arises leading to molecule formation while for the state characterized by the antisymmetric eigenfunction ψ_a there is repulsion for all R values. (The full line curves in Figure 2 result from calculations by James and Coolidge

which carried the original calculations of Heitler and London to higher approximations.)

The integral K (Coulomb integral) gives the interaction of the two charge clouds on a classical basis. The integral J (exchange integral) arises from the fact that the two electrons are indistinguishable and can be exchanged. The latter integral gives the major contribution to the potential energy of the molecule.

Since, according to the **Pauli principle**, only those states can occur whose total eigenfunction is antisymmetric, the stable state E_s can occur only with antisymmetric spin function, that is, with antiparallel electron spins. According to this theory, the ground state of H_2 should therefore be a singlet state. This is in agreement with spectroscopic observation.

(For more details see W. Heitler, *Elementary Wave Mechanics*, Oxford University Press, 1945.)

HYDROGEN, SPECIFIC HEAT OF. See specific heat of hydrogen.

HYDROSTATIC EQUATION. The form assumed by the vertical component of the **Navier-Stokes equation** when all Coriolis, earth curvature, frictional, and vertical acceleration terms are considered negligible compared with those involving the vertical **pressure force** and the force of **gravity**. Thus

$$\frac{\partial p}{\partial z} = -\rho g,$$

where p is the pressure, ρ the density, g the acceleration of gravity, and z the geometric height.

HYDROSTATIC EQUILIBRIUM. The state of a fluid whose surfaces of constant pressure and constant mass (or density) coincide and are horizontal throughout. Complete balance exists between the force of **gravity** and the **pressure force**. The relation between the pressure and the geometric height is given by the **hydrostatic equation**.

The analysis of atmospheric stability has been developed most completely for an atmosphere in hydrostatic equilibrium.

HYDROSTATICS. The study of the distribution of fluid pressure, and the forces on submerged bodies, in a fluid at rest.

Since there can be no shear stresses in a fluid at rest, the pressure gradient at any point

is vertical and equal to the weight of fluid per unit volume. That is,

$$\frac{dp}{dz} = -\rho g,$$

where z is measured vertically upward and ρ is the density of the fluid. (See also **Archimedes' principle**; **force on a submerged surface**; **stability of a floating body**.)

HYDROSTATIC STRESS. See **stress, hydrostatic**.

HYLLERAAS COORDINATES. A two-particle set of coordinates useful in the quantum mechanical problems of the helium atom, the singly ionized lithium atom, etc. The coordinates are $u = r_{12}$, where r_{12} is the separation between the two particles; $s = r_1 + r_2$, where r_1 and r_2 are the respective distances of the two particles from the origin; and $t = r_1 - r_2$. The volume element is then given by $dv_1 dv_2 = \pi 2u(s^2 - t^2) du ds dt$. The ranges of the variables are: $0 \leq u \leq s$; $-u \leq t \leq u$; $0 \leq s < \infty$.

HYPERBOLA. A conic section obtained by a plane cutting both nappes of a right-circular conical surface. It is the locus of a point which moves so that the difference of its distances from two foci is a constant. Its eccentricity is greater than unity.

The standard equation may be taken as $x^2/a^2 - y^2/b^2 = 1$. The curve is a central conic for it is symmetric about both the X - and Y -axes when placed in standard position with the coordinate origin at its center. The transverse axis, coincident with the X -axis, is of length $2a$; the conjugate axis, along the Y -axis, has length $2b$ ($b < a$). The distance from the center of the hyperbola to either focus is $\sqrt{a^2 + b^2}$; the eccentricity, $e = \sqrt{a^2 + b^2}/a$; the length of the latus rectum is $2b^2/a$; the equations for the directrices are $x = \pm a/e$, the same as for the **ellipse**. The distance from any point on the hyperbola to a focus is a focal radius and the differences between any two focal radii equals $2a$. The lines $y = \pm bx/a$ are asymptotes to the hyperbola. If the length of the transverse axis becomes equal to that of the conjugate axis ($a = b$), the curve is an equilateral or rectangular hyperbola. In this case, the asymptotes are perpendicular to each other. If the coordinate axes are rotated so that they coin-

cide with the asymptotes, the equation for the rectangular hyperbola becomes $xy = a^2/2$.

The polar equation of the hyperbola is $r = a(e^2 - 1)/(e \cos \theta - 1)$ and parametric equations are $x = a \operatorname{eosh} u$, $y = b \sinh u$ or $x = a \sec \phi$, $y = b \tan \phi$.

HYPERBOLA, GEODESIC. See **geodesic hyperbola on a surface**.

HYPERBOLIC EQUATION. See **hyperbolic partial differential equation**.

HYPERBOLIC FUNCTION. Combinations of $e^{\pm z}$ with properties similar to those of the trigonometric functions. They are defined by:

$$\sinh z = (e^z - e^{-z})/2 = z + \frac{z^3}{3!} + \frac{z^5}{5!} + \dots$$

$$\cosh z = (e^z + e^{-z})/2 = 1 + \frac{z^2}{2!} + \frac{z^4}{4!} + \dots$$

$$\tanh z = \sinh z / \cosh z; \quad \coth z = 1 / \tanh z$$

$$\operatorname{sech} z = 1 / \cosh z; \quad \operatorname{csch} z = 1 / \sinh z.$$

If n is a positive integer, $i = \sqrt{-1}$, $u = n\pi i$; $\sinh u = \tanh u = 0$; $\cosh u = (-1)^n$; $\sinh(z + u) = (-1)^n \sinh z$; $\cosh(z + u) = (-1)^n \cosh u$.

For real z , the hyperbolic functions are related to the **hyperbola** as the trigonometric functions are related to a **circle**.

Again with real z , hyperbolic and circular (trigonometric) functions are related as follows: $\sinh iz = i \sin z$; $\operatorname{eosh} iz = i \cos z$; $\tanh iz = i \tan z$. Additional formulas, similar to those familiar from trigonometry, are: $\operatorname{eosh}^2 z - \sinh^2 z = 1$; $1 - \tanh^2 z = \operatorname{sech}^2 z$; $\cosh^2 z + \sinh^2 z = \operatorname{eosh} 2z$; $2 \sinh z \operatorname{eosh} z = \sinh 2z$.

The inverse hyperbolic functions are also denoted in a manner similar to that for the inverse trigonometric functions. Thus, if $y = \sinh z$, the inverse function is the angle whose hyperbolic sine is y , or $z = \sinh^{-1} y = \operatorname{arc} \sinh y$.

HYPERBOLIC LOGARITHM. A logarithm to the base e ; a **natural logarithm**.

HYPERBOLIC PARABOLOID. See **paraboloid**.

HYPERBOLIC PARTIAL DIFFERENTIAL EQUATION. A second order partial differential equation. For the solution to be well defined ordinarily initial and bound-

any conditions are needed. In the simple case the equation can be reduced to the form $u_{xx} - u_{yy} + \dots = 0$, where omitted terms involve no derivatives of second or higher order. The usual difference scheme is representable

$$\begin{array}{c} 1 \\ \tau^2 \quad 2(1 - \tau^2) \quad \tau^2 \\ 1 \end{array}$$

where $\tau = \Delta y / \Delta x$. If initial conditions are given along a horizontal line, it is necessary that $\tau \leq 1$ for adequate **numerical stability**. (See **elliptic partial differential equation**; **partial differential equation**; **Cauchy problem for partial differential equations**.)

HYPERBOLIC POINT (ON A SURFACE).

A point at which the product of the principal curvatures (see **curvature of surface**, **radius of**) of the surface is negative. Hence, a singular point in a **streamline** field, constituting the intersection of a **convergence line** and a **divergence line**.

HYPERBOLOID. A **central quadric** with one or two negative terms in its equation. If there is only one, so that

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} - \frac{z^2}{c^2} = 1$$

the surface is a hyperboloid of one sheet, given this name because any point on the surface may be reached from any other point on the surface. A plane parallel to the XY -plane gives an **ellipse** but if the sections are parallel to the XZ - or YZ -planes the results are **hyperbolas**. When $a = b$, the sections by planes $z = \text{constant}$ are **circles** and the surfaces can be generated by revolving the hyperbola, $x^2/a^2 - z^2/c^2 = 1$ about its conjugate axis, the Z -axis.

If there are two negative terms in the equation

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} - \frac{z^2}{c^2} = 1$$

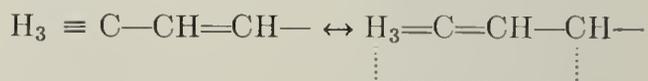

the surface is a hyperboloid of two sheets, separated into two parts symmetrically located above and below the planes $x = \text{constant}$. Traces parallel to the XY - and XZ -planes are hyperbolas and traces parallel to the YZ -planes are ellipses, provided $x > a$. When $b = c$, the sections by planes $x = \text{const.}$

are circles and a surface of revolution results when the hyperbola $x^2/a^2 - y^2/c^2 = 1$ is rotated about its X - or transverse axis.

HYPERCIRCLE METHOD. See **method of the hypereircle**.

HYPERCOMPLEX NUMBER. See **quaternion**.

HYPERCONJUGATION. The hypothesis of hyperconjugation has been advanced to interpret some properties of substances containing but 1 double bond by analogy with those of substances containing conjugated double bonds. Consider a substance with a terminal structure $\text{H}_3\text{C}-\text{CH}=\text{CH}-\dots$. One of the possible resonating structures of this group is

the dotted line indicating two unpaired electrons with opposite spins. Some authors have questioned the fact that hyperconjugation alone is sufficiently large to explain the observed anomalous properties of such substances (bond lengths and heats of formation).

HYPERFINE SPECTRUM. See **hyperfine structure**.

HYPERFINE STRUCTURE. The (in general, narrow) splitting of atomic and molecular spectral lines or energy levels due to the influence of the **nuclear spin**; also the narrow structure of atomic lines due to the **isotope effect**.

(a) Hyperfine structure due to the presence of nuclei with the same **atomic number** Z , but different masses M (isotope effect).

For the isotopes of the hydrogen atom the effect of the nuclear mass on the atomic energy levels can be accounted for by the dependence of the **Rydberg constant** on the nuclear mass M according to

$$R = \frac{2\pi^2 e^4}{ch^3} \frac{mM}{m + M},$$

where e and m are respectively charge and mass of the electron, c is the velocity of light, and h is Planck's constant. For more complicated atoms this approach is inadequate. According to the above formula the isotope effect for elements of moderately high atomic number Z would rapidly approach zero. However relatively large isotope shifts (of an order

similar to that of the effect of nuclear spin, see below) have been observed for heavy elements (e.g., Zn, P). Wave mechanical calculation of the hyperfine structure on the basis of different masses alone produce a result of the right order of magnitude for the lighter elements (e.g., Li, Ne). However for heavier elements the change of nuclear radius with nuclear mass has to be taken into account. (For more details see H. Kopfermann, *Nuclear Moments*, Academic Press, Inc., New York, 1958.)

(b) Hyperfine structure due to nuclear spin.

If the nucleus of an atom or one nucleus in a molecule has a spin $\mathbf{I} \neq 0$, the total angular momentum \mathbf{F} is the vector sum of \mathbf{I} and \mathbf{J} , the total angular momentum apart from spin. If more than one nucleus in a molecule has $\mathbf{I} \neq 0$, \mathbf{F} is the vector sum of \mathbf{J} and \mathbf{T} , the resultant nuclear spin. The corresponding quantum numbers are

$$F = J + I, J + I - 1, \dots, |J - I|$$

or

$$F = J + T, J + T - 1, \dots, |J - T|.$$

The number of hyperfine structure components, for large J , is $2I + 1$ and $2T + 1$ respectively. (Because of the very small interaction between the nuclear spins the additional splitting corresponding to the different possible values of T is very small. See below.)

The selection rules for F are

$$\Delta F = 0, \pm 1 \quad \text{and} \quad F = 0 \leftarrow | \rightarrow F = 0.$$

In general, the hyperfine structure splitting of an energy level is due to a combination of magnetic dipole and electric quadrupole interaction. If the magnetic interaction due to the nuclear magnetic moment

$$\mu I = \mu_{on} g_I$$

where μ_{on} is the **nuclear magneton**, g_I , the nuclear g -factor (see **gyromagnetic ratio**) predominates, the intervals between successive hyperfine structure components (F and $F + 1$) are proportional to $F + 1$ (**Landé's interval rule**).

(1) *Atoms*. For purely magnetic interaction of the nucleus with the rest of the atom the energy of the hyperfine structure levels is given by

$$W = W_o - A \frac{G}{2}$$

where W_o is the energy without hyperfine structure splitting,

$$G = F(F + 1) - I(I + 1) - J(J + 1)$$

and

$$A = \frac{\overline{\mu_I H(0)}}{IJ}.$$

Here $\overline{H(0)}$ is the mean value of the magnetic field produced at the position of the nucleus by the motion of the electrons.

For purely electrostatic interaction of a nucleus possessing an electric quadrupole moment \mathbf{Q} with the rest of the atom the energy of the hyperfine structure components is given by

$$W = W_o - B \frac{\frac{3}{8}G(G + 1) - \frac{1}{2}I(I + 1)J(J + 1)}{I(2I - 1)J(2J - 1)}$$

where

$$B = eQ\overline{\phi_{JJ}(0)}.$$

Here e stands for the charge of the electron and $\overline{\phi_{JJ}(0)}$ for the vector gradient of the electric field of the electrons at the position of the nucleus. $\overline{\phi_{JJ}(0)}$ is rotationally symmetric about the J -axis.

(2) *Molecules*. For purely magnetic interaction between one nucleus with $\mathbf{I} \neq 0$ and the rest of the molecule, the energies of the hyperfine structure components are given by

$$W = W_o + \left[\frac{aK^2}{J(J + 1)} + b \right] G$$

Here a and b are constants depending on the nuclear magnetic moment and on the magnetic moment due to molecular rotation; J and K are, respectively, the quantum numbers corresponding to the total angular momentum of the molecule apart from nuclear spin and its component in the direction of the figure axis.

For purely electrostatic interaction of a nucleus having $\mathbf{I} \neq 0$ and $\mathbf{Q} \neq 0$, with the rest of the molecule, the energy of the hyperfine structure components in diatomic, linear, and symmetric top molecules is given, to a good approximation, by

$$W = W_o - B \left[1 - \frac{3K^2}{J(J + 1)} \right] \left[\frac{\frac{3}{8}G(G + 1) - \frac{1}{2}J(J + 1)I(I + 1)}{I(2I - 1)(2J - 1)(2J + 3)} \right].$$

In general, for $Q \neq 0$, the electrostatic interaction of the nucleus with the rest of the molecule is predominant, and the magnetic interaction can be taken into account as a small perturbation. (For more detail, see H. Kopfermann, *l.c.*)

Influence of a magnetic field. In a magnetic field the hyperfine structure levels of an atom or molecule show a **Zeeman effect** and **Paschen-Baek effect** similar to that for ordinary fine structure. However because of the relatively weak interaction between \mathbf{J} and \mathbf{I} , the transition from the former to the latter effect takes place at lower field strength.

At moderate field strength each level corresponding to a total angular momentum \mathbf{F} will split into $2F + 1$ component levels with quantum numbers

$$M_F = F, F - 1, F - 2, \dots, -F.$$

The selection rules for M_F are

$$\Delta M_F = 0, \pm 1,$$

and

$$M_F = 0 \leftarrow | \rightarrow M_F = 0 \quad \text{for } F = 0.$$

At higher field strength, each level corresponding to a total angular momentum \mathbf{J} will split into $2J + 1$ equidistant component levels with quantum numbers

$$M_J = J, J - 1, J - 2, \dots, -J.$$

This is the ordinary Zeeman effect with line separations which, at sufficiently high field strengths, are considerably greater than those of the field-free hyperfine structure components. Each term with a given J is however once more split into $2I + 1$ components with quantum numbers

$$M_I = I, I - 1, I - 2, \dots, -I.$$

The selection rules for the quantum numbers M_J and M_I are

$$\Delta M_J = 0, \pm 1 \quad \text{and} \quad \Delta M_I = 0.$$

The energy of the component levels with different values of M_F is given by

$$W = W_0 - g_F M_F \mu_0 n H$$

where W_0 is the energy in zero field, H the magnetic field strength and

$$g_F = \frac{\left\{ \begin{array}{l} [F(F+1) + J(J+1) - I(I+1)]g_r \\ + [F(F+1) + I(I+1) - J(J+1)]g_I \end{array} \right\}}{2F(F+1)}.$$

Here g_r is the rotational g -factor, a number of the order 1, characteristic of the particular molecular state, and g_I the nuclear g -factor. (See **gyromagnetic ratio**.)

HYPERGEOMETRIC DISTRIBUTION. If a finite population of N units contains a proportion p of units of one type ("successes") and a proportion $q = 1 - p$ of units of another type ("failures"), the probability of obtaining r "successes" in a sample of n is

$$\frac{1}{N^{[n]}} \frac{n!}{r!(n-r)!} (Np)^{[r]} (Nq)^{[n-r]}$$

where $a^{[n]}$ denotes $a(a-1)(a-2)\dots(a-n+1)$.

The corresponding frequency distribution is called the hypergeometric distribution, as its terms are those of a hypergeometric series. The mean is np , the variance $\left(\frac{N-n}{N-1}\right) npq$.

The variance is smaller than that of the corresponding **binomial distribution** to which it tends as N tends to infinity.

HYPERGEOMETRIC EQUATION. See **Gauss hypergeometric equation**.

HYPERGEOMETRIC FUNCTION. The function, usually denoted by $F(a, b; c; z)$ defined by the hypergeometric series

$$1 + \frac{a \cdot b}{1 \cdot c} z + \frac{a(a+1)b(b+1)}{1 \cdot \dots \cdot c(c+1)} z^2 + \dots,$$

or also, equivalently, in other ways, e.g., by use of the **gamma function**. (See **Gauss hypergeometric equation**; and **confluent hypergeometric function**.)

HYPERMULTIPLY. In an atom with non-zero nuclear spin \mathbf{I} , each energy level with a given value of J , the quantum number of the resultant total electronic angular momentum, splits into a number of hyperfine structure levels with quantum numbers

$$F = J + I, J + I - 1, \dots, |J - I|.$$

The resulting hypermultiplet has $2I + 1$ components for $J > I$, and $2J + 1$ components for $J < I$. The intervals between successive hyperfine structure levels (F and $F + 1$) are proportional to $F + 1$ (Landé's interval rule).

(For more details, including hypermultiplet structure in molecules, see **hyperfine structure**, and the literature quoted under this heading.)

HYPersonic FLOW. If τ is the thickness ratio of a body in a stream of Mach number M , the product $M\tau$ is known as the *hypersonic similarity parameter*. Hypersonic flow is often defined as flow for which this parameter is of order 1, or greater. The linearized equation of supersonic flow is then no longer valid, because although the perturbation velocities may be small compared with the speed of flow they are not small compared with the speed of sound. This means that there are some additional non-linear terms in the equation which cannot be neglected.

Alternatively, hypersonic flow is sometimes defined as flow in which the Mach number M exceeds some arbitrarily specified value, often taken as 5.

In hypersonic flow the bow shock wave lies close to the body, and since flow disturbances are confined to the region between the body and the bow shock wave, the region of disturbed flow is a narrow one. The strength of the bow shock wave varies considerably with distance from the nose of the body, so that the flow in the disturbed region is rotational, even outside the viscous boundary layer. The variations of *speed* in the flow are quite small, the changes of Mach number being associated mainly with changes of temperature, and hence of the speed of sound.

HYPersonic SIMILARITY LAW. For hypersonic flow past a series of slender bodies or thin airfoils, related to each other by an **affine transformation**, the pressure coefficients at corresponding points are given by

$$C_p = \tau^2 P(M\tau), \quad (1)$$

where M is the stream Mach number, τ is the thickness ratio of the body, and P is a function depending on the shape of the body, when τ has been specified. The product $M\tau$ is known as the *hypersonic similarity parameter*.

Since, at hypersonic speeds, $M^2 \gg 1$, Equation (1) may also be written as

$$C_p = \tau^2 P[\tau(M^2 - 1)^{1/2}] \quad (2)$$

and it can be shown that in this form the law is consistent with the linearized equation of

supersonic flow. (See **hypersonic flow; subsonic and supersonic flow, linear equations**.) Thus Equation (2) applies over the whole range of supersonic and hypersonic speeds, for a slender body or thin airfoil.

HYPersonic SIMILARITY PARAMETER. See **hypersonic flow; hypersonic similarity law**.

HYPOTHESIS, STATISTICAL. A hypothesis concerning the form of a statistical (probability) **distribution** or some of its parameters, or of a process generating such a distribution. Many scientific hypotheses are of such a type and the testing of hypotheses forms a large and important part of statistical theory.

If the hypothesis concerns a parameter which, if known, would determine the parent population completely, it is said to be simple; in the contrary case it is composite.

HYSTERESIS. In general, the phenomenon exhibited by a system whose state depends on its previous history. This term usually refers to magnetic hysteresis, as exhibited by a ferromagnetic material. A quantitative study of the process indicates that, as the field strength, \mathbf{H} , is increased and then decreased, the magnetic induction, \mathbf{B} , follows the magnetization curve, which is of a type shown in the figure of the entry for **magnetization curve**. Note that the initial portion (solid line) of the curve is not retraced.

Electric hysteresis is a somewhat analogous phenomenon exhibited by dielectrics in the electric field.

Some solids exhibit either elastic hysteresis, in which the variables corresponding to \mathbf{H} and \mathbf{B} in the magnetic case are the stress and the strain or deformation; or plastic hysteresis, for which see **unloading**.

Hysteresis of an oscillator is a behavior that may appear in an oscillator wherein multiple values of the output power and/or frequency will correspond to give values of an operating parameter.

Hysteresis of a radiation counter tube is the temporary change in the counting rate versus voltage characteristic caused by previous operation.

I

ICE POINT. Temperature of equilibrium between air-saturated water and ice at a pressure of one standard atmosphere.

ICE-POINT DEPRESSION. The glass used in liquid-in-glass thermometers shows a considerable thermal lag: the volume change of the glass lags behind the temperature change, reaching its final value only after several hours. Thus, if a thermometer is immersed in an ice-water bath shortly after having been used at a higher temperature, the liquid (e.g., mercury) column falls somewhat below the 0°C (32°F) mark. This effect is known as ice-point depression. Good quality thermometers have an ice-point depression of less than 0.05°C on cooling from 100°C.

IDEAL ANGLE OF INCIDENCE. See **thin-airfoil theory**.

IDEAL CURRENT SOURCE. See **current source, ideal**.

IDEAL GAS. See **perfect gas**.

IDEALLY PLASTIC. Synonymous with **perfectly plastic**.

IDEAL SYSTEM. A thermodynamic system is called an ideal system when the **chemical potentials** of all the components are of the form

$$\mu_i = \mu_i(T, p) + RT \ln x_i \quad (1)$$

where $\mu_i(T, p)$ is a function only of the variables **absolute temperature**, T , and pressure, p . The x_i are the **mole fractions** of the components.

Systems for which μ_i has this form possess remarkably simple properties (see **law of mass action**; **vapor pressure of perfect solutions**). Moreover mixtures of **perfect gases** and very dilute **solutions** have these properties.

According to Equation 1, a system is called ideal if the chemical potential of component i varies linearly with the logarithm of the mole fraction of i , with a slope RT . This linear relation need not necessarily extend over the whole concentration range, so that the quantity

$\mu_i(T, p)$ is in general the value of μ_i extrapolated to $x_i = 1$ at constant T, p . If the system is ideal in a concentration range which extends to $x_i = 1$, then

$$\mu_i(T, p) = \mu_i^\circ(T, p) \quad (2)$$

where μ_i° is the chemical potential of the pure component i . They are two important cases: (a) The mixture is ideal for all values of x_i and for all i . It is then called a *perfect mixture* and Equation 2 is verified for all i . (b) The mixture is ideal when all components but one (index 1) are present in very small amount. Such systems are called *ideal dilute solutions*. Then Equation 2 is only valid for component 1.

Different kinds of ideal systems are distinguished by the form of $\mu_i(T, p)$. In a mixture of perfect gases $\mu_i(T, p)$ varies logarithmically with pressure, while for a liquid or solid solution one can, to a first approximation, regard μ_i as independent of pressure.

IDEAL VOLTAGE SOURCE. See **voltage source, ideal**.

IDEMPOTENT. A **matrix** which remains unchanged when multiplied by itself; e.g., the 3-rowed matrix,

$$\begin{pmatrix} 2 & -2 & -4 \\ -1 & 3 & 4 \\ 1 & -2 & -3 \end{pmatrix}.$$

IDENTIFYING INDEX. See **index, free**.

IDENTITY. An *equality* in which both members are equal for all values of the symbols for which the members are defined. Either member can be transformed into the other by use of the fundamental rules of operation. An identity involves a difference of form but not of value. It is frequently indicated by putting the symbol \equiv between the two members. Thus,

$$(a + b)(a - b) \equiv (a^2 - b^2).$$

I EFFECT. See **inductive effect and reactivity**.

IGNITION LIMIT. The velocity of combustion in a combustible mixture depends on its composition. It is reduced to zero at both ends of the scale, when the ignition limit is reached. The lower ignition limit corresponds to fuel deficiency, and the higher or upper ignition limit corresponds to oxygen deficiency.

IGNITION TEMPERATURE. See **combustion**.

IGNORABLE COORDINATE. A coordinate which does not appear in the **Lagrangian** function, although its time derivative may appear.

IKONAL. See **eikonal**.

ILLUMINANCE. See **illumination**.

ILLUMINANCE, RETINAL. A psychophysiological quantity, partially correlated with the **brightness** attribute of visual sensation, and measured in **trolands**.

ILLUMINATION (ILLUMINANCE). Illumination (at a point of a surface) is the quotient of the **luminous flux** incident on an infinitesimal element of surface containing the point under consideration by the area of that element. (See **quantity of illumination**.)

ILLUMINATION INTENSITY. The **flux density** of light incident upon a surface.

ILLUMINATION, QUANTITY OF. The product of an **illumination** and its duration.

IMAGE FOCAL LENGTH. See **focal length**.

IMAGE IMPEDANCE. That impedance which causes maximum power transfer, as dictated by the **Thevenin theorem**, from the **transducer** to which it is connected.

IMAGE NUMERICAL APERTURE. See **exit aperture**.

IMAGE PHASE CONSTANT. The imaginary part of the **transfer constant**. The prefix "image" may be omitted when there is no danger of confusion.

IMAGE RAY. See **ray**.

IMAGE-SIDE PUPIL. See **exit pupil**.

IMAGES, METHODS OF. (1) When electric charges are placed in the neighborhood of conductors, charges are induced on the surfaces of the conductors. The surface distribution of charges (together with the externally placed

charges) is such as to make the conducting surface an equipotential surface. The electric field and electrostatic potential external to the conductors is then the resultant field due to both the externally placed charges and the induced surface charges. In the method of images the field and potential external to the conductors are determined by imagining that the conductors are removed and that additional image charges are placed in such a way that equipotential surfaces are formed at what had been the conducting surfaces. All images must be placed in regions of space that are separated from the actual charges by the surface or surfaces at which the boundary conditions are to be satisfied. The method of images may also be used to solve problems involving dielectric rather than conducting boundaries. (See **boundary conditions on the electromagnetic field vectors**.)

(2) Similarly, the method of images may be used for the solution of magnetostatic, hydrodynamic, and other problems in which boundary conditions at the interface between two media determine the solution. In such cases, fictitious image magnetic dipoles, sources or sinks of fluid, etc., are introduced to satisfy the boundary conditions over the surfaces of the interfaces. (See following entry.)

(3) In the solution of problems in the theory of the diffusion and **slowing down** of **neutrons** in matter, this method is useful. In using it, the material under consideration is extended from finite to infinite extent, and the boundary condition satisfied by placing appropriate sources of positive or negative strength throughout the medium.

IMAGE SOURCES, SINKS, LINE VORTICES, ETC. The irrotational flow of an incompressible inviscid fluid in the presence of simply-shaped boundaries (e.g., planes, spheres, circular cylinders) can often be computed by finding a system of **sources**, **sinks**, **vortices**, etc., with the whole of space occupied by fluid, which together produce a flow in which the boundaries of the given system are in the same position as streamlines in the new system. The sources, sinks, etc., required in addition to those of the given system must be outside the region of the given fluid, and are the images of the given system in the given boundaries. There is a complete analogy with simple electrostatic systems in which the boundaries are equipotentials.

IMAGINARY. See **complex number**.

IMMITTANCE. A group of electrical quantities consisting of **impedances** and **admittances**.

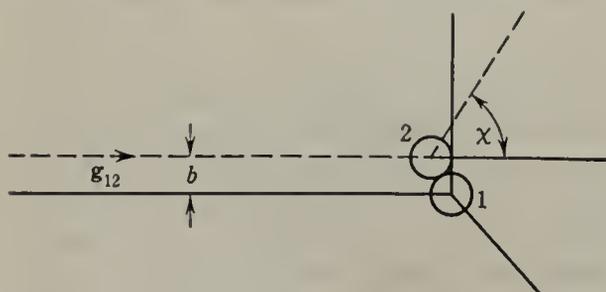

IMPACT. The action of two bodies in collision, whereby the velocity of one or both bodies is changed. In the case of direct impact, the velocity of the moving bodies is in the direction of the normal (perpendicular) to the bodies at the point of contact. Otherwise the impact is oblique. The impact is central when the centers of mass of the two bodies lie on the line of impact (normal to the bodies at the point of contact). Impact is a term which implies a short time of contact during which the impulse of the external forces, with the possible exception of some reactions, is negligible. The impulse of the (large) equal and opposite forces of impact is strictly zero. Therefore the momentum of a system of unsupported bodies is not changed during the impact.

IMPACT BUCKLING. See **buckling, impact**.

IMPACT, ELASTIC. In the impact of elastic bodies some energy appears as vibratory motion. Elementary theory ignores this loss and assumes that rigid body kinetic energy is conserved. The coefficient of restitution (see **restitution, coefficient of**) is taken as unity. (See **impact**.)

IMPACT, INELASTIC. During inelastic impact, the rigid body kinetic energy is spent partly in vibratory or wave motion of the impacting bodies and partly in inelastic deformation in the region of contact. In the extreme case the coefficient of restitution (see **restitution, coefficient of**) is zero.

IMPACT PARAMETER. Consider (see figure) a collision between two molecules. In the

Impact parameter. Collision between two hard spheres. The trajectory of sphere 2 in the coordinate system in which 1 is stationary is indicated by the broken line. χ is the angle of deflection.

system of coordinates chosen, molecule 1 is at rest, while molecule 2 moves with the relative velocity g_{12} . The axis is parallel to g_{12} . The *impact parameter* b is the minimum distance at which molecule 2 would pass by molecule 1 if the two molecules did not interact.

For hard spheres, the amount of momentum and energy exchanged during the collision depends on b alone; for other more realistic models, where the interaction potential energy depends on distance, the momentum and energy exchange depends both on the impact parameter and on the initial relative velocity. (See also **angle of deflection**.)

IMPACT, PLASTIC. A collision between two bodies whose coefficient of **restitution** has a value less than unity. In such a collision kinetic energy is lost. The amount of energy lost is given by the formula:

$$\Delta K = \frac{1}{2}M_1(e^2 - 1)u_{1e}^2 + \frac{1}{2}M_2(e^2 - 1)u_{2e}^2$$

where M_1 is the mass of the first body, M_2 is the mass of the second body, e is the coefficient of restitution between the two bodies, u_{1e} is the final velocity of the first body with respect to center of mass, u_{2e} is the final velocity of the second body with respect to center of mass.

The total momentum remains unchanged in a plastic impact.

A collision in which the coefficient of restitution is zero is often called a perfectly inelastic impact.

IMPEDANCE. The term expresses the relation between a sinusoidally varying quantity (such as force, pressure, voltage, electric field strength, temperature) and a second quantity (such as velocity, current, magnetic field strength, heat flow) which is a measure of the response of a physical system to the first. For most systems, the impedance depends on the frequency of the disturbance. When the impedance is stated for a given frequency, it connects the disturbing quantity and the response only when a steady state is reached—during the transient period the response to a sinusoidal disturbance is not, in general, itself sinusoidal.

The most common use of the term is in connection with alternating current circuits, in which the impedance Z is defined as the (complex) ratio of the (complex) potential differ-

ence V applied across a circuit element to the (complex) current I flowing in the element:

$$Z = V/I = (V_0/I_0)e^{i\phi},$$

where V_0 and I_0 are the amplitudes of the sinusoidally varying potential differences and current, respectively, and ϕ is the phase angle.

If the disturbing quantity is a sinusoidally varying force acting on a mechanical system, the force may be written in the complex form $F = F_0e^{i\omega t}$ and the velocity of motion as $v = v_0e^{i(\omega t - \phi)}$. The mechanical impedance is then

$$Z_m = F/v = (F_0/v_0)e^{i\phi}.$$

Thus, for a mass M , subject to a restoring force equal to $-kx$ (where x is the displacement of the mass from its equilibrium position and k is a constant) and to a dissipative force equal to $-R_m dx/dt$, where R is a constant, the mechanical impedance is

$$Z_m = R_m + i(\omega M - k/\omega).$$

Here R_m is exactly analogous to electrical resistance (R), M to inductance (L), and k to inverse capacitance (C) in an electric circuit having R , C , and L in series. The elements of the mechanical system (mass, springs, resistive effects) are thus analogs of circuit elements. The quantity $(\omega M - k/\omega)$ is the mechanical reactance of the system.

The concept of impedance as outlined above is satisfactory as long as the physical dimensions of the electrical circuit elements, or their mechanical analogs, are sufficiently small so that the currents or velocities may be considered to be the same everywhere throughout them. When this condition is not satisfied, it must be recognized that any disturbance will be propagated as a wave. Under such circumstances, the impedance offered to an electromagnetic wave is taken as \mathbf{E}/\mathbf{H} , where \mathbf{E} is the (complex) electric field strength at any point and \mathbf{H} is the (complex) magnetic field strength at the same point. The impedance is measured in ohms, as is the impedance for circuits with lumped parameters. For a longitudinal acoustic wave, the impedance is defined as the ratio of the (complex) pressure excess to the (complex) volume velocity, i.e., the velocity times the area perpendicular to the direction of motion. This ratio is known as the acoustic impedance. In the cgs system of units it is measured in acoustical ohms ($\text{gm cm}^{-4} \text{sec}^{-1}$).

(See also **impedance, transform** and other entries immediately following.)

IMPEDANCE, ACOUSTIC. The acoustic impedance of a sound medium on a given surface lying in a wave front is the complex quotient of the **sound pressure** (force per unit area) on that surface by the flux (**volume velocity**, or linear velocity multiplied by the area), through the surface. When concentrated, rather than distributed, impedance of a portion of the medium is defined by the complex quotient of the pressure difference effective in driving that portion, by the flux (volume velocity), the acoustic impedance may be expressed in terms of mechanical impedance, acoustic impedance being to the mechanical impedance divided by the square of the area of the surface considered. The commonly used unit is the **acoustical ohm**. Velocities in the direction along which the impedance is to be specified are considered positive. This definition pertains to single-frequency quantities in the steady state and to systems whose properties are independent of the magnitudes of these quantities. Various other definitions have been proposed, but their application has been less widespread: (a) the quotient of the force by the **particle velocity** (Crandall); (b) the quotient of the sound pressure by the **volume displacement** (Webster); (c) the quotient of the sound pressure by the particle velocity (Brillié).

IMPEDANCE, BLOCKED. Of a transducer, the impedance at the input when the impedance of the output system is made infinite. For example, in the case of an electromechanical transducer, the blocked electric impedance is the impedance measured at the electric terminals when the mechanical system is blocked or clamped; the blocked mechanical impedance is measured at the mechanical side when the electric circuit is open-circuited.

IMPEDANCE, CHARACTERISTIC, ACOUSTIC. The characteristic impedance of a medium is given by the ratio of the effective **sound pressure** and the effective **particle velocity** for a plane progressive sound wave propagated through that medium. It is equal to the product of the density of the medium and the velocity of sound in the medium. The unit is the **rayl** (dyne-sec/cm^2) (or the MKS rayl newton-sec/m^2).

IMPEDANCE, CHARACTERISTIC OF A LINE OR GUIDE. Electromagnetic waves are often transmitted over lines or waveguides. The impedance of such a guide, at any particular frequency, depends on the length of the guide and on the conditions at the far end of the line. For example, a coaxial cable that is one-eighth wavelength long and has a short circuit at the far end, acts like an **inductance**, while one three-eighths of a wavelength long, similarly short-circuited, acts like a capacitance. These variations in impedance result from reflections of the wave from the far end. Were the guide infinitely long, there would be no effect of reflections. The impedance of a guide of infinite wavelength is known as the characteristic impedance of the guide. It follows that a finite guide having as a termination an element with impedance equal to the characteristic impedance will have no reflections from its far end—such a termination is equivalent to an infinite length of line extending beyond the end. The characteristic impedance of a lossless line is equal to the square root of the product of the inductance per unit length and the capacitance per unit length.

The characteristic impedance of either an electromagnetic or an acoustic waveguide is a pure resistance, whose magnitude is dependent on the dimensions of the cross section of the guide and on the medium in which the wave is transmitted, but is independent of frequency.

IMPEDANCE CHARACTERISTIC, OF A MEDIUM. As indicated under **impedance, characteristic, of a line or guide**, this quantity depends on the dimensions of the cross section of the guide. If a plane sinusoidal wave is being propagated through space without a guide, the ratio of the amplitude of the electric field strength to that of the magnetic field strength (or of the pressure amplitude to the velocity amplitude) at any point is the same as at any other. This ratio is the characteristic impedance of the medium in which the wave travels. For an electromagnetic wave in a non-dissipative medium it is equal to the square root of the ratio of the absolute permeability to the permittivity, i.e., $Z_c = \sqrt{\mu/\epsilon}$ (377 ohms for empty space).

IMPEDANCE CIRCLE. Consider a nondissipative transmission line terminated by a fixed **impedance**. As the line length is varied,

the (complex) input impedance describes a circle in the R, X plane.

IMPEDANCE, DRIVING-POINT. At a driving point of a transducer, the complex ratio of the applied sinusoidal potential difference, force, or pressure to the resultant current, velocity, or volume velocity, respectively, at this point, all inputs and outputs being terminated in any specified manner.

IMPEDANCE, FREE. Of a transducer, the impedance at the input of the transducer when the impedance of its load is made zero. The approximation is often made that the free electric impedance of an electroacoustic transducer designed for use in water is that measured with the transducer in air.

IMPEDANCE, FREE MOTIONAL. Of a transducer, the complex remainder after the blocked impedance has been subtracted from the free impedance.

IMPEDANCE, IMAGE. See **image impedance**.

IMPEDANCE, ITERATIVE. Of a transducer, that impedance which, when connected to one pair of terminals, produces a like impedance at the other pair of terminals.

IMPEDANCE LEVEL. The value of circuit **impedance** which is used in matching several **networks** to each other or to their terminal impedances is called the impedance level in that part of the circuit.

IMPEDANCE, MECHANICAL. The complex quotient of the alternating force applied to a system by the resulting linear velocity in the direction of the force at its point of application. The unit is the **mechanical ohm**.

IMPEDANCE, MECHANICAL ROTATIONAL (ROTATIONAL IMPEDANCE). The complex quotient of the alternating torque applied to the system by the resulting angular velocity in the direction of the torque at its point of application. The unit is the **rotational ohm**.

IMPEDANCE, MOTIONAL (LOADED MOTIONAL IMPEDANCE). Of a transducer, the complex remainder after the blocked impedance has been subtracted from the loaded impedance.

IMPEDANCE, MUTUAL. The impedance that is common to two meshes of a network is their mutual impedance. Equivalently, if a set of voltages and currents are related by

$$E_1 = Z_{11}I_1 + Z_{12}I_2 + \cdots + Z_{1n}I_n$$

$$E_n = Z_{n1}I_1 + Z_{n2}I_2 + \cdots + Z_{nn}I_n$$

the coefficient $Z_{ij} = Z_{ji}$ is called the mutual impedance between the i th and j th meshes.

IMPEDANCE, NORMALIZED (WITH RESPECT TO A WAVEGUIDE). An impedance divided by the characteristic impedance of the waveguide.

IMPEDANCES, CONJUGATE. Impedances having resistance components which are equal and reactance components which are equal in magnitude but opposite in sign. Conjugate impedances are expressible by conjugate complex quantities.

IMPEDANCES, IMAGE, OF A TRANSDUCER. The impedances which will simultaneously terminate all of the inputs and outputs of the transducer in such a way that at each of its inputs and outputs the impedances in both directions are equal.

IMPEDANCE, SPECIFIC ACOUSTIC (UNIT AREA ACOUSTIC IMPEDANCE). At a point in a medium, the complex ratio of sound pressure to particle velocity.

IMPEDANCE, SURFACE TRANSFER. When an electromagnetic wave is guided along the surface of a conductor having finite conductivity, the ratio of tangential electric field at the surface to the current induced at the surface of the conductor in the conductor.

IMPEDANCE, THROAT ACOUSTIC. The acoustic impedance (see **impedance, acoustic**) at the input end of a horn.

IMPEDANCE, TRANSFER. Between two points of a transducer, the complex ratio of the applied sinusoidal potential difference, force, or pressure at one point to the resultant current, velocity, or volume velocity at the other point, all inputs and outputs being terminated in any specified manner.

IMPEDANCE, TRANSFORM. The analogy for transient situations of the steady state impedances, viz., the ratio of the one-sided

Laplace transforms of two quantities such as voltage and current.

IMPERFECT GAS. See **real gas**.

IMPLICIT FUNCTION. A function y of x defined by an equation such as $F(x,y) = 0$. The *implicit function theorem* can be stated in varying degrees of generality; usually in applications something like the following. If the function $F(x,y) = 0$ is continuous and has continuous first partial derivatives in a neighborhood of a point $x = a, y = b$, where $F(a,b) = 0$, and if $\partial F/\partial y \neq 0$ at (a,b) , then there exists a unique function $y = f(x)$, continuous in a neighborhood of $x = a$, such that $F(x,f(x))$ is identically zero and $f(a) = b$. Generalizations to a larger number of variables can be made directly.

IMPORTANCE FUNCTION. In the theory of neutron chain reactors, the increase of the overall level of neutron population due to the introduction of a single neutron of speed v at point \mathbf{r} in the system.

IMPROPER FRACTION. A fraction whose numerator is not less in absolute value than its denominator.

IMPROPER INTEGRAL. A definite integral such that the integrand becomes infinite at one or more points in the interval of integration, or at least one of the limits of integration is infinite.

IMPULSE. A vector quantity defined by the time integral of the force \mathbf{F} acting on a particle over a finite interval, for example,

$$\int_{t_1}^{t_2} \mathbf{F} dt$$

for the interval from t_1 to t_2 . The impulse-momentum theorem states that the impulse equals the change in momentum experienced by a particle during the corresponding time interval.

IMPULSE, ANGULAR. See **angular impulse**.

IMPULSE FUNCTIONS. (1) *Definitions.* A class of functions defined not by their values, but by their integral properties.

Unit impulse function of t , of order one (see below for higher orders), at $t = t_0$, denoted by $\delta(t - t_0)$ is such that

$$\int_{\alpha}^{\beta} \delta(t - t_0) dt = 1 \quad \text{for all } \alpha, \beta \text{ such that } \alpha < t_0 < \beta$$

$$= 0 \quad \text{for all } \alpha, \beta \text{ such that } \alpha < \beta < t_0$$

$$\text{or } t_0 < \alpha < \beta.$$

An alternative definition, which includes the above as a particular case, is

$$\int_{\alpha}^{\beta} \delta(t - t_0) f(t) dt = f(t_0) \quad \text{for all } \alpha, \beta \text{ such that } \alpha < t_0 < \beta$$

$$= 0 \quad \text{for all } \alpha, \beta \text{ such that } \alpha < \beta < t_0$$

$$\text{or } t_0 < \alpha < \beta$$

provided $f(t)$ is continuous at $t = t_0$ and bounded elsewhere.

(2) *Right-Handed, Left-Handed and Symmetrical Impulse Functions.* It will be noticed that the above definitions do not cover the possibilities $t_0 = \alpha$ or $t_0 = \beta$. The value of the integrals in either of these cases demands a more precise definition. If $\delta(t)$ is a "right-handed" function, then, in addition to the above,

$$\int_{\alpha}^{\beta} \delta(t - t_0) dt = 1 \quad \text{when } t_0 = \alpha$$

$$= 0 \quad \text{when } t_0 = \beta.$$

If $\delta(t)$ is a "left-handed" function, then, in addition to the definitions in (1) above,

$$\int_{\alpha}^{\beta} \delta(t - t_0) dt = 1 \quad \text{when } t_0 = \beta$$

$$= 0 \quad \text{when } t_0 = \alpha.$$

If $\delta(t)$ is a "symmetrical" function, then, in addition to the definitions in (1) above,

$$\int_{\alpha}^{\beta} \delta(t - t_0) dt = \frac{1}{2} \quad \text{when } t_0 = \alpha \text{ or } t_0 = \beta.$$

(3) *The Impulse Function as a Limit Function.* The implications of the above definitions are perhaps clarified by considering the impulse function as the limiting form of a normal function when a suitable function parameter tends to a limiting value.

If for instance any function $\phi(t)$ is integrable over any range of t and is such that $\int_{-\infty}^{\infty} \phi(t) dt = 1$

then the same is clearly true of the function $k\phi(kt)$, where k is any positive constant. The effect of increasing k , however, is to compress the abscissae while expanding the ordinates and as $k \rightarrow \infty$ the function $k\phi(kt)$ will tend to $\delta(t)$.

Instances of such limit approximations to $\delta(t)$ are

$$\lim_{k \rightarrow \infty} \frac{\sin kt}{\pi t}, \quad \lim_{k \rightarrow \infty} \frac{k \operatorname{sech} kt}{\pi}, \quad \lim_{k \rightarrow \infty} \frac{k}{2} e^{-k|t|},$$

which are all symmetrical, and

$$\lim_{k \rightarrow \infty} f(k, t)$$

where $f(k, t) = k$ in the interval $0 < t < \frac{1}{k}$ and $f(k, t) = 0$ outside this interval, which is a widely used form of right-handed impulse function.

(4) *The Impulse Function of Order One as the Derivative of the Step-Function.* It is clear

from the above definition of $\delta(t)$ that $\int_{-\infty}^t \delta(t) dt = 0$ or 1 according as $t \leq 0$, and is therefore unit step function at the origin, $u(t)$. Conversely it would appear that $\delta(t)$ is therefore the derivative of $u(t)$. Although $u(t)$ is not differentiable at $t = 0$, it may be made so by considering it also as a limit function. For instance if $\delta(t)$ is identified with $\lim_{k \rightarrow \infty} \frac{\sin kt}{\pi t}$ then $u(t)$ may be expressed as the limit form of

$$\int_{-\infty}^t \frac{\sin kt}{\pi t} dt = \frac{1}{2} + \int_0^t \frac{\sin kt}{\pi t} dt$$

$$= \frac{1}{2} + \frac{1}{\pi} \operatorname{Si}(kt)$$

where $\operatorname{Si}(x) = \int_0^x \frac{\sin x}{x} dx$. Any objections raised on the ground that the integral of a limit is here identified with the limit of an integral may be discounted by arguing that k need not be infinite, that the limit is therefore never reached, that we can produce two differentially related functions which approximate as closely as we please to $u(t)$ and $\delta(t)$ and finally that in any case true discontinuous functions such as $u(t)$ and $\delta(t)$ never occur in physical problems, but only approximations to them.

(5) *Impulse Functions of Higher Order.* Unit impulse function of order $n (> 1)$ at $t = t_0$ may be defined by

$$\int_{\alpha}^{\beta} \delta_n(t - t_0) dt = \delta_{n-1}(t) \quad \text{if } \alpha < t_0 < \beta$$

$$= 0 \quad \text{if } \alpha < \beta < t_0 \text{ or } t_0 < \alpha < \beta$$

with similar extended definitions to cover the cases $t_o = \alpha$ or $t_o = \beta$ according as right-handed, left-handed or symmetrical functions are envisaged. Thus, using the above limit approach $\delta_n(t - t_o)$ may be considered as the derivative of $\delta_{n-1}(t - t_o)$. From this point of view, identifying $\delta_1(t) \equiv \delta(t)$ with such a limit function as $\frac{\sin kt}{\pi t}$ has the obvious advantage that all the derivatives of the limit function exist; if a right- (or left-) handed limit function is used, this property is lost.

(6) *Laplace Transform of Impulse Functions.* The Laplace transform of $\delta(t)$, by virtue of its definition integral, is unity provided either (i) the lower limit of the Laplace integral is 0 — or (ii) the lower limit is 0 and $\delta(t)$ is defined in a right-handed manner.

Under the same conditions the Laplace transform of $\delta_n(t)$ is s^{n-1} .

IMPULSE-MOMENTUM PRINCIPLE. The time integral of Newton's second law for a mass particle,

$$\mathbf{F} = m\mathbf{a} = \frac{d}{dt}(m\mathbf{v}),$$

is the impulse-momentum principle,

$$\int_{t_1}^{t_2} \mathbf{F} dt = (m\mathbf{v})_2 - (m\mathbf{v})_1.$$

This statement that impulse equals change in momentum applies also to the generalization

$$\mathbf{F} = \frac{d}{dt}(m\mathbf{v}_c)$$

where \mathbf{F} represents the sum of all forces acting on a system of total mass m and \mathbf{v}_c is the velocity of the center of mass.

IMPULSE-WEIGHT RATIO. A measure of the efficiency of propulsive systems that is used to compare **propellants**. It is defined as the ratio of total **impulse** to take-off weight, and may be found from the expression:

$$I/W = \frac{Ft}{W}$$

where I/W is the impulse-weight ratio, F is the thrust, t is the time of burning of the motor, and W is the total weight of the rocket at take-off.

IMPULSIVE MOTION. Motion induced in a fluid by the impulsive motion of the bound-

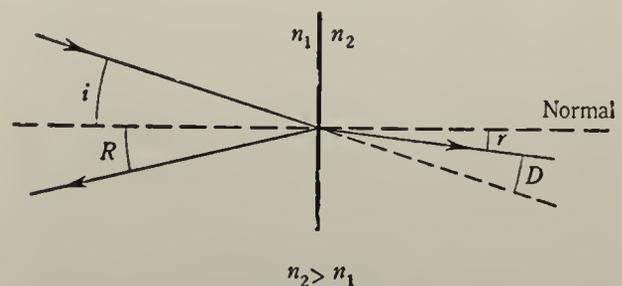

aries. If the fluid is incompressible and of uniform density and the impulsive pressure is $\omega (= P\Delta t)$, the impulsive motion is irrotational with velocity potential $\phi = -\omega/\rho$.

IMPULSIVE SOUND EQUATION.

$$\frac{E}{V} = e^{\frac{c\bar{\alpha}S}{4V}},$$

where E is the total sound energy produced by a single impulse, V is the volume of room, $\bar{\alpha}$ is the mean **sound absorption coefficient**, S is the exposed surface area, t is the duration of impulsive sound, and c is the velocity of sound.

INCIDENCE, ANGLE OF. (1) The angle between the chord line of an airfoil and the direction of the relative air stream. (Also known as **angle of attack**.) In the case of a twisted wing the angle of incidence varies along the span. It is usual then to specify the angle of incidence at a particular spanwise position, e.g., the wing root or the center line. (2) The angle at which one body or material or radiation strikes a surface, measured from the line of direction of the moving entity to a line perpendicular to the surface at the point of impact. The term is used commonly in regard

to the impact of radiant energy upon a material surface. In the figure, i is the angle of incidence, R , the angle of reflection, D , the angle of deviation, and r the angle of refraction.

INCIDENCE, ANGLE OF, IDEAL. See **thin-airfoil theory**.

INCIDENCE FOR ZERO LIFT. See **thin-airfoil theory**.

INCIDENCE, PRINCIPAL, ANGLE OF. See **angle of principal incidence**.

INCIDENT. A **vertex** and an **edge** are incident with each other if the vertex is an end-point of the edge.

INCOMMENSURABLE. Two numbers a and b are said to be incommensurable if there exists no number contained in each of them an integral number of times. Thus 1 and $\sqrt{2}$ are incommensurable. A number, such as $\sqrt{2}$, which is incommensurable with the integers is irrational.

INCOMPLETE BETA FUNCTION. The incomplete beta function is defined by

$$B_x(p, q) = \int_0^x x^{p-1}(1-x)^{q-1}dx, \quad 0 \leq x \leq 1, \\ p > 0, \quad q > 0.$$

INCOMPLETE BLOCK. A layout used in the design of experiments. If the experiment is divided into blocks and there are more treatments than can be inserted in any one block, the blocks are called incomplete. If the design is such that there are the same number of treatments in each block and every pair of treatments occurs together in the same number of blocks, the design is said to be *balanced*.

INCOMPLETE COMBUSTION. See **combustion**.

INCOMPLETE GAMMA FUNCTION. The function defined by

$$\Gamma_x(n) = \int_0^x e^{-x}x^{n-1}dx, \quad n > 0, \quad 0 \leq x \leq \infty.$$

INCREMENTAL THEORY OF PLASTICITY. A plastic flow law which expresses strain increments of plastic flow in terms of the applied stress and possibly stress increments. This is the more natural type of plastic flow law since plastic strain is permanent and does not have to be maintained by the applied stress. (See also **deformation theory of plasticity**.)

INDEPENDENCE. See **independent**.

INDEPENDENT. (1) A set of n quantities p_1, p_2, \dots, p_n (e.g., vectors, functions, etc.) for which addition is defined and also multiplication by a scalar, is *linearly independent* if for any set of n scalars a_1, a_2, \dots, a_n not all zero, we have

$$a_1p_1 + a_2p_2 + \dots + a_np_n \neq 0.$$

A set of n functions f_1, f_2, \dots, f_n of the n independent variables x_1, x_2, \dots, x_n is (functionally) independent if there does not exist any identically vanishing function $F(f_1, f_2, \dots,$

$f_n)$ with not all $\partial F/\partial f_i$ equal to zero. If f_1, f_2, \dots, f_n have continuous first partial derivatives, they will be independent in the neighborhood where not all the $\partial F/\partial f_i$ vanish, provided their **Jacobian** does not vanish identically.

(2) In the theory of probability, A and B are independent if the probability of A for given B is equal to the probability of A with B unspecified, viz.,

$$P(A/B) = P(A).$$

It follows that

$$P(A \text{ and } B) = P(A)P(B).$$

Likewise two **random variables** are independent if their frequency functions are related by

$$f(x_1, x_2) = f_1(x_1)f_2(x_2).$$

Analogous definitions apply to more than two variables.

INDEPENDENT COMPONENTS. The number of independent components of a thermodynamical system is the total number of components c less the number of **independent reactions** r' other than transfers of molecules from one phase to another

$$c' = c - r'.$$

INDEPENDENT REACTIONS. In a system containing c components which can undergo r' reactions other than transfers of molecules from one phase to another, there is for each reaction a **stoichiometric equation**

$$\sum_i \nu_{i\rho} M_i = 0, \quad (i = 1, \dots, c; \quad \rho = 1, \dots, r'). \quad (1)$$

The reactions $1, \dots, r'$ are said to be independent (from a thermodynamic point of view) if none of these equations can be derived by linear combination of the others.

INDEPENDENT VARIABLE. (1) For the mathematical meaning of this term, see **function**. (2) That independent quantity or condition which, through the action of the control system of an automatic controller, directs the change in the controlled variable according to a predetermined relationship.

INDETERMINACY PRINCIPLE. A consequence of quantum mechanics that asserts that in the simultaneous determination of the values of two canonically conjugated variables, the product of the smallest possible un-

certainties in their values is of the order of magnitude of the Planck constant h . If Δq is the uncertainty in the value for the coordinate q of a particle, and Δp is the uncertainty in the simultaneous determination of the corresponding component of its momentum p , then $\Delta p \cdot \Delta q = h/4\pi$. Similarly if ΔE and Δt are the uncertainties in the simultaneous determination of the energy and the time, $\Delta E \cdot \Delta t = h/4\pi$.

INDETERMINATE FORM. Limiting processes applied to special combinations of **functions** sometimes result in meaningless expressions such as $0/0$, ∞/∞ , $0 \cdot \infty$, $\infty - \infty$, 1^∞ , 0^∞ , ∞^0 , etc. These are called indeterminate forms. To evaluate them, **L'Hospital's rule**, or modifications of it may be used, as will now be shown for several special cases.

(1) The case $0/0$. The limiting value of $f(x)/\phi(x)$ for $x = a$ is $f^{(n)}(a)/\phi^{(n)}(a)$, where the lowest-order **derivatives** which do not vanish are to be evaluated.

(2) The case ∞/∞ . Let $f(x) = 1/g(x)$, $\phi(x) = 1/h(x)$ and evaluate $h^{(n)}(a)/g^{(n)}(a)$ as in case (1). The same procedure works when $a = -\infty$.

(3) The case $0 \cdot \infty$. If $f(x)\phi(x)$ becomes indeterminate, reduce the expression to case (1) or case (2) by writing it as $f(x)h(x)$ or $g(x)\phi(x)$.

(4) The case $\infty - \infty$. The indeterminate form is $f(x) - \phi(x) = 1/g(x) - 1/h(x) = (h - g)/gh$, which is now case (1).

(5) The cases 0^0 , ∞^0 , 1^∞ . The function has the form $f(x)^{\phi(x)}$. Its **logarithm**, however, is $\phi(x) \ln f(x)$ which is case (3).

INDETERMINATE STRUCTURE. A statically indeterminate structure is one that cannot be analyzed by means of the equations of static equilibrium alone. The properties of the material of which the structure is composed enter the problem through the stress-strain relations. Also the requirements of geometry or continuity must be considered.

INDEX. (1) An exponent. (2) A subscript or superscript used in **indicial notation**. (For index of a subgroup, see **eoset**.)

INDEX, DUMMY. See **summation convention**.

INDEX, FREE. An index on a symbol or product of symbols which is not repeated (cf. dummy index in entry on **summation convention**). Also called *identifying index*.

INDEX, IDENTIFYING. See **index, free**.

INDEX OF PROBABILITY. Gibbs' name for the natural logarithm of the **coefficient of probability**.

INDEX OF REFRACTION, ABSOLUTE. For a non-absorbing medium the absolute index of refraction may be defined by either: (1) The velocity of radiation *in vacuo* divided by the velocity of the same radiation in a specified medium. Because of **Snell's law**, the index of refraction may also be defined as the ratio of the sine of the angle of **incidence** (*in vacuo*) to the **angle of refraction**. Because the difference is small, the index of refraction is frequently measured with respect to air rather than with respect to free space (vacuum). (See **index of refraction, relative**.) Excepting a few very special cases (x-rays; light in metal films) the index of refraction is a number greater than unity. A few representative values are:

$$n_{\text{water}} = 1.34, n_{\text{glass}} = 1.5-1.9,$$

$$n_{\text{germanium}} = 4.25 \text{ (infrared radiation).}$$

(2) The square root of the relative dielectric constant of a medium $\sqrt{\epsilon/\epsilon_0}$. The index of refraction is invariably a function of the frequency or wavelength of the radiation. When definition (2) is used, the appropriate value of ϵ is often not the permittivity observed with static fields.

(For absorbing media, see **index of refraction, complex**.)

INDEX OF REFRACTION, COMPLEX. The dynamic dielectric constant k of a medium is in general a complex number and the complex index of refraction is $\sqrt{k} = n + im = n(1 - ik)$ where the real part n is the refractive index and m , or alternatively, k is the absorption constant or **absorption index** of the medium. The second form is especially useful in the study of metallic reflection. (See **Fresnel equations for metallic reflection**.)

INDEX OF REFRACTION, ELECTRON-OPTICAL. See **electron-optical index of refraction**.

INDEX OF REFRACTION FOR METALS. See **index of refraction, complex**.

INDEX OF REFRACTION, RELATIVE. If v_i is the velocity of light in a non-absorbing medium M_i then the relative index of refraction

tion M_2 in M_1 is $n_1 = v_1/v_2$. In many applications M_1 is air and since the absolute index of refraction of air under common conditions of temperature and pressure is approximately 1.00029, the absolute index of M_2 is often used as an approximation to the relative index of M_2 in air and referred to as the index of M_2 .

INDEX OF REPULSION. See **point centers of repulsion**.

INDEX, UMBRAL. See **summation convention**.

INDICATED EFFICIENCY. In a reciprocating gas compressor, the ratio of the indicated power IP_i , measured on an indicator diagram, to the ideal power consumption. The latter can be calculated on two alternative bases: (a) assuming an isothermal process, IP_T , (b) assuming an isentropic process IP_S . Hence

$$\eta_i = \frac{IP_T}{IP_i} \quad \text{or} \quad \eta'_i = \frac{IP_S}{IP_i}.$$

The indicated efficiency is a measure of how well the actual engine performs the stipulated ideal process ($T = \text{const.}$ or $S = \text{const.}$). Since compressors are usually cooled, and since IP_T represents the minimum work, it is found that $\eta_i < 1$ always, but η'_i may become larger than 1.

INDICATED MEAN EFFECTIVE PRESSURE. See **mean effective pressure**.

INDICATED THERMAL EFFICIENCY. In a reciprocating prime mover (internal combustion engine, steam engine), the ratio of indicated work W_i to heat Q supplied to working fluid:

$$\eta_i = \frac{W_i}{Q}.$$

The indicated work is measured on an *indicator diagram* and, consequently, excludes mechanical losses. The indicated thermal efficiency is a measure of the perfection of the thermodynamic design of the engine, i.e., a measure of how well the heat supplied Q has been transformed into mechanical work. In an internal combustion engine

$$Q = BH_n$$

per unit time; here B is the fuel consumption and H_n its lower **calorific value**. In a steam engine

$$Q = h - h_w$$

per unit mass of working fluid, where h is the enthalpy of the steam at admission, and h_w is the enthalpy of the feed-water to the boiler.

INDICATRIX (AT A POINT P OF A SURFACE). In a two-dimensional rectangular Cartesian coordinate system x, y with axes in the principal directions at P , for which the principal curvatures are κ_x and κ_y , the ellipse $|\kappa_x|x^2 + |\kappa_y|y^2 = 1$, if P is an elliptic point; the two hyperbolas $\kappa_x x^2 + \kappa_y y^2 = \pm 1$, if P is a hyperbolic point; a pair of parallel straight lines in the tangent plane at P , parallel to the principal direction for which the principle curvature is zero, if P is a parabolic point. $|\kappa_x|$ and $|\kappa_y|$ denote the absolute values of κ_x and κ_y .

These curves are similar and similarly situated to the real curves of intersection with the surface of planes parallel to the tangent plane at P on both sides of it and infinitely close to it. Also called *Dupin's indicatrix*.

INDICATRIX OF DIFFUSION. The surface formed by the extremities of the radii vectors drawn in all directions from an element of a surface of a secondary source, or from an element of volume of a translucent solid, when each radius vector represents the (relative) **luminous intensity** or the (relative) **luminance** in the corresponding direction. (1) In many cases only a meridian section of this indicatrix is required. (2) The term indicatrix is often used to denote, instead of the surface, the curve obtained in a similar manner in a plane normal to the element concerned.

INDICATRIX OF REFRACTION. An indicatrix of refraction at a point O of an anisotropic medium is a set of points P so that the distance OP is proportional to the index of refraction of the medium in the direction OP .

INDICIAL EQUATION. As an attempt to find a series solution valid near a point $x = c$ of a linear homogeneous ordinary differential equation

$$y^{(n)} + a_1 y^{(n-1)} + \cdots + a_{n-1} y' + a_n y = 0,$$

we may substitute

$$y = \sum_{k=0}^{\infty} a_k (x - c)^{k+s}$$

in the equation. When k is put equal to zero, and the coefficient of the lowest power of x is

set equal to zero, the result is called the indicial equation, since it serves to determine the values of s . These values are called the **exponents** of the differential equation.

The indicial equation may be: (1) independent of s , in which case no series solution of the type assumed exists; (2) a **polynomial** in s , of degree equal to the order of the differential equation; depending on the nature of the roots of the indicial equation, there may then be n distinct series solutions of the differential equation or fewer; (3) a polynomial in s of degree less than the order of the differential equation in which there will be fewer than n distinct series solutions.

In case (2) the point c is a regular singularity (see **singular point of a differential equation**) of the differential equation, and setting successive coefficients equal to zero in the above power series in x , obtained by substituting the above y into the given differential equation, will, in general, determine the successive a_k . But if the roots of the indicial equations differ by an integer, the general solution will involve logarithms. This method is often named after Frobenius, who made an important contribution to its theoretical justification.

INDICIAL NOTATION. The notation in which a set of quantities, called a *system*, is denoted by a symbol carrying one or more indices which may be superscripts or subscripts. These are usually lower case Latin italics and it is understood that each of the indices may take independently the integral values 1, 2, \dots , n (say). For example, with $n = 3$, the symbol a_j^i denotes the nine quantities $a_1^1, a_2^2, a_3^3, a_3^2, a_2^3, a_1^3, a_3^1, a_2^1, a_1^2$. With $n = 4$, the symbol $a_{pq}b^r$ denotes the sixty-four quantities obtained by assigning to p, q and r the values 1, 2, 3, 4 independently.

The individual quantities obtained by assigning values from 1 to n to each of the indices are called the *elements* or *components* of the system. Systems of quantities depending on one index are called *systems of the first order* or *simple systems*. Those depending on two indices are called *systems of the second order* or *double systems*, and so on.

INDICIAL RESPONSE. The **normal response** of a system to an input in the form of **unit step function** at the origin.

If the output quantity is $q_o(t)$ the input $\theta(t)$ and their **Laplace transforms** for an initially quiescent system are related by

$$Q_o(s) = F(s) \cdot \Theta(s)$$

where $F(s)$ is the transfer function connecting them, then if $\theta(t)$ is unit step function, $\Theta(s) = \frac{1}{s}$ and therefore

$$Q_o(s) = F(s)/s.$$

Hence

$$\begin{aligned} q_o(t) &= \int_0^t \{\mathcal{L}^{-1}F(s)\} dt \\ &= \int_0^t W(t) dt \end{aligned}$$

where $W(t)$ is the **weighting function** (the response to unit **impulse function** at $t = 0$). Thus indicial response is the time integral of the weighting function. Similarly, the response to unit ramp function input is the integral of the indicial response.

INDIFFERENT LINE. See **Saurel theorem**.

INDIFFERENT STATES. Let us consider a closed system whose state (see **Duhem theorem**) is determined completely by T, p , the weight fractions w_i^α of each component ($i = 1 \dots c$) in the various phases α ($\alpha = 1 \dots \phi$) and the mass of each phase, i.e., by the variables

$$T, p, w_1^1, \dots, w_c^\phi, m^1 \dots m^\phi. \quad (1)$$

Suppose the system is initially in the state (1).

Let us then consider the set of states accessible to this closed system, i.e., compatible with the conservation of mass (see **conservation of mass in closed systems**). If there exists in this set states which differ from (1) in the mass of at least one of the phases, but in which all the weight fractions are the same, the state (1) is called an **indifferent state**. The system is then called an *indifferent system*. This terminology is due to Duhem.

A simple example is given by the decomposition of calcium carbonate

where (s) means a solid phase and (g) a gas. CaCO_3 and CaO are two distinct solid phases.

If a molecule of CaCO_3 decomposes, then it increases the amount of CaO and CO_2 without altering the composition of any of the phases, each phase being formed by a simple com-

ponent. All states of the system are indifferent.

The **azeotropic systems** are also special cases of indifferent systems.

The properties of indifferent systems are very similar to those of azeotropic systems. For example, one has the generalized **Gibbs-Konovalov theorems**: *If in any isothermal (isobaric) equilibrium change the system passes through an indifferent state, then the pressure (temperature) passes through an extreme value, and conversely.* (See also **Saurel theorem**.)

INDUCED DRAG. See **drag**.

INDUCED POLARIZATION. The **polarization** brought about by the action of an electric field in a dielectric that does not contain permanent **dipoles**.

INDUCTANCE. See **inductance, self**; and **inductance, mutual**.

INDUCTANCE, MUTUAL. The mutual inductance, M , between two circuits or two circuit elements is defined as the ratio $M = \phi/I$ where ϕ is the flux linked by one and being produced by a current I in the other. From the Faraday law of electromagnetic induction, the voltage, V , induced in the first circuit or circuit element is given by $V = -MdI/dt$, where dI/dt is the time rate of change of the current in the second circuit or element. Mutual inductances are measured in henries. (See also **inductance, self**; **circuits**.)

INDUCTANCE, SELF. The self inductance, L , is defined as the ratio $L = \phi/I$, where ϕ is the magnetic flux linked and produced by a circuit or circuit element and I is the current in the same circuit or element. From the Faraday law of electromagnetic induction the back emf is given by $V = -LdI/dt$. Self inductances are measured in henries. (See also **inductance, mutual**.)

INDUCTION DRAG. A velocity-dependent resistive force which acts on a conducting fluid to dampen its motion perpendicular to the magnetic lines of force.

INDUCTION EFFECT. See **van der Waals forces**.

INDUCTION, ELECTRIC AND MAGNETIC. The word induction is often used to indicate the generation or alteration of charge

or current distributions, or magnetic dipole distributions in a substance, brought about by the presence or approach of an electrified body, a magnet or any other source of electric or magnetic field.

INDUCTION ENERGY. See **Debye energy**.

INDUCTION FIELD. See **field, induction**.

INDUCTION FORCES. When a charged particle a (for example an ion) interacts with a neutral molecule, the charged particle a *induces* on the neutral molecule b a dipole moment. If the **polarizability** of molecule b is α_b the energy of interaction between the charge e_a and this induced moment is

$$\phi(r) = -\frac{e_a\alpha_b}{2r^4}. \quad (1)$$

Similarly, there exists a potential energy of interaction between a point dipole μ_a and an induced dipole produced in a neutral molecule of polarizability α_b . When averaged over the angles, the result is

$$\phi(r) = -\frac{\mu_a^2\alpha_b}{r^6}. \quad (2)$$

It is important to note that (1) and (2) correspond always to an *attraction*. This effect was discussed for the first time by Debye.

INDUCTION, INTRINSIC (B_i) (INTENSITY OF MAGNETIZATION). The intrinsic induction or magnetic polarization of a medium is the vector difference between the **magnetic induction** at the point of interest, and the induction which would exist at that point, for the same **magnetizing force** if the medium were a vacuum there.

$$\mathbf{B} = \gamma_m \mathbf{H} + \mathbf{B}_i,$$

where γ_m is the magnetic constant (μ_0). In unrationalized systems of units the magnetic polarization is defined by

$$\mathbf{P}_m = \mathbf{B}_i/4\pi,$$

whereas in rationalized systems,

$$\mathbf{P}_m = \mathbf{B}_i.$$

In any system, the polarization is related to the **magnetic moment density** by $\mathbf{P}_m = \gamma_m \mathbf{M}$.

INDUCTION THEOREM. Consider a medium comprising two homogeneous regions (which may have different or identical prop-

erties) separated by a closed surface S . An impressed electromagnetic field $\mathbf{E}_i, \mathbf{H}_i$ gives rise to an induced field; the induced field is composed of a field reflected from the surface and a field transmitted by the surface. The induced field is the same as that produced by electric and magnetic current-sheets on the surface, of densities

$$\mathbf{J} = \mathbf{n}_i \times \mathbf{H}_i$$

$$\mathbf{M} = \mathbf{E}_i \times \mathbf{n}.$$

This is a consequence of **Green's theorem** applied to **Maxwell's equations**.

INDUCTIVE CAPACITY. See **permittivity** or **dielectric constant**.

INDUCTIVE EFFECT AND REACTIVITY.

The term is used to describe the tendency of electronegative or electropositive groups or atoms in organic molecules to polarize the remainder of the molecule, i.e., to decrease or increase the electron density of the neighboring atoms. For molecules containing double bonds (and particularly **conjugated double bonds**), the inductive effect can be quite important, because of the mobility of the π -electrons. It affects the tendency of the molecule to react with *electrophilic* or *nucleophilic* atoms or groups of atoms. (See also **resonance effect**.)

INDUCTOR. A device whose primary purpose is to introduce **inductance** into an electric circuit or network.

INEQUALITIES, METHOD OF. A procedure for computing the plastic limit load of a frame based upon the solution of systems of linear inequalities. The inequalities express the fact that at each critical section the bending moment cannot exceed the positive moment or be algebraically less than the negative limit moment.

INEQUALITY. For various inequalities, e.g., **Abel**, **Hölder**, **Minkowski**, see the respective names.

INEQUALITY THEOREMS, METHOD OF. A technique for the **X-ray analysis of crystal structure** in which use is made of certain fundamental inequalities, which must be satisfied by the **structure factors**, to estimate their phases.

INERTANCE, ACOUSTIC (ACOUSTIC MASS). The quantity which, when multiplied by 2π times the frequency, gives the acoustic reactance (see **reactance, acoustic**) associated with the kinetic energy of the medium. It is measured in acoustic ohms.

INERTANCE, SPECIFIC ACOUSTIC. The coefficient which, when multiplied by 2π times the frequency, gives the positive imaginary part of the specific acoustic impedance. (See **impedance, specific acoustic**.)

INERTIA. A property manifested by all matter, representing the resistance to any alteration in its state of motion. **Mass** is the quantitative measure of inertia.

INERTIA, AREA MOMENT OF. If the area lies in the xy -plane, the moment of inertia about the y -axis is $I_y = \int_A x^2 dA$, about the x -axis is $I_x = \int_A y^2 dA$ and about a perpendicular or polar axis $I_p = \int_A r^2 dA$, where r is measured from the polar axis. If the polar axis is erected at the intersection of the x and y axes, $I_p = I_x + I_y$.

INERTIA, AREA PRODUCT OF. If the area is taken to be in the xy -plane the product of inertia $I_{xy} = \int_A xy dA$. The product of inertia is zero if either axis is a line of symmetry or, more generally, a principal axis.

INERTIA ELLIPSOID. The quadric surface associated with the inertia tensor. (See **angular momentum**.)

INERTIA FORCES. Forces equal and opposite to the reaction of matter on its surroundings when it is accelerated; represented in an equation of motion by the rate of change of momentum; equal to the resultant of all the other forces.

INERTIAL COORDINATE SYSTEM. See **inertial frame**.

INERTIAL FLOW. Flow in the absence of external forces.

INERTIAL FRAME. A **frame of reference** in which Newton's laws are valid, is termed an inertial frame. Axes fixed on the earth, a rotating body in **curvilinear motion**, are most

often taken to be a sufficiently good approximation to an inertial frame. **Coriolis** and **centrifugal** effects, however, do play a significant role in problems of missiles and satellites, wind and weather.

INERTIAL INSTABILITY. (1) (Also called dynamic instability.) Generally, **instability** in which the only form of energy transferred between the steady state and the disturbance is **kinetic energy**.

(See **Helmholtz instability**, **barotropic instability**.)

(2) The hydrodynamic **instability** arising in a rotating fluid mass when the velocity distribution is such that the kinetic energy of a disturbance grows at the expense of kinetic energy of the rotation.

INERTIA, MOHR CIRCLE FOR. See **Mohr circle for inertia**.

INERTIA, MOMENTS AND PRODUCTS OF. In the general case of the motion of a particle or aggregate of particles with respect to a single fixed point, the angular momentum can be written as having three components with respect to a coordinate system based at the fixed point.

$$H_x = \omega_x \sum m_i (y_i^2 + z_i^2) - \omega_y \sum m_i x_i y_i - \omega_z \sum m_i x_i z_i$$

$$H_y = -\omega_x \sum m_i x_i y_i + \omega_y \sum m_i (x_i^2 + z_i^2) - \omega_z \sum m_i y_i z_i$$

$$H_z = -\omega_x \sum m_i x_i z_i - \omega_y \sum m_i y_i z_i + \omega_z \sum m_i (x_i^2 + y_i^2)$$

where $\omega_x, \omega_y, \omega_z$ are components of angular velocity, m_i is the mass of i th particle, x_i, y_i, z_i are coordinates of i th particle.

The terms $\sum m_i (y_i^2 + z_i^2), \sum m_i (x_i^2 + z_i^2), \sum m_i (x_i^2 + y_i^2)$ are called moments of inertia with respect to the $x, y,$ and z axes, respectively, and are symbolized by $I_{xx}, I_{yy},$ and I_{zz} .

The terms $\sum m_i x_i y_i, \sum m_i x_i z_i,$ etc., are called the products of inertia and are symbolized by $I_{xy}, I_{xz},$ etc.

For a continuous rigid body the summations are replaced by integrals over the volume of the body. In a rigid body, it is sometimes easier to choose coordinate axes, called moving axes, which are fixed in the body. There always exists one set of such axes, called principal axes, such that the products of inertia

vanish and the angular momentum can be expressed in terms of the moments of inertia alone. Following are formulae for the moments of inertia of certain homogeneous solids with respect to the axes specified (M is the total mass of the body in each case):

Particle distant r from axis	Mr^2
Sphere of radius R , with respect to any diameter	$\frac{2}{5}MR^2$
Cube of edge L , with respect to axis through center parallel to edge	$\frac{1}{6}ML^2$
Rectangular plate, dimensions $A \times B$, with respect to axis perpendicular to it at center	$\frac{M}{12}(A^2 + B^2)$
Cylinder of length L and radius R , with respect to axis perpendicular to its length at center	$M \left(\frac{L^2}{12} + \frac{R^2}{4} \right)$
Cylinder of radius R , with respect to its own longitudinal axis	$\frac{1}{2}MR^2$
Any body with respect to any axis distant r from the center of mass, the value for a parallel axis through that point being I_0	$I_0 + Mr^2$

Experimental methods of obtaining moments of inertia by the use of a torsion pendulum are explained in any laboratory manual of elementary dynamics.

For certain purposes it may be desirable to know at what one distance from the axis all the particles of the body of mass M would have to be placed to give it the same moment of inertia I that it actually has. This distance is the radius of gyration, and is expressed by the formula

$$k = \sqrt{\frac{I}{M}}$$

The "principal axes" of a body through a given point are axes of maximum or minimum moment of inertia.

The quantity expressed by

$$I = \int r^2 da,$$

in reference to any plane figure, is called the areal moment of inertia of the figure with

respect to a given straight line in its plane. The figure is divided into elements of area da , each element multiplied by the square of its distance r from the axis, and the products summed as indicated above to get the areal moment of inertia. This quantity is purely geometric and has of course no actual connection with inertia or mass. One of its important applications is in the theory of **flexure** of elastic rods or beams. If E is the (Young's) elastic modulus of the material and I the areal moment of inertia of the cross-section with respect to the **neutral axis**, the bending moment or flexural torque required to bend the rod to a **curvature** κ is given by

$$M = EI\kappa.$$

INERTIA, ROUTH RULE OF. See **Routh rule of inertia**.

INFINITE ABSORBER MODEL. In the theory of resonance capture of neutrons in a chain reacting system, the calculational model in which it is assumed that the heavy atom which does the capturing may be ascribed infinite mass, i.e., the capturing atom does not moderate. (See **narrow resonance model**.)

INFINITE GRAPH. See **graph, infinite**.

INFINITE MULTIPLICATION. See **multiplication, infinite**.

INFINITESIMAL. The word infinitesimal is properly defined only as part of a phrase. Thus a function $y = y(x)$ is sometimes said to be an infinitesimal if there is a value of x , call it a (usually $a = 0$ or $a = \infty$), such that $y \rightarrow 0$ as $x \rightarrow a$, but more properly one should say that y becomes infinitesimal at a . The idea of the *order of an infinitesimal* is often convenient. Thus if y and z become infinitesimal at a , but their quotient remains between finite (non-zero) limits, then y and z are said to be infinitesimals of the same order. If y^n and z are of the same order, then z is said to be of the n th order relative to y , and so forth.

INFINITESIMAL DEFORMATION. A **deformation** in which the displacement gradients in a rectangular Cartesian coordinate system are sufficiently small so that terms of second degree in them may be systematically neglected in comparison with terms of first-degree; terms of third degree may be systematically neglected in comparison with terms of second degree and so on.

INFINITESIMAL RING OF A GROUP OF LINEAR TRANSFORMATIONS. Let G be a group of linear transformations (see, e.g., **Lie group**), i.e., a group of $n \times n$ (real or complex) matrices M whose elements (at least for small values of the p_i) are differentiable functions of r parameters p_1, p_2, \dots, p_r so chosen that $M(0, 0, \dots, 0)$ is the unit **matrix**. E.g., for rotations through an angle ϕ in the plane $n = 2, r = 1, p_1 = \phi$ and the matrices are given by

$$\begin{pmatrix} \cos \phi, & -\sin \phi \\ \sin \phi, & \cos \phi \end{pmatrix}.$$

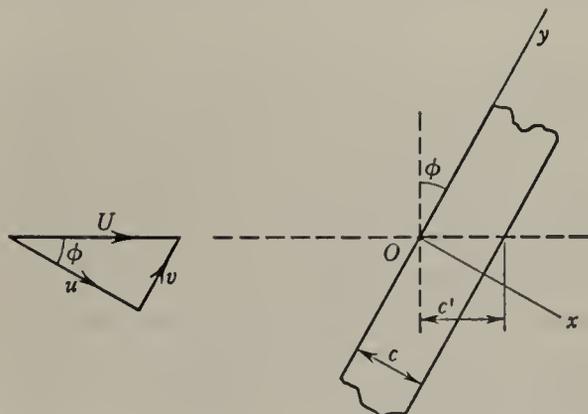

Consider all possible ways of selecting a one-parameter family $M(\theta)$ from G with $M(0) = 0$, and form the corresponding matrix $M'(0)$. The set of all such matrices $M'(0)$ is called the infinitesimal ring G^0 of the group G . E.g., in the above case the infinitesimal ring for rotations in the plane consists of multiples of the matrix

$$\begin{pmatrix} 0, & -1 \\ 1, & 0 \end{pmatrix}.$$

It is easy to prove that if G^0 contains the matrices U and V , then it also contains $W \equiv UV - VU$, and is actually a (non-commutative, non-associative) ring if W is defined as the product of U and V . The ring G^0 is in fact the most important special case of an abstract **Lie ring**.

INFINITE YAWED WING. The theory of an infinite yawed wing of constant chord is of interest, because it is relatively simple and gives some insight into the more complicated case of a swept back wing of finite span.

The system to be considered is shown in the figure. The wing is yawed at an angle ϕ and is placed in an infinite uniform stream

Infinite yawed wing.

of velocity U . Resolving the velocity U into components u and v , parallel to the axes Ox and Oy , it is clear that if viscous effects are neglected the pressure distribution on the wing depends only on the component u , and is independent of v . Thus the pressure, lift and moment coefficients on the yawed wing (denoted by symbols with primes) can be related simply to the coefficients on the same wing at zero yaw (symbols without primes) by the equation

$$\frac{C'_p}{C_p} = \frac{C'_L}{C_L} = \frac{C'_m}{C_m} = \cos^2 \phi. \quad (1)$$

Except in cases where the compressibility of the fluid can be neglected, this equation must be applied to the yawed wing at a Mach number M' and to the unyawed wing at a Mach number $M = M' \cos \phi$. This illustrates the important effect of sweep back in delaying to higher Mach numbers the changes that occur on an unswept wing at Mach numbers approaching 1.

In deriving Equation (1) it has been assumed that the incidence of the unyawed wing is the same as that of the yawed wing measured in a plane normal to the axis OY . Also, the chord used in defining C'_m is c' (and not c) and the pitching moment is measured about an axis perpendicular to the velocity U .

It can be shown that for a **laminar boundary layer** on an infinite yawed wing the equations for flow in the plane xz are independent of the flow in the plane yz . Hence the flow in the plane xz can be calculated without considering the flow in the plane yz , and the results then used to calculate the latter.

When the boundary layer is **turbulent** the evidence regarding this "independence principle" is conflicting, but at present it seems likely that the principle does *not* apply.

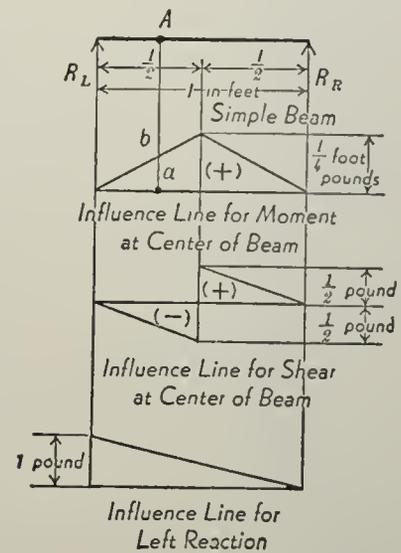

INFINITY. The word infinity is usually defined only as part of a phrase. Thus a function $f(x)$ is said to approach infinity at a point $x = a$ if after choice of any number N , a number $\delta > 0$ can be found such that $f(x) > N$ for all x if $|x - a| < \delta$.

INFLECTION, POINT OF. A point on a curve, $y = f(x)$, where the **derivative** dy/dx changes sign but where neither a maximum nor a minimum occurs. It may be distinguished from these two cases, for, at a point of inflection, $d^2y/dx^2 = 0$.

The bending moment in a beam is zero at a point of inflection.

INFLUENCE COEFFICIENTS. The magnitude of the effect produced at one point by a unit disturbance at another, as for example, a component of stress, force, moment, or deflection at one point of a structure produced by a unit force or deflection at another.

INFLUENCE LINE. An influence line is a graphical way of representing the effect of a certain variable circumstance upon a given condition. In particular, the influence line as applied in structural engineering represents the

variable effect of a single moving unit concentrated load upon the shear, bending moment, reaction, or any other function of a structure such as a beam, **truss**, or **bridge**. The influence line is plotted in reference to a base or zero line. Positive or tensile effects are represented above the line and negative or compressive effects below. The ordinate of the influence line is the ratio of the effect to the concentrated load producing it. If the load is in lbs. or tons the effect is in lbs. or tons. It is very useful for locating the position of the load which will produce maximum effect. For instance, the influence line for **bending moment** at the center of the beam shown above indicates that the maximum moment for this point will occur when the moving load which may be taken as unity is directly over the point. Any other ordinate such as ab represents the bending moment at the center due to a load of unity at point A . The maximum moment at the center of this beam due to a **uniform** load of w lbs. per linear ft., covering the

entire length, may be computed by multiplying the area of the influence line by w .

$$\text{Area} = \frac{l}{4} \times l \times \frac{1}{2} = \frac{l^2}{8}$$

$$\text{Maximum moment at center} = \frac{wl^2}{8}$$

Such quantitative results can also be obtained by the usual analytical methods. However, since influence lines are almost invariably drawn to indicate how a structure subjected to moving loads should be loaded, it is usually convenient, and faster, to use the ordinates and areas of the influence line to obtain moments, stresses, etc.

Influence lines for statically **determinate structures** are composed of straight lines. Those for **indeterminate structures** are curved or have straight segments the intersections of which lie on curves. (See **Mueller-Breslau principle**.)

INFORMATION. (1) See **information content** and **information theory**. (2) Apart from its ordinary meaning, this term occurs in statistics in a specialized sense. If a sample of n values is drawn from a frequency function $f(x, \theta)$ the amount of information about θ in the sample is defined as

$$n \int_{-\infty}^{\infty} \left(\frac{\partial}{\partial \theta} \log f(x, \theta) \right)^2 f(x, \theta) dx.$$

In a multivariate situation the matrix whose $(i, j)^{th}$ element is the expectation of $n \frac{\partial \log f}{\partial \theta_i} \times \frac{\partial \log f}{\partial \theta_j}$ is called the *information matrix*.

INFORMATION CONTENT (OF A MESSAGE OR A SYMBOL FROM A SOURCE). The negative of the logarithm of the probability that this particular message or symbol will be emitted from the source. The choice of logarithmic base determines the unit of information content. (See **bit** and **hartley**.) The probability of a given message or symbol being emitted may depend on one or more preceding messages or symbols. The quantity has been called *self-information*.

INFORMATION CONTENT, AVERAGE. (PER SYMBOL) (INFORMATION RATE FROM A SOURCE, PER SYMBOL.) The average of the information content per symbol

emitted from a source. The terms entropy and negentropy are sometimes used to designate average information content.

INFORMATION CONTENT, CONDITIONAL. (OF A FIRST SYMBOL GIVEN A SECOND SYMBOL.) The negative of the logarithm of the conditional probability of the first symbol, given the second symbol. The choice of logarithmic base determines the unit of information content. (See **bit** and **hartley**.) The conditional information content of an input symbol given an output symbol, averaged over all input-output pairs, is the *equivocation*. The conditional information content of output symbols relative to input symbols, averaged over all input-output pairs, has been called *spread*, *prevarication*, *irrelevance*, etc.

INFORMATION MATRIX. See **matrix, information**.

INFORMATION THEORY. A mathematical theory relating to the problems of the processing and transmission of information. Information is measured quantitatively in terms of equally likely yes or no decisions called **bits**. A communication channel is characterized by a capacity measured in bits per second. The capacity determines the maximum rate at which the channel can convey information. The central problem in information theory is that of finding methods of coding information which make for the most efficient use of a channel.

INFRARED RADIATION. Any radiation whose monochromatic components lie for practical purposes within the wavelength range 780–10⁵ millimicrons.

INFRARED SPECTRA OF MOLECULES. See **rotation spectra of molecules**, **rotation-vibration spectra of molecules**.

INFRARED SPECTRUM. See **spectrum, infrared**.

INHOMOGENEOUS LORENTZ TRANSFORMATION. An inhomogeneous Lorentz transformation, $L = \{a, \Lambda\}$ is defined by

$$x'_\mu = \sum_{\nu=0}^3 \Lambda_\mu^\nu x_\nu + a_\mu$$

where Λ is a **homogeneous Lorentz transformation** and the term a_μ corresponds to a space-

time translation by the amount $a_\mu = \{a_0, a_1, a_2, a_3\}$. The multiplication law for Lorentz transformations is

$$\{a_1, \Lambda_1\} \cdot \{a_2, \Lambda_2\} = \{a_1 + \Lambda_1 a_2, \Lambda_1 \Lambda_2\}$$

The set of all inhomogeneous Lorentz transformations form a 10 parameter continuous group. If one denotes the **generators** for infinitesimal space time-translations by p_μ , and the generators for rotations in the $x^\mu x^\nu$ plane by $M_{\mu\nu} = -M_{\nu\mu}$ the commutation rules obeyed by these operators are

$$\begin{aligned} [p_\mu, p_\nu] &= 0 \\ [M_{\mu\nu}, M_{\rho\sigma}] &= -i(g_{\mu\rho}M_{\nu\sigma} - g_{\nu\rho}M_{\mu\sigma} \\ &\quad + g_{\mu\sigma}M_{\rho\nu} - g_{\nu\sigma}M_{\rho\mu}) \\ [M_{\mu\nu}, p_\sigma] &= i(g_{\nu\sigma}p_\mu - g_{\mu\sigma}p_\nu). \end{aligned}$$

IN HOUR (INVERSE HOUR). In the theory of neutron chain reactors, a unit of **reactivity**. It is the amount of positive reactivity required to give a particular reactor a steady positive period of one hour or 3600 seconds, and so, as a unit, varies from system to system. The inhour formula, expressed in terms of inhours, becomes:

$$\rho^{(ih)} = \frac{\frac{l}{k_{eff}T} + \sum_i \frac{\beta_i}{1 + \lambda_i T}}{\frac{l}{3600k_{eff}} + \sum_i \frac{\beta_i}{1 + 3600\lambda_i}}$$

if λ_i and l are expressed in terms of seconds.

IN HOUR (INVERSE HOUR) FORMULA. In the theory of neutrons chain reactions, a formula relating reactor period (see **period, reactor**) to effective **multiplication**. A form very often used is:

$$\rho = \frac{k_{eff} - 1}{k_{eff}} = \frac{l}{k_{eff}T} = \sum_i \frac{\beta_i}{1 + \lambda_i T}$$

where ρ denotes the reactivity, k_{eff} the effective multiplication, l the neutron lifetime, T the reactor period, β_i the yield fraction and λ_i the decay constant for the i^{th} group of delayed neutrons. If N groups of delayed neutrons are considered, N real periods T_j emerge as solutions, but no more than one may be positive.

INITIAL MODULUS. The value of the **tangent modulus** at zero stress.

INITIAL-VALUE PROBLEMS. For **ordinary differential equations**, those for which the

initial values of the dependent variables are specified; for **partial differential equations**, those of parabolic or hyperbolic type, requiring the specification of initial conditions as well as possibly conditions along the boundary.

In mechanics and fluid mechanics, initial-value problems include particularly those dynamical or transient problems in which the state of the system changes, as contrasted with **steady-state** problems, and is determinable at any time from the initial conditions.

INITIAL VERTEX. See **vertex, initial**.

INNER MULTIPLICATION OF TENSORS. See **tensors, inner product of**.

IN, OUT FIELD. See **S matrix and QT**.

INSPECTIONAL ANALYSIS. The reduction of the mathematical equations of a problem to non-dimensional units of space, time, and mass; or testing such equations for invariance under any group of transformations. The procedure stands in close relation to **dimensional analysis** and usually gives rise to a set of **non-dimensional numbers** appearing as coefficients in the governing equations. These can always be arranged to be the same as the non-dimensional numbers or parameters of a corresponding dimensional analysis.

INSTABILITY. A property of the **steady state** of a system such that certain disturbances or perturbations introduced into the steady state will increase in magnitude, the maximum perturbation amplitude always remaining larger than the initial amplitude.

The method of **small perturbations**, assuming **permanent waves**, is the usual method of testing for instability; unstable perturbations then usually increase exponentially with time. An unstable non-linear system may or may not approach another steady state; and the method of small perturbations is incapable of making this prediction. (See also entries under **stability**.)

INSTANTANEOUS AXIS OF ROTATION. In rigid body motion, the line in the body or an extension of the body which is instantaneously at rest. For a cylinder rolling down an inclined plane without slipping, the instantaneous axis is the line of contact between the cylinder and the plane.

INSTANTANEOUS CENTER. A term applicable to plane motion. It is the point of

intersection of the **instantaneous axis of rotation** with the **plane of motion**. The instantaneous center is a point about which the body may be considered to be in pure **rotation** (i.e., without **translation**) at any instant. It is not necessarily on the body. In the case of **rectilinear motion** it is infinitely distant.

INSTANTANEOUS FREQUENCY. See **frequency, instantaneous**.

INTEGRABLE SQUARE. A function $f(x)$ having the property that

$$\int f^*(x)f(x)dx < \infty$$

is integrable square (f^* is the complex conjugate of f). The definition is very often used of real functions $f(x)$, where it becomes

$$\int f^2(x)dx < \infty;$$

the type of integration referred to is usually that of Lebesgue.

INTEGRAL. The function $\phi(x)$ is an integral of $f(x)$ if $d\phi/dx = f(x)$. The process of finding an integral is integration or the inverse of **differentiation**. If C is any real number, then $\phi(x) + C$ is also an integral of $f(x)$. (See **constant of integration**.) Thus, if one integral exists, an infinite number of others may be obtained by adding an arbitrary constant. These are called indefinite integrals and indicated symbolically as

$$\int f(x)dx = \phi(x) + C.$$

(For various types of definite integral, e.g., **Riemann**, **Stieljes**, **Lebesgue**, and others, see the respective names.)

INTEGRAL, CAUCHY. See **Cauchy integral**.

INTEGRAL, CIRCULATORY. An integral of a vector function \mathbf{F} :

$$\oint \mathbf{F} \cdot d\mathbf{s}$$

over a closed **contour**. It is a measure of the tendency of lines of force to close up. If \mathbf{F} refers to a fluid, then the circulatory integral is a measure of the flow around the path chosen. When the vector field has a potential, this integral is zero and the field is said to be **irrotational**.

INTEGRAL CONTROL. See **control, proportional, derivative and integral**.

INTEGRAL, CONVOLUTION. See **convolution integral**.

INTEGRAL, DEFINITE. See **integral**.

INTEGRAL DOMAIN. See **domain**.

INTEGRAL, ELLIPTIC. See **elliptic integral**.

INTEGRAL EQUATION. An equation in which the unknown function occurs under an integral sign. A *linear integral equation of the third kind* is of the form

$$g(x)\phi(x) = f(x) + \lambda \int_a^b K(x,z)\phi(z)dz,$$

where the functions $g(x)$, $f(x)$ and $K(x,z)$ are known and it is desired to find the unknown ϕ as a function of x . The function $K(x,z)$ is called the kernel (or nucleus) of the equation. The limits of integration a and b are either constants or known functions of x , and λ is a parameter. When one or both of the limits become infinite or when the kernel becomes infinite at one or more points in the range of integration, the equation is called singular.

The most important special cases are:

(1) Fredholm equation of the first kind:
 $g(x) = 0$; a and b constant.

(2) Fredholm equation of the second kind:
 $g(x) = 1$; a and b constant.

(3) Volterra equation of the first kind:
 $g(x) = 0$; $a = 0$, $b = x$.

(4) Volterra equation of the second kind:
 $g(x) = 1$; $a = 0$, $b = x$.

(See also **Fredholm determinant**; **Liouville-Neumann series**.)

INTEGRAL FUNCTION. Synonym of **entire function**.

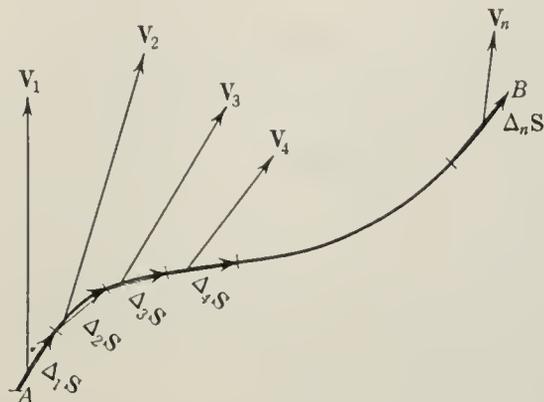

INTEGRAL, IMPROPER. See **improper integral**.

INTEGRAL, LEBESGUE. See **Lebesgue integral**.

INTEGRAL, LEBESGUE-STIELJES. See **Lebesgue-Stieljes integral**.

INTEGRAL, LINE. Given a **vector function** of position $\mathbf{V}(x,y,z)$ which is defined for all

points on a curve such as $A-B$ in the figure, one may replace the curve approximately by a series of equal, directed chords $\Delta_1S, \Delta_2S, \dots, \Delta_nS$. The magnitude and direction of the vector \mathbf{V} may then be determined at some point in each segment of the curve. The sum of the scalar products:

$$\sum_{j=1}^n \mathbf{V}_j \cdot \Delta_j S,$$

can then be obtained. The line integral is defined as

$$\int_A^B \mathbf{V} \cdot d\mathbf{S} = \lim_{n \rightarrow \infty} \sum_{j=1}^n \mathbf{V}_j \cdot \Delta_j S.$$

The usefulness of the line integral will be immediately recognized if a special case is considered. Suppose that \mathbf{V} is the force acting on a particle in a field of force. Then the line integral is just the work done on the particle as it moves from A to B under the action of the force.

When the line integral is taken over a closed path, or contour, starting and ending at the same point, it is usually denoted as

$$\int_C \mathbf{V} \cdot d\mathbf{S} \quad \text{or} \quad \oint \mathbf{V} \cdot d\mathbf{S}$$

and is sometimes called a *contour integral* or a *circulatory integral*.

The choice of the direction in which $d\mathbf{S}$ shall be counted as positive is a matter of convention, but cases arise (e.g., in connection with **Stokes theorem**) when consistency of convention must be assured. The magnitude of the integral is related by Stokes theorem to the integral of $\nabla \times \mathbf{V}$ (curl \mathbf{V}) over any surface bounded by the path.

In the particular case in which \mathbf{V} is the gradient of a potential ϕ ,

$$\int_A^B \mathbf{V} \cdot d\mathbf{S} = \phi_B - \phi_A,$$

i.e., to the difference of potential between B and A . Over a closed contour, then

$$\oint \mathbf{V} \cdot d\mathbf{S} = 0$$

and the field of \mathbf{V} is described as irrotational.

INTEGRAL, LOGARITHMIC. The definite integral

$$Li(z) = \int_0^z \frac{dt}{\ln t}.$$

If $z = e^x$, the function is also called the exponential integral

$$Ei(x) = Ci(x) + i Si(x) + \frac{i\pi}{2}$$

where $Ci(x)$, $Si(x)$ are the improper integrals called the cosine integral and sine integral, respectively:

$$\begin{aligned} Ci(x) &= -\int_x^\infty \frac{\cos t}{t} dt \\ &= C + \ln x - \int_0^x \frac{(1 - \cos t)dt}{t} \\ Si(x) &= \int_0^x \frac{\sin t}{t} dt = \frac{\pi}{2} - \int_x^\infty \frac{\sin t}{t} dt \end{aligned}$$

and C is the **Euler-Mascheroni constant**.

INTEGRAL, MULTIPLE. The definition of an **indefinite integral** can be extended to cover the case of a function of several variables and then more than one **integration** will be required to evaluate the integral. The subject can be considered in various ways but one simple approach is that of partial integration as the inverse to partial **differentiation**. Thus, given the double integral

$$u = \iint f(x,y) dx dy$$

one wishes to determine u so that it will satisfy the partial **differential equation** $u_{xy} = f(x,y)$. The first integration is performed with respect to x , for example, holding y constant, and the second with respect to y , although the order of integrating does not matter. Constants of integration added to the result complete the work, although these are not really constants but arbitrary functions of the variables.

Further generalization to triple, quadruple, etc., integrals offers no further difficulty in principle. Often, for ease in printing, a single integral sign is used for multiple integrals.

The definite multiple integral is commonly of more importance and it may be interpreted geometrically. For example, a function of three variables $f(x,y,z) = 0$ can be considered as a surface. Double integrals, with the appropriate limits, can then be formulated to give the volume of a solid bounded by two or more surfaces, the area of the surface itself, and the moment of inertia of a plane area. Similarly, a triple integral may be used to obtain the volume of a solid or of a closed surface. When given these geometrical interpretations double and triple integrals are often called surface and volume integrals.

INTEGRAL OPERATOR. An operator L involving integrals, usually of some such form as

$$Lf(x) = \int_a^b f(x)K(x,s)ds,$$

or similarly in several variables, where the function $K(x,s)$ is called the kernel of the operator. (Compare **integral transform**.)

INTEGRAL, RESONANCE. See **resonance integral**.

INTEGRAL, RIEMANN. See **Riemann integral**.

INTEGRAL, STIELJES. See **Stieljes integral**.

INTEGRAL, SURFACE. See **integral, multiple**.

INTEGRAL THEOREMS OF VECTOR ANALYSIS.

$$(1) \oint_C \mathbf{F} \cdot d\mathbf{R} = \iint_S (\mathbf{n} \cdot \nabla) \times \mathbf{F} da$$

(Stokes Theorem)

$$(2) \oint \oint_S \mathbf{F} \cdot \mathbf{n} da = \iiint_V \nabla \cdot \mathbf{F} dv$$

(Gauss Theorem)

$$(3) \oint_C f d\mathbf{R} = \iint_S \mathbf{n} \times \nabla f da$$

$$(4) \oint_C d\mathbf{R} \times \mathbf{F} = \iint_S (\mathbf{n} \times \nabla) \times \mathbf{F} da$$

$$(5) \oint \oint_S f \mathbf{n} da = \iiint_V \nabla f dv$$

$$(6) \oint \oint_S \mathbf{n} \times \mathbf{F} da = \iiint_V \nabla \times \mathbf{F} dv$$

$$(7) \iiint_V \mathbf{A}(\nabla \cdot \mathbf{B}) dv$$

$$= \oint \oint_S \mathbf{A}(\mathbf{n} \cdot \mathbf{B}) da - \iiint_V (\mathbf{B} \cdot \nabla) \mathbf{A} dv$$

Time Derivatives of Integrals

$$(8) \frac{d}{dt} \iint_S \mathbf{A} \cdot \mathbf{n} da$$

$$= \iint_S \left\{ \frac{\partial \mathbf{A}}{\partial t} + \mathbf{v} \operatorname{div} \mathbf{A} + \operatorname{curl} [\mathbf{A} \times \mathbf{v}] \right\} \cdot \mathbf{n} da$$

$$= \iint_S \left\{ \frac{d\mathbf{A}}{dt} + \mathbf{A} \operatorname{div} \mathbf{v} + (\mathbf{A} \cdot \nabla) \mathbf{v} \right\} \cdot \mathbf{n} da$$

$$(9) \frac{d}{dt} \iiint_V f dv = \iiint_V \left\{ \frac{\partial f}{\partial t} + \operatorname{div} (f\mathbf{v}) \right\} dv$$

$$= \iiint_V \left\{ \frac{df}{dt} + f \operatorname{div} \mathbf{v} \right\} dv$$

Explanation of symbols:

$d\mathbf{R}$ is a vector element of arc-length,

da is a surface element, \mathbf{n} its normal,

dv is an element of volume,

\mathbf{v} is the velocity of a surface element or volume element,

C is the boundary curve of surface S ,

S is the surface boundary of volume V .

Green's Formulae

$$(10) \iiint_V u \nabla^2 w dv + \iiint_V (\nabla u) \cdot (\nabla w) dv$$

$$= \oint \oint_S u \frac{\partial w}{\partial n} da$$

$$(11) \iiint_V \{u \nabla^2 w - w \nabla^2 u\} dv$$

$$= \iint_S \left\{ u \frac{\partial w}{\partial n} - w \frac{\partial u}{\partial n} \right\} da$$

If f is a scalar depending on x,y,z,t , it can be represented as the following integral:

$f(x,y,z,t)$

$$= \frac{1}{4\pi} \iiint_V \frac{1}{r} \left\{ b^2 \frac{\partial^2 f}{\partial t^2} - \text{div grad } f \right\}_{t+br} dv$$

$$- \frac{1}{4\pi} \oint \oint_S \left\{ \frac{b}{r} \mathbf{r}_o \cdot \mathbf{n} \frac{\partial f}{\partial t} + f \mathbf{n} \cdot \nabla \frac{1}{r} - \frac{\mathbf{n} \cdot \nabla f}{r} \right\}_{t+br} da.$$

If \mathbf{B} is a vector depending on x,y,z,t , it can be represented as the following integrals:

$\mathbf{B}(x,y,z,t)$

$$= \frac{1}{4\pi} \iiint_V \frac{1}{r} \left\{ b^2 \frac{\partial^2 \mathbf{B}}{\partial t^2} + \text{curl curl } \mathbf{B} \right\}_{t+br} dv$$

$$- \frac{\nabla}{4\pi} \iiint_V \left\{ \frac{\text{div } \mathbf{B}}{r} \right\}_{t+br} dv$$

$$+ \frac{\nabla}{4\pi} \oint \oint_S \left\{ \frac{\mathbf{B} \cdot \mathbf{n}}{r} \right\}_{t+br} da$$

$$+ \frac{\text{curl}}{4\pi} \oint \oint_S \left\{ \frac{\mathbf{B} \times \mathbf{n}}{r} \right\}_{t+br} da$$

$$- \frac{1}{4\pi} \oint \oint_S \left\{ \frac{\mathbf{n} \times \text{curl } \mathbf{B}}{r} \right\}_{t+br} da$$

$$= \frac{1}{4\pi} \iiint_V \frac{1}{r} \left\{ b^2 \frac{\partial^2 \mathbf{B}}{\partial t^2} + \text{curl curl } \mathbf{B} \right\}_{t+br} dv$$

$$- \frac{\nabla}{4\pi} \iiint_V \left\{ \frac{\text{div } \mathbf{B}}{r} \right\}_{t+br} dv$$

$$+ \frac{b}{4\pi} \frac{\partial}{\partial t} \oint \oint_S \left\{ \frac{\mathbf{r}_o \times [\mathbf{n} \times \mathbf{B}]}{r} \right\}_{t+br} da$$

$$- \frac{1}{4\pi} \oint \oint_S \left\{ \mathbf{B} \mathbf{n} \cdot \nabla \frac{1}{r} \right\}_{t+br} da$$

$$+ \frac{1}{4\pi} \oint \oint_S \left\{ \left(\nabla \frac{1}{r} \right) \times (\mathbf{n} \times \mathbf{B}) \right\}_{t+br} da$$

$$- \frac{b}{4\pi} \frac{\partial}{\partial t} \oint \oint_S \left\{ \frac{\mathbf{r}_o}{r} (\mathbf{n} \cdot \mathbf{B}) \right\}_{t+br} da$$

$$- \frac{1}{4\pi} \iiint_S \left\{ \frac{\mathbf{n} \times \text{curl } \mathbf{B}}{r} \right\}_{t+br} da.$$

The subscript $t + br$ means that after the expression has been evaluated in terms of x,y,z,t , the time t is to be replaced by $t + br$. The constant b is the reciprocal of the wave-velocity with which the physical disturbance is propagated; r is the distance from the point x,y,t to a point of V or S ; \mathbf{r}_o is a unit vector along r ; \mathbf{n} is the outer normal of the closed surface, S .

INTEGRAL TRANSFORM. Consider a homogeneous integral equation

$$f(y) = \int K(x,y)F(x)dx$$

with kernel $K(x,y)$. The function $f(y)$ is an integral transform of $F(x)$. Given $F(x)$, presumably $f(y)$ may be found explicitly. Regarding the equality as an integral equation, however, one wishes to solve for $F(x)$, or invert the transform. Thus, if the transform can be inverted the result will be the solution of the integral equation for the given kernel.

Many special cases have been studied and given special names. The reciprocal relations, written in the form

$$f = C \int K F dx \quad \text{and} \quad F = C' \int K' f dy$$

are shown in the following table for the more familiar integral transforms.

Name	Constants	Integration Limits
1. Fourier	$C = C' = 1/\sqrt{2\pi}$	$\pm \infty$
2. Sine (cosine)	$C = C' = \sqrt{2/\pi}$	$\infty, 0$
3. Laplace	$C = 1, C' = 1/2\pi i$	$\infty, 0; c \pm i\infty$
4. Mellin	$C = 1, C' = 1/2\pi i$	$\infty, 0; c \pm i\infty$
5. Hankel	$C = C' = 1$	$\infty, 0$
6. Hilbert	$C = C' = 1/2\pi$	$\pm \pi$

Name	K	K'
1. Fourier	e^{ixy}	e^{-ixy}
2. Sine (cosine)	$\sin (\cos) xy$	$\sin (\cos) xy$
3. Laplace	e^{-xy}	e^{xy}
4. Mellin	x^{y-1}	x^{-y}
5. Hankel	$J_m(xy)$	$J_m(xy)$
6. Hilbert	$1 + \cot (x - y)/2$	K

Notes for table: (1) The constant factor is sometimes omitted or modified. (3) The constant c is any real number such that $\int_0^\infty e^{-cx}|f(x)|dx$ is bounded. The symbol p is almost invariably used in place of y . (5) This is often called the Fourier-Bessel transform. The kernel, J_m is a **Bessel function** of order m . (6) The principal value of the integral is to be taken, that is:

$$\int_{-\pi}^{\pi} = \lim_{\delta \rightarrow 0} \left[\int_{-\pi}^{y-\delta} + \int_{y+\delta}^{\pi} \right].$$

All of these relations must be used with proper care as to the conditions under which they are valid. These properties, as well as tables of the pairs $f(y)$ and $F(x)$ in explicit form, may be found in *Formulas and Theorems for the Special Functions of Mathematical Physics*, W. Magnus and F. Oberhettinger, translated by John Vermer, Chelsea Publishing Co.

INTEGRAL TRANSPORT EQUATION.

The Boltzmann transport equation, an integro-differential equation for the angular flux $vN(\mathbf{r}, E, \hat{\Omega})$ may, in certain cases, be integrated to yield an integral transport equation, (1) for the total flux, or (2) the angular flux integrated over angle. The conditions for (2) are: the neutron sources be isotropic, and the scattering in the laboratory system must be independent of angle. The further condition that scattering produces no change in neutron energy makes (1) possible. Equation (2) has the form:

$$vN(\mathbf{r}, E) = \frac{1}{4\pi} \int \frac{d^3\mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^2} \exp(-\Sigma(E)|\mathbf{r} - \mathbf{r}'|) \\ \times \left[4\pi S(\mathbf{r}', E) \right. \\ \left. + \int dE' \Sigma(E') v' N(\mathbf{r}', E') C(E') f(E', E) \right]$$

in a geometrically simple homogeneous body. See **neutron transport theory** for definition of symbols.

INTEGRAL, VOLUME. See **integral, multiple**.

INTEGRAND. A function which is to be integrated.

INTEGRATING FACTOR. An integrating factor for a differential equation $M(x, y)dx + N(x, y)dy = 0$ is a function $\mu(x, y)$ such that $\mu M dx + \mu N dy = 0$ is exact, that is, such that

$$\frac{\partial(\mu M)}{\partial y} = \frac{\partial(\mu N)}{\partial x}.$$

INTEGRATION. See **integral**.

INTEGRATION, CONTOUR. See **contour integration**.

INTEGRATION, NUMERICAL. See **quadrature formulas**.

INTENSITY DISTRIBUTION, CURVE OF.

A curve, generally polar, which represents the **luminous intensity** in a plane passing through the source, as a function of the angle measured from some given direction. (1) When the source has an axis of symmetry, the plane is generally a meridian plane. (2) The pole of the polar curve is at the point representing the position of the light source. (3) When the reference direction is vertical, angles are measured from the downward vertical.

INTENSITY DISTRIBUTION, SURFACE OF.

The surface formed by the extremities of all the radii vectors drawn from a common origin, the length of each radius vector being proportional to the luminous intensity of the source in the corresponding direction.

INTENSITY, MEAN HORIZONTAL. See **mean horizontal intensity**.

INTENSITY, MEAN SPHERICAL. See **mean spherical intensity**.

INTENSITY METHOD OF MEASURING TOTAL ABSORPTIVITY.

A method, due to Knudsen, of measuring the total absorptivity (see **sound absorption coefficient**) of a room, in which the maximum steady state energy density is measured before and after the addition of a known amount of absorption. The total absorptivity α can then be determined by the relation

$$\alpha = \frac{\alpha'}{\frac{E_{max}}{E'_{max}} - 1}$$

where E'_{max} is the maximum steady state energy density after α' units of absorption have been added.

INTENSITY OF A SOURCE OF PARTICLES. The total number of particles emitted per unit area per unit time.

INTENSITY OF A SPECTRAL LINE. The intensity of a spectral line in emission (energy emitted by the source per second) is given by

$$I_{em.}^{nm} = N_n h c \nu_{nm} A_{nm}.$$

Here N_n is the number of atoms in the initial (upper) state, h is Planck's constant, c is the velocity of light, ν_{nm} is the wave number, and A_{nm} is Einstein's transition probability for spontaneous emission

$$A_{nm} = \frac{64\pi^4 \nu_{nm}^3}{3h} |R^{nm}|^2$$

where R^{nm} is the matrix element of the transition (see **quantum mechanical transition**).

The intensity of a spectral line in absorption (energy absorbed from an incident beam of 1 cm cross section) is, for a sufficiently thin absorbing layer Δx , given by

$$I_{abs.}^{nm} = \rho_{nm} N_m B_{mn} \Delta x h c \nu_{nm}.$$

Here N_m is the number of atoms per cm^3 in the initial (lower) state, ρ_{nm} is the density of radiation of the incident beam, and B_{mn} is Einstein's transition probability for absorption

$$B_{mn} = \frac{8\pi^3}{3h^2 c} |R^{nm}|^2.$$

INTENSITY OF A SPHERICAL SOUND WAVE, FORMULA FOR. The intensity of a spherical sound wave in a dissipative medium is given by

$$I = \frac{P e^{-\alpha r}}{4\pi r^2},$$

where I is intensity in $\text{ergs/cm}^2\text{-sec}$, P is power output of source in ergs/sec , r is distance from source in cm , α is amplitude absorption coefficient in nepers/cm .

INTENSITY OF RADIATION. The energy or the number of photons or of particles, flowing through unit area per unit time. For parallel radiation, the area usually refers to a surface normal to the direction of propagation.

INTENSITY OF RADIOACTIVITY. The number of atoms disintegrating per unit time, or derivatively, the number of scintillations or other effects (roentgens per hour at one meter) observed per unit time.

INTENSITY, RADIANT (OF A SOURCE). The rate of transfer of radiant energy per unit solid angle.

INTENSITY RULES FOR MULTIPLETS. In the case of **Russell-Saunders coupling** (small multiplet splitting) the line intensities in a **multiplet** are determined by the following rule (Burger-Dorgelo-Ornstein's sum rule): The sum of the intensities of all the lines of a multiplet which belong to the same initial or final state is proportional to the statistical weight $2J + 1$ of the initial or final state, re-

spectively. From the sum rule the following rules can be derived: (a) The components of a multiplet for which the quantum numbers J and L alter in the same manner are more intense than those for which they alter unequally. (b) The components belonging to a large J value are more intense than those with small J .

The detailed multiplet intensity rules, as derived from quantum mechanics, are:

For transitions $(L - 1) \rightarrow L$

$(J - 1) \rightarrow J$

$$I = \frac{\left\{ \begin{array}{l} B(L + J + S + 1)(L + J + S) \\ (L + J - S)(L + J - S - 1) \end{array} \right\}}{J}$$

$J \rightarrow J$

$$I = \frac{\left\{ \begin{array}{l} -B(L + J + S + 1)(L + J - S) \\ (L - J + S)(L - J - S - 1)(2J + 1) \end{array} \right\}}{J(J + 1)}$$

$(J + 1) \rightarrow J$

$$I = \frac{\left\{ \begin{array}{l} B(L - J + S)(L - J + S - 1) \\ (L - J - S - 1)(L - J - S - 2) \end{array} \right\}}{J + 1}$$

For transitions $L \rightarrow L$

$(J - 1) \rightarrow J$

$$I = \frac{\left\{ \begin{array}{l} -A(L + J + S + 1)(L + J - S) \\ (L - J + S + 1)(L - J - S) \end{array} \right\}}{J}$$

$J \rightarrow J$

$$I = \frac{\left\{ \begin{array}{l} A[L(L + 1) + J(J + 1)] \\ -S(S + 1)^2(2J + 1) \end{array} \right\}}{J(J + 1)}$$

$(J + 1) \rightarrow J$

$$I = \frac{\left\{ \begin{array}{l} -A(L + J - S + 2)(L + J - S + 1) \\ (L - J + S)(L - J - S - 1) \end{array} \right\}}{(J + 1)}$$

The constants A and B depend on temperature and wave-number and can be omitted in the calculation of the relative intensities, as long as the multiplet splitting is small.

INTENSIVE PROPERTIES. The properties which are independent of the mass of a system, such as the pressure p and the temperature T , and which take well-defined values at each point of a system.

INTENSIVE VARIABLE. See **intensive property**.

INTERACTION. Whenever two or more bodies exert mutual forces on one another, they are said to interact. The term interaction is often used loosely for the force of interaction, i.e., the mutual force exerted by one body on another. (See the various types of interaction and also the various entries under **coupling**.)

INTERACTION CONFIGURATION. See **configuration, interaction**.

INTERACTION CROSS SECTION. The interaction cross section is given by $\sigma = 1/n\lambda$, where n is the number of nuclei per unit volume and λ is the **interaction mean free path**.

INTERACTION CURVE. A limiting relation between two independent quantities, especially one required by design specifications. The curve giving the combinations of axial force P and bending moment M which will cause failure in a particular column provides an example of actual interaction. The straight line design formula

$$\frac{P}{P_{max}} + \frac{M}{M_{max}} \leq 1$$

is an example of a specification requirement where P_{max} is the maximum axial force allowed when $M = 0$, and M_{max} the maximum moment allowed when $P = 0$.

INTERACTION ENERGY. The energy of **interaction** is the work that must be done against the force(s) of interaction to establish a physical system referred to infinity as an origin.

INTERACTION, EXCHANGE. See **exchange force**.

INTERACTION FAST EFFECT. See **fast effect, interaction**.

INTERACTION, FERMI. See **universal Fermi interaction**.

INTERACTION, MAJORANA. See **majorana force**.

INTERACTION, MANY-BODY. See **many-body force**.

INTERACTION MEAN FREE PATH. The average distance which a given particle travels before experiencing an **interaction** with another particle.

INTERACTION PICTURE. Suppose the **Hamiltonian** H of a system is composed of two parts: an unperturbed Hamiltonian H_o , and an interaction (perturbation) Hamiltonian H_I

$$H = H_o + H_I \quad (1)$$

so that in the **Schrödinger picture** the time behavior of the state vector describing the system is governed by the equation

$$i\hbar\partial_t\Phi_S(t) = (H_o + H_I)\Phi_S(t). \quad (2)$$

Introduce the vector

$$\Psi_{IR}(t) = e^{iH_o t/\hbar}\Phi_S(t), \quad (3)$$

which by virtue of (2) satisfies the equation

$$\begin{aligned} i\hbar\partial_t\Phi_{IR}(t) &= e^{iH_o t/\hbar}H_I e^{-iH_o t/\hbar}\Phi_{IR}(t) \\ &= H_I^{(IR)}(t)\Psi_{IR}(t). \end{aligned} \quad (4)$$

The scheme which describes the physical system by the vector $\Psi_{IR}(t)$ and operators $Q_{IR}(t)$

$$Q_{IR}(t) = e^{+iH_o t/\hbar}Q_S e^{-iH_o t/\hbar} \quad (5)$$

is called the interaction picture. In the interaction picture the time dependence of the operators is determined by the unperturbed Hamiltonian, with

$$-i\hbar\partial_t Q_{IR}(t) = [H_o, Q_{IR}(t)]. \quad (6)$$

(Note $H_o^{IR} = H_o^S$.) The time dependence of the state vector is determined by the interaction Hamiltonian as indicated by Equation (4).

In relativistic field theoretic application the advantage of the interaction picture stems from the fact that the field operators satisfy field-free equations, so that **covariant commutation rules** can be written down for all times. It also permits a generalization of Equation (4) which makes it covariant. Equation (4) is not covariant, since it singles out a special Lorentz frame in defining the time derivative. (See **Tomanaga-Schwinger equation**.)

INTERATOMIC POTENTIAL. The potential energy of two atoms. The three most important potentials used are the Lennard-Jones "12-6" potential,

$$U(r) = Ar^{-12} - Br^{-6},$$

the "exp-6" potential,

$$U(r) = Ce^{-\alpha r} - Dr^{-6},$$

and the Morse potential,

$$U(r) = E\{1 - \exp[-\beta(r - r_0)]\}^2,$$

where α , β , A , B , C , D , E , and r_0 are constants, and $U(r)$ is the potential energy for a distance apart r .

INTERCOMBINATION LINES. Spectral lines corresponding to transitions between electronic energy levels of different **multiplicity**. Such transitions involve a violation of the (approximate) **selection rule** $\Delta S = 0$ which applies as long as **Russell-Saunders coupling** is a good approximation. As a rule, therefore, intercombination lines are very weak, especially for elements of low **atomic number**. For heavier elements where Russell-Saunders coupling does not hold, the intensity of intercombination lines may approach that of ordinary lines from the same energy level.

INTERFERENCE. The variation of wave amplitude with distance or time, caused by the superposition of two or more waves. As most commonly used, the term refers to the interference of waves of the same or nearly the same frequency. Wave interference is characterized by the phenomenon of the occurrence of local maxima and minima of **wave amplitude**, which cannot be described by the ray approximation to solutions of the wave equation. In terms of the **Huygens approximation**, interference can occur whenever wave disturbance can be propagated from a source to a region of space by two or more paths of different length. There is (destructive) interference if the phases and amplitudes of the disturbances arriving by the various routes are such as to reduce the square of the resultant amplitude below the sum of the squares of the amplitudes of the components. If the square of the resultant amplitude exceeds the sum of the squares of the component amplitudes, constructive interference occurs. Interference effects are observed with electromagnetic waves, sound waves, water waves, as well as with

matter waves (i.e., electron and neutron waves).

INTERFERENCE COEFFICIENTS OF THERMODYNAMICS OF IRREVERSIBLE PROCESSES. See **phenomenological relations and reciprocity relations**.

INTERMITTENCY EFFECT. The departure from the **reciprocity law** when the **exposure** of a photographic emulsion is made in a series of discrete installments rather than in a continuous exposure to the same total energy.

INTERMOLECULAR FORCES. Our knowledge of the intermolecular forces comes mainly from the following sources:

(1) Thermodynamic properties of gases at low densities (see **real gases**; **statistical mechanics**).

(2) Transport processes in dilute gases, for example, viscosity, diffusion, etc. (see **kinetic theory of gases**).

(3) Thermodynamic properties of crystals near $^{\circ}\text{K}$.

It is convenient, though somewhat arbitrary, to classify intermolecular forces in two types (excluding **chemical interactions**):

(1) *Repulsive short range forces.*

(2) *Attractive long range forces.*

The short range forces become significant when the molecules come close enough together for their electron clouds to overlap. The exact analytical form of these forces is complicated (see **Lennard-Jones potential**, **Buckingham potentials**). The corresponding energy is called the *overlap energy*.

The various contributions to the long range forces are:

(1) The electrostatic contribution.

(2) The dispersion contribution (see **dispersion forces**).

(3) The induction contribution (see **induction forces**).

INTERNAL ABSORPTANCE. The ratio of the **luminous flux** absorbed between the entry and exit surface of the filter or the plate, to the flux which leaves the entry surface.

INTERNAL COMBUSTION ENGINE. A reciprocating, usually high-speed, engine working on the two-stroke or four-stroke principle, which produces power by virtue of the internal combustion of a spray of liquid fuel, or a

vaporized liquid fuel, in the engine cylinder. (See **diesel engine**; **spark-ignition engine**.)

INTERNAL CONVERSION. In an electromagnetic transition between two states of an atomic nucleus differing by energy E , a γ -ray of energy E is usually emitted. An alternative mode of decay, however, is that an atomic electron of energy $E - \epsilon$ may be emitted from one of the inner shells of the atom through direct interaction with the electromagnetic field of the nucleus, where ϵ is the binding energy of the electron. Thus, one speaks of K -conversion, L -conversion, etc., corresponding to electrons ejected from the K , L , \dots , shells. If the transition in question follows a β -decay transition, the spectrum of electrons observed will therefore consist of a number of discrete energy groups, corresponding to the conversion electrons, superimposed upon the continuous spectrum coming from the β -decay itself. The process is more probable the lower the energy E of the transition.

INTERNAL CONVERSION COEFFICIENT. The ratio of the number of internal conversion electrons to the number of quanta emitted plus the number of conversion electrons emitted in a given mode of de-excitation of a nucleus. Partial conversion coefficients refer to conversion fractions for various electron shells, e.g., K -conversion fractions, L -conversion coefficients, etc. Sometimes called conversion fraction.

INTERNAL ENERGY. The energy ascribed to a given state of a system, which is determined only by the state itself (and is thus a scalar quantity) and is not accounted for by the kinetic energy of bulk motion or potential energy in external force fields. By thermodynamics, the change in the internal energy when the system goes adiabatically from one state to another is equal to the external work performed in bringing about the change. On a molecular scale, the internal energy is the sum of the kinetic energy of the thermal motion of the molecules and the sum of their potential energies in each other's fields of force. By the first law of thermodynamics, the change of internal energy in any process is equal to the difference of the heat gained and the external work done. (See **thermodynamics**, **first law of**.)

INTERNAL ENERGY FLUX VECTOR. See **flux vector**.

INTERNAL FIELDS IN DIELECTRICS. The interactions between the molecules in a dielectric can be broadly subdivided in two classes: (1) the short range intermolecular forces (**dispersion**, **repulsion forces**, and eventually, **chemical interactions**) which result practically in nearest neighbor interactions only; (2) the dipolar interactions having longer ranges: in order to predict their effect, one must consider a very large number of interacting pairs.

Lorentz and later authors have evaluated the electric field acting on the individual charges inside the dielectric (inner or internal field) as follows: a small sphere is chosen, large enough to manifest the same properties as a macroscopic system, yet small enough for the dipolar interactions within the sphere to be calculable exactly. The long range dipolar interactions of the molecules within the sphere with the surrounding material are treated by means of macroscopic equations.

The internal field, appears thus as a sum of two terms, one of which is evaluated by microscopic equations, the other by assuming the whole system to be continuous. One assumes often that the sum of the interaction within the sphere leads to a negligible field; this hypothesis is justified exactly for some models. (See also under **reaction** and **cavity field**.)

INTERNAL FRICTION. See **friction**, **internal**.

INTERNAL HEAT OF EVAPORATION. See **latent heat**.

INTERNAL OPTICAL DENSITY. The logarithm to base ten of the reciprocal of the internal transmission factor.

INTERNAL TRANSMITTANCE. The ratio of the **luminous flux** reaching the exit surface of a filter or a plate to the flux which leaves the entry surface.

INTERNAL VERTEX. See **vertex**, **internal**.

INTERNATIONAL ANGSTROM. See **angstrom**.

INTERPOLATION. The approximation from tabulated values of a function, and possibly of its derivatives, of values not included in a

table. Let $f(x)$, and possibly derivatives, be tabulated at x_0, \dots, x_m . Usually one selects a set of functions ϕ_0, \dots, ϕ_n , which may be polynomials, trigonometric functions, exponentials, or of any other convenient class, and applies some criteria for selecting coefficients α_i , such that $\alpha_0\phi_0 + \dots + \alpha_n\phi_n$ is accepted as an approximation $P[f|x]$ to $f(x)$. The most common criteria are agreement of P with f (and possibly derivatives) at the x_i . Most commonly the term "interpolation" is applied only when criteria of this type are applied. (Cf. **difference operators**; **Aitken method**; **Lagrange interpolation formula**; **Hermite interpolation formula**; **Newton interpolation formula**; and, for other criteria, **minimax approximation**; **least squares**.)

INTERQUARTILE RANGE. The interquartile range is defined as $Q_3 - Q_1$ where Q_3 and Q_1 are the third and first **quartiles** in a distribution. It is sometimes used as a measure of **dispersion**.

INTERVAL BETWEEN EVENTS. If two **events** occur at the positions and times represented by

$$x^\mu \text{ and } x^\mu + dx^\mu \ (\mu = 1, 2, 3, 4),$$

the interval between is given by

$$ds^2 = g_{\mu\nu}dx^\mu dx^\nu,$$

where $g_{\mu\nu}$ is the metric of space-time. In Minkowski space, the interval is given by:

$$ds^2 = c^2dt^2 - dr^2.$$

INTERVAL RULE, LANDE'S. See **Landé's interval rule**.

INTERVAL, SOUND. The interval between two sounds is their spacing in pitch or frequency, whichever is indicated by the context. The frequency interval is expressed by the ratio of the frequencies or by a logarithm of this ratio.

INTRINSIC DERIVATIVE OF TENSOR FIELD. $t_{pq\dots r}^{ij\dots k}$ are the components in a generic coordinate system x of a tensor field of weight W , which is defined along a curve by its dependence on a parameter τ . The intrinsic derivative of the tensor field with respect to τ is the tensor with components $\delta t_{pq\dots r}^{ij\dots k}/\delta\tau$ in the coordinate system x , defined by

$$\frac{\delta t_{pq\dots r}^{ij\dots k}}{\delta\tau} = t_{pq\dots r,m}^{ij\dots k} \frac{dx^m}{d\tau},$$

where $t_{pq\dots r,m}^{ij\dots k}$ are the components in the system x of the covariant derivative of the tensor field. Also called *absolute derivative*.

INTRINSIC DERIVATIVE, SURFACE. See **surface, intrinsic derivative**.

INTRINSIC EQUATIONS OF A CURVE. See **curve, intrinsic equations of**.

INTRINSIC GEOMETRY OF A SURFACE. See **intrinsic properties of a surface**.

INTRINSIC PROPERTIES OF A SURFACE. Those properties of the surface which can be described without reference to the surrounding space. The description of these properties is the *intrinsic geometry of the surface*.

INVARIANCE, GAUGE. See **gauge invariance**.

INVARIANCE PRINCIPLE. A principle whereby a relationship must be invariant under certain transformations. For special cases, see discussions of **Lorentz invariants** and various articles on **relativity**.

INVARIANT, OR ABSOLUTE INVARIANT (UNDER A TRANSFORMATION OF COORDINATES). An entity which is unaltered by the transformation. For example, a point in space, as distinct from the coordinates of the point; an absolute **tensor** or **vector** as distinct from the components of the tensor or vector in a particular coordinate system. Most frequently used to signify **scalar field** and in this sense often referred to as *scalar invariant*. Entities such as relative tensor fields or relative scalar fields are also called *relative invariants*. The term invariant may be used to signify either an absolute or relative invariant.

INVARIANT POINT. State of a given system where the number of degrees of freedom is zero, e.g., the triple point: the condition that solid, liquid, and vapor phases shall exist in equilibrium completely determines the state of the system. (See **freedom, degree of (2)**.)

INVERSE ELEMENT. The inverse of a group element A is the element A^{-1} such that $A^{-1}A = AA^{-1} = I$, where I is the unit element.

INVERSE FUNCTION. If $y = f(x)$, the inverse function is $x = g(y)$.

INVERSE HYPERBOLIC FUNCTION. See *hyperbolic function*.

INVERSE INTERPOLATION. The approximation, from an interpolating polynomial, of the value of an abscissa corresponding to a given ordinate. This amounts to solving an algebraic equation of degree equal to the polynomial. (See Zdenek Kopal, *Numerical Analysis*, John Wiley & Sons, Inc., 1955; E. T. Whittaker and G. Robinson, *The Calculus of Observations*, Blackie & Sons, Ltd., 1940.)

INVERSE MATRIX. The inverse of an $n \times n$ matrix A whose **determinant** is not zero is the unique $n \times n$ matrix A^{-1} such that $AA^{-1} = A^{-1}A = I$, where I is the unit matrix of order n .

INVERSE OPERATOR. An operator symbol which cancels the process directed by another operator. Thus A, B are inverse operators if they mean addition and subtraction of a constant, respectively, or if they are defined as differentiation and integration.

INVERSE SQUARE FIELD, MOTION IN. See *motion in inverse square field*.

INVERSE SQUARE LAWS. (1) Laws of force in which the force of interaction between two particles varies as $1/r^2$ where r is the distance of separation between the particles. The gravitational force and the **Coulomb law of force** between electrical charges follow inverse square laws. (2) The intensity of radiation from a point source emitting isotropic radiation decreases as $1/r^2$ from the source in a non-absorbing medium. This law is a consequence of the law of conservation of energy.

INVERSE SURFACES. Let \mathbf{r} be the vector drawn from a fixed point C to a generic point P on a surface S . Let Q be a point on the line CP such that the vector drawn from C to Q is $(c^2/r^2)\mathbf{r}$, where c is a real constant and r is the length of the vector \mathbf{r} . Then the locus of the point Q is a surface S' . The surfaces S and S' are inverse surfaces. C is the *center of inversion*, c the *radius of inversion*. The process by which the surface S' is generated from S is called *inversion*.

INVERSE TRIGONOMETRIC FUNCTIONS. See *trigonometric functions, inverse*.

INVERSION. (1) See *inverse surfaces*. (2) Literally, a condition in which the temperature

of the air increases upwards, this being an inversion of the more normal condition of a decrease with height. More loosely it is used to refer to a shallow layer of great static stability which inhibits the mixing of the air above and below and therefore acts as a ceiling to convection from warm ground or to the dispersal of pollution from the ground. Alternatively the term is sometimes used to indicate a state in which the **potential temperature** increases upwards, i.e., one of static stability. (3) The alteration of the normal **Boltzmann distribution** in such a manner that the population of the higher energy levels is greater than that of the lower. (See *temperature, negative*.) (4) See *spectrum, inversion*. (5) See *inversion of coordinates*.

INVERSION, CENTER OF. See *inverse surfaces*.

INVERSION DOUBLING. In a nonplanar symmetric top molecule a reflection of all particles at the origin (inversion) leads to a configuration which cannot also be obtained by rotation of the molecule. Corresponding to these two configurations of the molecule, each rotational level J, K is doubly degenerate as long as the potential hill separating these two configurations is infinitely high. For a finite potential hill, a splitting occurs into two sublevels which have opposite symmetry with respect to an inversion. The eigenfunctions of these sublevels contain equal contributions from both "original" levels.

INVERSION INTEGRAL. See *Laplace transform*.

INVERSION OF COORDINATES. Strictly, the transformation of a coordinate system that carries each coordinate into the negative of itself; for example, in the rectangular Cartesian coordinate system, the transformation $x \rightarrow -x, y \rightarrow -y, z \rightarrow -z$.

The term is sometimes used loosely to indicate a transformation that reverses the sign of one or more, but not all, of the coordinates. For example in a mirroring transformation only one of the three spatial coordinates is inverted and the other two are left invariant. Another example is in *Minkowski* four-dimensional space, where *spatial inversion* inverts the three spatial coordinates and leaves the time coordinate invariant; or alternately, *time*

inversion, which inverts the time coordinate but not the spatial coordinates.

INVERSION, RADIUS OF. See **inverse surfaces**.

INVERSION SPECTRA. See **microwave spectra of molecules**.

INVERSION TEMPERATURE. At sufficiently low temperatures, the Joule-Thomson coefficient is positive (see **throttling experiment**), and cooling by throttling is the result. This coefficient becomes negative at higher temperatures, and the temperature at which the effect changes sign is called the *inversion temperature*.

INVERTED MULTIPLY. See **multiplet**.

INVISCID FLUID. Alternatively called a "perfect" or "ideal" fluid, a fluid in which the only stress across any element of area is normal to it and is the fluid pressure. There are no shearing stresses, and vorticity is not diffused.

INVOLUTE (OF A CURVE). If the tangents to the curve C are normals to the curve C' , then C' is an involute of C and C is an *evolute* of C' .

INVOLUTE (OF A SURFACE). Take a singly-infinite system of geodesics (see **geodesic line**) on a surface S . At each point P on S draw the tangent to the geodesic of the family which passes through P . On this tangent take a point Q such that the distance PQ is constant. Then the locus of Q is a surface S' which is called an involute of the surface S . The surface S is called the *evolute* of the surface S' .

ION. An atom or molecularly-bound group of atoms which has gained or lost one or more electrons, and which has thus a negative or positive electric charge; sometimes a free electron or other charged subatomic particle. Ions may be produced in gases by the action of radiation of sufficient energy; ionic solids are built up of ions bound together by their electrostatic forces, and when dissolved in a polar liquid, such as water, the salt dissociates into its ions, which have an independent existence.

IONIC BOND. See **heteropolar bond; atomic bond; bond type**.

IONIC BOND CHARACTER. Consider a diatomic molecule AB , of which A is the more electronegative atom. Let ψ_{cov} be the symmetrical wave function $\psi_A(1)\psi_B(2) + \psi_A(2)\psi_B(1)$ representing the pure covalent bond and ψ_{ion} the "ionic" wave function $\psi_A(1)\psi_A(2)$. Neglecting the ionic configuration with both electrons attached to atom B , one can write for the total wave function:

$$\psi = \psi_{cov} + \lambda\psi_{ion}$$

where λ is a constant. The percentage ionic character of the bond (Coulson) is then $100\lambda^2/(1 + \lambda^2)$.

A rough experimental determination of the ionic character can be obtained by comparing the dipole moment of the bond to that which one would observe if atoms A and B carried, respectively, a whole negative and positive charge each.

IONIC CONFIGURATION. See **atomic bond energy**.

IONIC STRENGTH. The ionic strength I of an electrolyte solution is defined by

$$I = \frac{1}{2}\sum z_i^2 m_i \quad (1)$$

where z_i is the charge number of ion i (see **electroneutrality**) and m_i , its **molality**.

Instead of molalities, other concentration scales, for example, molar concentrations, may also be used in (1).

IONIZATION, DEGREE OF. The ratio, usually stated as a percentage, of the number or the concentration of the particles in a system which become ionized, to those which remain unionized. If the system is a solution, the reference particles are the molecules of a specified component.

IONIZATION ENERGY. See **ionization potential**.

IONIZATION, MINIMUM. The smallest possible value of the specific ionization (see **ionization, specific**) that a charged particle can produce in passing through a particular substance.

IONIZATION POTENTIAL. The ionization potential of an electron is the energy absorbed when the electron is detached from an atom, molecule or ion and brought to rest at infinity, resulting in an ion in its ground electronic state. When it is not otherwise specified, the

ionization potential of an atom, molecule or ion is the lowest of the ionization potentials of its electrons.

For polyatomic molecules, one distinguishes often between the *vertical* and the *adiabatic ionization potential*. The *vertical ionization potential* is the energy absorbed during the instantaneous removal of the electron: the bond lengths of the molecule remaining unaltered, i.e., the resulting ion is not necessarily in its **fundamental state**. It may still contain a large amount of vibrational energy.

The *adiabatic ionization potential* is the energy absorbed when the electron is detached adiabatically, i.e., infinitely slowly and reversibly. The vibrational degrees of freedom of the molecule have time to adjust continually during the ionization. At the end of this process, the ion is in its fundamental state. Whence

$$I_{\text{adiabatic}} \leq I_{\text{vertical}}.$$

IONIZATION, SPECIFIC. The number of **ion pairs** formed per unit distance along the track of an ion passing through matter. This is sometimes called the total specific ionization to distinguish it from the primary specific ionization, which is the number of ion clusters produced per unit track length. The relative specific ionization is the specific ionization for a particle of a given medium relative either to that for (1) the same particle and energy in a standard medium, such as air at 15°C and 1 atm, or (2) the same particle and medium at a specified energy, such as the energy for which the specific ionization is a maximum.

IONIZATION, TOTAL. (1) The total electric charge on the ions of one sign when the energetic particle that has produced these ions has lost all of its kinetic energy. For a given gas the total ionization is closely proportional to the initial energy and is nearly independent of the nature of the ionizing particle. It is frequently used as a measure of particle energy. (2) The total number of ion pairs produced by the ionizing particle along its entire path.

ION PAIR. (1) A positive ion and a negative ion or electron, having charges of the same magnitude, and formed from a neutral atom or molecule by the action of radiation or by any other agency that supplies energy. (2) As postulated in the **Debye-Hückel theory**,

in concentrated solutions of strong electrolytes (two or more), ions may occasionally approach each other so closely that they may form pairs (or groups) without entering into permanent chemical combination.

ION(S), STANDARD ENTROPY OF. The quantity called the standard **entropy** of an ion is really the relative partial entropy of the ion in a solution of unit activity, that of the hydrogen ion being assumed to be zero.

ION(S), STANDARD FREE ENERGY OF. The **free energy** of formation of the particular ions, taking that for the formation of hydrogen ions at unit activity from the gas at 1 atmosphere pressure to be zero.

IRRADIANCE. Irradiance (at a point of a surface) is the quotient of the radiant power incident on an infinitesimal element of surface containing the point under consideration, by the area of that element.

IRRADIATION. (1) Descriptively, irradiation is the exposure of an object to radiation. (2) Quantitatively, irradiation is the product of an **irradiance** and its duration.

IRREVERSIBLE PROCESS. A process occurring in a system such that, in order to reverse the direction of the process, a finite change in the parameters of the system must be made, e.g., the compression or expansion of a gas in a cylinder by means of a piston, when friction is present between piston and cylinder.

IRREVERSIBLE PROCESSES, LINEAR RELATIONS IN THERMODYNAMICS OF. See **phenomenological relations in thermodynamics of irreversible processes**.

IRROTATIONAL FLOW. Flow in which the **vorticity**, or rotation, of the fluid is zero (curl $\mathbf{v} = 0$) and the velocity is the gradient of a potential, i.e., $\mathbf{v} = \text{grad } \phi$. It is therefore called potential flow. If the fluid is also incompressible the equation of continuity is **Laplace's equation**, $\nabla^2 \phi = 0$, and the flow is everywhere uniquely determined if ϕ , or the normal component of the velocity, is specified at all points of the boundary.

In general the motion can only remain irrotational if the density is uniform and there is no tangential force at the boundaries (which in practice requires that the fluid be inviscid).

IRROTATIONAL VECTOR. See **vector, irrotational**.

IRROTATIONAL WAVES. See **wave(s), dilatational**.

ISALLOBAR. A line along which the local rate of change of pressure is constant, usually drawn as lines of constant pressure tendency.

ISALLOBARIC WIND. The ageostrophic component of the wind due to a changing pressure field. It is equal to

$$v_I = -\frac{1}{\rho f^2} \text{grad}_H \frac{\partial p}{\partial t}$$

where ρ is the density, f is twice the vertical component of the earth's rotation, and grad_H denotes the horizontal gradient. It is therefore directed towards regions of greatest pressure fall.

ISENTROPIC. Occurring at constant **entropy**. Any reversible process in an isolated system.

ISENTROPIC BULK MODULUS. See **bulk modulus**.

ISENTROPIC ENTHALPY DROP. See **enthalpy drop**.

ISENTROPIC HEAT DROP. See **enthalpy drop**.

ISING MODEL. A model of a binary alloy, in which it is assumed that the two types, A and B , of atoms are arranged in a regular array. In the state of perfect order, all A atoms are on α -sites and all B atoms on β -sites, so chosen that each atom has the same neighbors as do others of the same type. Thus, in one dimension, the array

represents perfect order. When any two atoms are interchanged, e.g., if the above array becomes

the change in the internal energy of the crystal may be computed by considering the number of pairs of the types $A-B$, $A-A$, and $B-B$ that have been created or destroyed. Thus in the case considered above, the increase in internal energy is

$$\epsilon_{BB} + \epsilon_{AA} - 2\epsilon_{AB}$$

where ϵ_{BB} , ϵ_{AA} , and ϵ_{AB} are the energies of the pairs of the types indicated by the subscripts.

The model has been of great value in the consideration of order-disorder transitions, but is of limited validity, even when next nearest neighbors are considered. (See also **cooperative phenomena**.)

ISOBAR. (1) A line along which the pressure is constant. In meteorology isobars are drawn for horizontal surfaces. (2) One of two or more atomic species, or elements, which have the same **mass number**, but differ in other respects, such as **atomic number** or **energy state**.

ISOBARIC SURFACE. A surface of constant pressure; represented on a meteorological chart by contours of height above sea level. The **geostrophic wind** is then given by the spacing and orientation of the contours.

ISOCANDELA CURVE. (1) A curve traced on an imaginary sphere with the source at its center and joining all the points corresponding to those directions in which the luminous intensity is the same. (2) A plane projection of this curve.

ISOCHORIC. Of equal or constant volume, usually applied to a thermodynamic process during which the volume of the system remains unchanged.

ISOCHROMATIC STIMULI. Color stimuli which, when acting simultaneously, give rise to identical color sensations. The identity of color may result from the identity of spectral distribution or it can occur when the spectral distributions are different if the **tristimulus values** are the same (metameric lights). In photometry it is usual to describe lights as isochromatic if they have the same **chromaticity**.

ISOCHRONE. A line connecting points having the same time values, as points of the same gelation time for colloidal solutions.

ISOELECTRONIC PRINCIPLE. Similar molecules which have the same number of valence electrons should have similar molecular orbitals. Their properties should therefore be quite analogous. Such similarities are evident for carbon monoxide and nitrogen, for example.

ISOGONIC. Having equal magnetic declination.

ISOLATED SYSTEM. A system which is isolated from, and therefore does not exchange matter or energy with, its surroundings. The conservation laws of energy, momentum, and angular momentum only hold in systems which are isolated with respect to the agents that cause changes in the conserved quantities. Thus an isolated system for the conservation of energy is one on whose boundaries no work is done and across whose boundaries no heat flows. Similarly, momentum is conserved only in a system isolated in the sense that no net force acts across its boundaries. (See also **closed system**; **open system**; **thermodynamic system**.)

ISOLUX. A curve or surface of equal light intensity. (Also called **isophot**.)

ISOMAGNETICS. Lines connecting points at which some property of the earth's magnetic field (such as the magnitude, the vertical component, or the horizontal component) remains constant. Isomagnetic lines may indicate local magnetic anomalies such as caused by magnetic ore bodies, magnetic minerals in sediments, or the vertical rather than the horizontal deviation of the compass or magnetic needle.

ISOMETRIC CONFORMAL REPRESENTATION. See **representation**.

ISOMETRIC LINES ON A SURFACE. If in terms of the parameters u and v , the first ground forms for a surface takes the form

$$\lambda[U(du)^2 + V(dv)^2],$$

where λ is a function of u and v , U is a function of u only and V is a function of v only, then the curves $u = \text{constant}$ and $v = \text{constant}$ are called **isometric lines**; u and v are called **isometric parameters**. The term **isothermal** or **isothermic** is also used instead of **isometric**.

ISOMETRIC PARAMETERS. See **isometric lines on the surface**.

ISOMORPHIC GRAPHS. See **graphs**, **isomorphic**.

ISOMORPHISM. See **homomorphism**.

ISOPERIMETRIC PROBLEM. In the calculus of variations, the problem of making an integral **stationary**, while one or more integrals involving the same variables are to be kept constant (accessory conditions). It is so-

called from a particular example, that of finding the figure of maximum area with a fixed **perimeter**. The method of **Lagrange multipliers** may be used.

ISOPHOT. A curve or surface of equal light intensity. (Also called **isolux**.)

ISOPLANASIE CONDITION. See **Staeble-Lihotzky condition**.

ISOTHERMATURE LOCI. Lines on a **chromaticity diagram** connecting points having equal correlated color temperatures. (See **temperature**, **correlated color**.)

ISOTHERMAL. (1) Occurring at, or pertaining to, constant temperature. (2) See also **isometric lines on the surface**.

ISOTHERMAL ATMOSPHERE. (Also called **exponential atmosphere**.) An atmosphere in **hydrostatic equilibrium** in which the temperature is constant with height and in which, therefore, the pressure decreases exponentially upward. In such an atmosphere the thickness between any two levels is given by

$$z_B - z_A = \frac{R_d T_v}{g} \ln \frac{P_A}{P_B},$$

where R_d is the gas constant for dry air, T_v the virtual temperature ($^{\circ}\text{K}$), g the acceleration of gravity, and P_A and P_B the pressures at the heights z_A and z_B , respectively. In the isothermal atmosphere there is no finite level at which the pressure vanishes.

ISOTHERMAL BULK MODULUS. See **bulk modulus**.

ISOTHERMAL COMPRESSION. Compression during which the temperature remains constant. In general, this will entail flow of heat into or out of the system.

ISOTHERMAL EXPANSION. Expansion during which the temperature remains constant. In general, this will entail flow of heat into or out of the system.

ISOTHERMIC. See **isometric lines on the surface**.

ISOTHERMS. Lines (or surfaces) consisting of points at the same temperature, e.g., corresponding to a given temperature in the equa-

tion of state. (See **critical point**; **Maxwell theorem**.)

ISOTOPE. One or two or more nuclides having the same atomic number, hence constituting the same element, but differing in mass number.

ISOTOPE CHARTS (Z-N, Z-A, A-Z, A-2Z, TRILINEAR). Any of a set of charts in which the properties of atomic nuclei, including their modes of radioactive decay, are summarized. In the trilinear chart, the neutron number $A-Z$ is plotted against the atomic number Z , the axes being inclined at an angle of 60 degrees; the result is that nuclides with the same mass number are found in the same vertical row, while each horizontal row contains species with the same neutron excess $A-2Z$.

ISOTOPE EFFECT IN ATOMIC SPECTRA. See **hyperfine structure(a)**.

ISOTOPE EFFECT IN MOLECULAR SPECTRA. The internuclear potential field of a molecule is, to a very good approximation, not affected by isotopic substitution of the nuclei. As a consequence, an isotope effect on the molecular electronic energy levels can, as a rule, be neglected, and the vibrational and rotational effects be treated on the assumption that the equilibrium internuclear distances are the same in all isotopic molecules.

In the case of a *diatomic molecule* the **vibrational constants** of an isotopic molecule [designated by the superscript (i)] are related to those of the "normal" molecule by the formulas

$$\omega_e^{(i)} = \rho\omega_e, \quad \omega_e^{(i)}x_e^{(i)} = \rho^2\omega_e x_e,$$

$$\omega_e^{(i)}y_e^{(i)} = \rho^3\omega_e y_e, \dots$$

where

$$\rho = \sqrt{\frac{\mu}{\mu^{(i)}}}$$

and μ and $\mu^{(i)}$ are the **reduced masses** of the "normal" and the isotopic molecules, respectively. The vibrational absorption bands of an isotopic molecule are given by the formula

$$\nu_{\text{abs}}^{(i)} = \rho\omega_e[(v + \frac{1}{2}) - \frac{1}{2}]$$

$$- \rho^2\omega_e x_e[(v + \frac{1}{2})^2 - \frac{1}{4}]$$

$$+ \rho^3\omega_e y_e[(v + \frac{1}{2})^3 - \frac{3}{8}] + \dots$$

The vibrational isotope shift is therefore

$$\Delta\nu = \nu_{\text{abs}} - \nu_{\text{abs}}^{(i)}$$

$$= \omega_e(1 - \rho)v - \omega_e x_e(1 - \rho^2)(v^2 + v)$$

$$+ \omega_e y_e(1 - \rho^3)(v^3 + \frac{3}{2}v^2 + \frac{3}{4}v) + \dots$$

If ρ is close to one, the vibrational isotope shift is approximately given by the expression

$$\Delta\nu = (1 - \rho)v\Delta G_{v+\frac{1}{2}}$$

where $\Delta G_{v+\frac{1}{2}}$ stands for the separation of successive **vibrational energy levels**.

The **rotational constants** of an isotopic molecule are related to those of the "normal" molecule by the formulas

$$B_e^i = \rho^2 B_e, \quad \alpha_e^i = \rho^3 \alpha_e, \quad D_e^i = \rho^4 D_e,$$

$$\beta^i = \rho^5 \beta, \dots$$

The rotational isotope shift, neglecting the rotational constant β is therefore

$$\Delta\nu_r = \nu_r - \nu_r^i = (1 - \rho^2)[B'_e J'(J' + 1)$$

$$- B''_e J''(J'' + 1)]$$

$$- (1 - \rho^3)[\alpha'_e(v' + \frac{1}{2})J'(J' + 1)$$

$$- \alpha''_e(v'' + \frac{1}{2})J''(J'' + 1)]$$

$$- (1 - \rho^4)[D'J'^2(J' + 1)^2$$

$$- D''J''^2(J'' + 1)^2].$$

In the case of a rotation-vibration spectrum the above formula is greatly simplified since $B'_e = B''_e$, $\alpha'_e = \alpha''_e$, $D' \approx D''$. The second and third terms are, in general, very small compared to the first. Therefore, to a first approximation,

$$\Delta\nu_r = (1 - \rho^2)\nu_r.$$

The rotational isotope shift is thus, to a good approximation, proportional to the distance from the **zero line**.

For two isotopic *polyatomic molecules* the product of the $\omega^{(i)}/\omega$ values for all vibrations of a given symmetry type is independent of the potential constants and depends only on the masses of the atoms and the geometrical structure of the molecule according to the following formula (Teller-Redlich product rule):

$$\frac{\omega_1^{(i)} \omega_2^{(i)} \cdots \omega_f^{(i)}}{\omega_1 \omega_2 \cdots \omega_f} = \sqrt{\left[\left(\frac{m_1}{m_1^{(i)}} \right)^\alpha \left(\frac{m_2}{m_2^{(i)}} \right)^\beta \cdots \left(\frac{M}{M^{(i)}} \right)^t \right] \times \left(\frac{I_x^{(i)}}{I_x} \right)^{\delta x} \left(\frac{I_y^{(i)}}{I_y} \right)^{\delta y} \left(\frac{I_z^{(i)}}{I_z} \right)^{\delta z}}$$

Here quantities with the superscript (*i*) refer to one of the isotopic molecules, quantities without superscript to the other; $\omega_1, \omega_2, \dots, \omega_f$ are the zero order frequencies of the *f* (genuine) vibrations of the symmetry type considered; m_1, m_2, \dots are the masses of the representative atoms of the various sets (each set consisting of those identical atoms that are transformed into one another by the symmetry operations permitted by the molecule); α, β, \dots are the numbers of vibrations (inclusive of nongenuine vibrations) that each set contributes to the symmetry type considered; M is the total mass of the molecule; t is the number of translations of the symmetry type considered; I_x, I_y, I_z are the moments of inertia about the *x, y, and z* axes; $\delta x, \delta y, \delta z$ are 1 or 0 depending on whether or not the rotation about the *x, y, or z* axis is a nongenuine vibration of the symmetry type considered. Both on the left and right hand side (in $\alpha, \beta, \dots, t, \delta x, \delta y, \delta z$) a degenerate vibration is counted only once.

ISOTOPE EFFECT IN SUPERCONDUCTIVITY. The critical temperature T_c of superconductors varies with the isotopic mass M . The relation $T_c \propto M^{-1/2}$ suggests that the superconducting transition depends on the velocity of sound, a result predicted by the Fröhlich-Bardeen theory.

ISOTOPE MIXTURE, VALUE OF. A measure of the difficulty of preparing a quantity of an isotope mixture. It is proportional to the amount of the mixture, and is also a function of the composition of the mixture. The change in value created by a cascade is directly proportional to the number of separating elements it contains. For a binary mixture, the value of Q moles of mixture, taking the equimolar mixture as the reference state, is given by

$$Q(2N - 1) \ln R$$

when N is the mole fraction of either component, R is $N/1 - N$, the molecular abundance ratio.

When referred to an arbitrary mole fraction N_0 as the reference state the value of Q moles of mixture is

$$V = \left\{ (2N - 1) \ln \frac{N(1 - N_0)}{N_0(1 - N)} + \frac{(N - N_0)(1 - 2N_0)}{N_0(1 - N_0)} \right\} Q.$$

The total value created by a separating plant is the difference between the total value of all outgoing materials and the total value of all ingoing materials. This resultant is independent of N_0 .

ISOTOPE SEPARATION FACTOR. The ratio of the abundance ratio of two isotopes after processing to their abundance ratio before processing. It is given by the following equation:

$$r = \frac{n'_1/n'_2}{n_1/n_2}$$

where n_1 and n_2 are the mole fractions of isotopes of mass numbers m_1 and m_2 respectively, and n'_1 and n'_2 are the corresponding quantities after processing. The term "enrichment factor" is sometimes used for $r - 1$.

ISOTOPIC ABUNDANCE. The relative amount (expressed as number of atoms) of a particular isotope in a sample of an element.

ISOTOPIC ABUNDANCE, FRACTIONAL. The ratio of the number of atoms of a particular isotope to the total number of atoms of the element, both in a given sample. It is usually expressed as a percentage.

ISOTOPIC ABUNDANCE, RELATIVE. The number of atoms of a particular isotope relative to a specified number of atoms of a specified isotope, both in a given sample. Usually the meaning is more specific, as the number of atoms of a particular isotope relative to 100 atoms of the most abundant isotope, or to 1 atom of the least abundant isotope.

ISOTOPIC (ISOBARIC) NUMBER. Synonymous with **neutron excess**.

ISOTOPIC SPIN (ISOBARIC SPIN). A concept introduced by Heisenberg as a convenient device for the description of states of particles between which there are charge-independent forces. The isotopic spin is defined in analogy with the ordinary spin angular mo-

momentum of elementary particles, and is usually denoted by T . The isotopic spin of the nucleon (neutron and proton) is taken to be $\frac{1}{2}$: its two "magnetic" substates having $M_T = \pm \frac{1}{2}$ then refer to neutron and proton respectively. States of two nucleons may then be characterized by isotopic spin zero or unity, the former of which can only refer to a neutron and a proton since $M_T = 0$ necessarily in this case, while the latter can refer to a pair of neutrons ($M_T = +1$) or it can refer to a pair of protons ($M_T = -1$). If forces are charge-independent, they may depend upon T but not upon M_T . Similarly, one ascribes isotopic spin unity to the π -mesons whose substates with $M_T = \pm 1, 0$ then refer to the two charged, and the single uncharged, pions. One is then able to describe the charge independent interactions between pions and nucleons in a correspondingly concise manner. The concept of isotopic spin has been extremely useful in classifying the quantum states of light nuclei, and it is now proving of even greater significance in the theory of fundamental particles.

ISOTOPIC SPIN QUANTUM NUMBER.

See **quantum number, isobaric spin**.

ISOTROPIC. A medium M is isotropic with respect to a function f defined on M if f is a scalar field over M . If M is not isotropic, then M is anisotropic or anelotropic.

ISOTROPIC MATERIAL. A material in which different directions are indistinguishable by physical experiment. In elasticity theory, a material in which the elastic properties are independent of direction.

ISOTROPIC STATE OF STRESS (AT A POINT). A state of stress in an element of material at a point, such that the normal components of the Cartesian stress tensor at the point are all equal and the tangential components are all zero. Also called *spherical state of stress*. If the equal normal components are negative, the state of stress is called a *hydrostatic pressure*; if they are positive, *negative hydrostatic pressure* or *hydrostatic tension*. For more general states of stress at a point, the negative of the mean of the three normal components of the stress tensor at the point is called the *hydrostatic pressure at the point*. Alternatively, a system of surface forces acting on a body, everywhere directed

normally inwards to the surface and such that the surface force per unit area measured in the state of deformation existing is constant over the surface is called a *hydrostatic pressure*.

ISOTROPIC TENSOR. See **tensor, isotropic**.

ITERATED FISSION EXPECTATION. In a **critical assembly**, the value after large time of the number of fissions per generation time arising from the daughter neutrons of a given neutron. This is a specific normalization of the **importance function**.

ITERATED LOGARITHM, LAW OF. A theorem in probability to the effect that in a series of n binomial trials with probability p , the difference between the number of successes S and the expected number np is of the order $(2npq \log \log n)^{1/2}$ and tends to that quantity with probability unity as n tends to infinity.

ITERATION, METHOD OF. In **neutron transport theory**, a specific application of the general idea of constructing progressively more accurate solutions to an integral equation by iteration. In the case of the one-velocity integral equation it can be shown that an increase in accuracy does indeed occur. An initial trial function might be obtained from the diffusion approximation.

ITERATIVE IMPEDANCE. See **impedance, iterative**.

ITERATIVE METHODS (FOR SOLVING EQUATIONS, WHETHER ALGEBRAIC OR TRANSCENDENTAL). These methods are, in fact, methods of successive approximation in which, having given one or more approximations to a solution, it is used in computing an improved one. Only the case of a single equation in a single variable will be considered here (see **matrix inversion** and the solution of linear equations, and **simultaneous equations**; also Alston S. Householder, *Principles of Numerical Analysis*, McGraw-Hill Book Co., 1953, for further development of the theory).

If the equation to be solved is

$$f(x) = 0,$$

let

$$\phi(x) = x - g(x)f(x),$$

where throughout some region containing α , the root to be determined, $g(x)$ nowhere vanishes or becomes infinite. Then

$$\alpha = \phi(\alpha),$$

and if, for some x_0 in this region, every

$$x_{i+1} = \phi(x_i)$$

is again in the region and the sequence of x_i converges, it necessarily converges to a root. A sufficient condition for this is that

$$|\phi'(x)| \leq k < 1$$

at every point of the region. Moreover, if ϕ is analytic in some circle about x_0 , and if it can be shown that for some positive $k < 1$,

$$|\phi(x') - \phi(x'')| < k|x' - x''|,$$

whenever both x' and x'' are in the circle, then it can be concluded that every x_i will, in fact, fall within the circle and that the equation has a root α to which the sequence converges.

Newton's method is obtained with

$$g(x) = 1/f'(x),$$

and one is assured of convergence if, for real α ,

$$f(x_0)f''(x_0) > 0,$$

and neither f' nor f'' changes sign between α and x_0 .

J

JACOBIAN. Let F_1 and F_2 be two functions of u and v . Then

$$J = \begin{vmatrix} \frac{\partial F_1}{\partial u} & \frac{\partial F_1}{\partial v} \\ \frac{\partial F_2}{\partial u} & \frac{\partial F_2}{\partial v} \end{vmatrix} = \frac{\partial F_1}{\partial u} \frac{\partial F_2}{\partial v} - \frac{\partial F_1}{\partial v} \frac{\partial F_2}{\partial u}$$

is the functional **determinant** or Jacobian of F_1 and F_2 with respect to u and v . It is frequently denoted by $\partial(F_1, F_2)/\partial(u, v)$.

In general if F_1, F_2, \dots, F_n are functions of u_1, u_2, \dots, u_n , then

$$J = \frac{\partial(F_1, F_2, \dots, F_n)}{\partial(u_1, u_2, \dots, u_n)} = \begin{vmatrix} \frac{\partial F_1}{\partial u_1} & \frac{\partial F_1}{\partial u_2} & \dots & \frac{\partial F_1}{\partial u_n} \\ \frac{\partial F_2}{\partial u_1} & \frac{\partial F_2}{\partial u_2} & \dots & \frac{\partial F_2}{\partial u_n} \\ \dots & \dots & \dots & \dots \\ \frac{\partial F_n}{\partial u_1} & \frac{\partial F_n}{\partial u_2} & \dots & \frac{\partial F_n}{\partial u_n} \end{vmatrix}.$$

(See also **Hessian**.)

JACOBI METHOD. A method for computing **eigenvalues** of a **Hermitian matrix**.

JACOBI POLYNOMIALS. The class of **special functions** $J_n(\alpha, \beta, x)$ obtained by orthogonalizing over the interval $[-1, 1]$ the sequence of powers, $1, x, x^2, \dots$ with the weighting function $w(x) = (1-x)^\alpha (1+x)^\beta$, with $\alpha, \beta > -1$. (Thus, for $\alpha = \beta = 0$, they reduce to the **Legendre polynomials**.) They satisfy the differential equation

$$(1-x^2)y'' + [\beta - \alpha - (\alpha + \beta + 2)x]y' + n(\alpha + \beta + n + 1)y = 0.$$

Their **Rodrigues formula** is

$$J_n(\alpha, \beta, x) = \frac{(-1)^n}{2^n n!} (1-x)^{-\alpha} (1+x)^{-\beta} \frac{d^n}{dx^n} \times [(1-x)^{\alpha+a} (1+x)^{\beta+b}].$$

JACOBI THEOREM IN OPTICS. There is a general theorem of Jacobi that applies to the differential equation of geometrical optics: Let $V(x, y, z, a, b)$ be a complete integral of the equation

$$V_x^2 + V_y^2 + V_z^2 = n^2$$

where the subscript notation is used for partial derivatives. A complete integral is defined as a set of solutions depending on two parameters a, b and such that the matrix

$$\begin{bmatrix} V_{xa} & V_{ya} & V_{za} \\ V_{xb} & V_{yb} & V_{zb} \end{bmatrix}$$

is of rank two. Then the light rays of the medium of refractive index $n = n(x, y, z)$ are given by

$$\frac{\partial}{\partial a} V(x, y, z, a, b) = c_1, \quad \frac{\partial}{\partial b} V(x, y, z, a, b) = c_2$$

where c_1, c_2 are arbitrary constants.

JEANS LAW. See **black body radiation**.

JET, BENT OVER. A turbulent jet emerging into a smooth cross-wind gradually assumes the speed of the wind as it mixes with it and therefore becomes bent over. It becomes bifurcated so that it appears to consist of two contra-rotating parallel rolls with exterior fluid passing up between.

After becoming bent over the momentum in the direction of emission (z -axis) is still retained but the velocity and concentration decrease as z^{-2} , as it entrains exterior air.

If it possesses a significant amount of buoyancy and emerges vertically into a horizontal cross-wind, ultimately the upward momentum acquired from the buoyancy becomes dominant and the upward velocity decreases as $z^{-1/2}$ and the concentration as z^{-2} .

Bent over jets can also be formed when heavy or light fluid emerges horizontally into stationary fluid.

JET, BUOYANT. Sometimes called a *plume*, similar in appearance to a turbulent jet (see

jet, turbulent) but necessarily having a vertical axis. If the motion is produced by buoyancy and not significantly by a large efflux velocity the entrainment velocity and mean upward velocity are proportional to $z^{-1/2}$, while the concentration decreases as $z^{-5/2}$ in the axis-symmetric case, z being measured from the apex of the cone which envelopes the jet. In a two-dimensional plume rising from a horizontal line source of buoyancy up a wedge, the mean velocity is independent of height and the concentration decreases like z^{-1} . The plumes from two equal parallel horizontal line sources flow together if there is a rigid boundary below them and then rise as a single plume as if from a line midway between them. (See **correlation coefficient**.)

JET, TURBULENT. The configuration of motion produced by the emergence of fast moving fluid into otherwise stationary surroundings. In the case of a round orifice the motion becomes turbulent at the boundary of the issuing fluid and the region of turbulence grows outwards and inwards.

The region of smooth flow in the center, called the *potential core*, decreases conically until the turbulence reaches the axis. Exterior fluid is entrained by the mixing on the outside and is carried in the direction of the axis. There is therefore a velocity towards the axis of the jet in the exterior fluid.

From the place where the turbulence occupies the whole section the motion is similar at all stages. The turbulent region occupies a cone of semi-vertical angle about 9° . The inflow velocity, the mean velocity within the jet in the direction of its axis, and the mean turbulent velocity, is proportional to z^{-1} , z being measured from the apex of the cone enveloping the jet. This is proved from the assumption that the flux of momentum along the jet is constant.

The emerging fluid is diluted by mixing with the environment, and the concentration is proportional to z^{-1} .

The profiles of time-mean velocity and time-mean concentration across the jet are not identical but rather similar, the profile being almost Gaussian except at the edges.

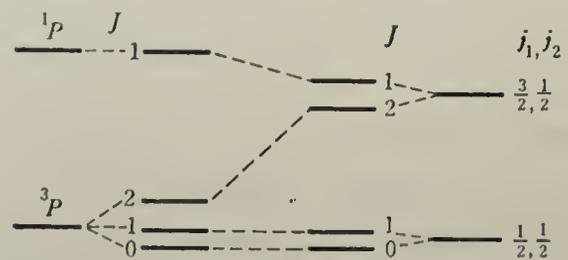

Plane jets have similar properties but the velocity and concentration are proportional to $z^{-1/2}$, z being measured from the edge of the enveloping wedge. (See **correlation coefficient**.)

JEZEK METHOD. An approximate solution of the instability problem for eccentrically-loaded columns, based on an elastic-perfectly plastic material and the assumption of a sine wave deflection. Jezek also gave an exact solution based upon the idealized stress-strain relation.

(j, j) COUPLING. Theoretical limiting case for the **coupling** of the spins s_i and the orbital angular momenta l_i of the individual electrons in an atom: strong coupling between the s_i and l_i of each individual electron, adding up (in two possible ways, see **angular momentum vectors, quantum theoretical addition of**) to the total angular momentum j_i of the individual electrons; weak coupling between the individual j_i , resulting in the total angular momentum J of magnitude $J(h/2\pi)$ of the atom. Written symbolically:

$$(l_1s_1)(l_2s_2)(l_3s_3) \cdots = (j_1j_2j_3 \cdots) = J.$$

Pure (j, j) coupling holds for some of the excited states of atoms of high **atomic number** Z , but occurs relatively seldom. More frequent are transitions cases between (j, j) coupling and **Russell-Saunders coupling**. The figure illustrates (for a *ps* electron configuration) the

Relative positions of the terms of a *ps* electron configuration. To the left, Russell-Saunders coupling; to the right, (j, j) coupling.

relative positions of the energy levels in the two limiting cases, and their correlation.

JOHANSEN THEORY. See **rupture line theory**.

JOHNSON AND LARK-HOROWITZ FORMULA. A formula for the resistivity of a metal or degenerate **semiconductor** due to the presence of impurities which scatter the electrons. It may be written

$$\rho = 6270n^{-1/2} \text{ ohm-cm}$$

where n is the number density of impurity atoms per cm^3 .

JOINT. The intersection or junction of members of a **truss** or a **frame** is called a joint. A *pinned joint* permits freedom of rotation and no moment at the ends of the members at the joint. A *rigid joint* permits no relative rotation between the members framing into the joint.

JOINT EFFICIENCY. This term refers to a strength ratio in connection with either riveted or welded joints. The joint efficiency is defined as the ratio of the strength of a section of the joint to the strength of an analogous section of solid plate. The joint efficiency, in pressure vessel design, usually requires an increase in the theoretical thickness of the plate which would otherwise be required for a seamless vessel. To illustrate, if the theoretical thickness of a seamless vessel, for a given set of conditions, is 1", the same vessel with a welded joint having an efficiency of 80% would require a wall thickness of 1¼". Welded joint efficiencies vary from 55 to 95%; riveted joint efficiencies from 45 to 95%, but most of them have values between 60 and 70%.

JOINTS, METHOD OF. The method of solving for the forces in the members of a **truss** by summing forces at each joint. If the number of joints is j there will be $2j$ independent joint equations for a plane truss and $3j$ for a space truss.

JORDAN CURVE. A simple, closed **curve**.

JORDAN-HÖLDER THEOREM. Any two **composition-series** of a **group** consist of the same number of subgroups, and lead to two sets of factor groups which, except for the order in which they occur, are identical with each other.

JORDAN MATRIX. A **matrix** whose elements are equal and non-zero along the principal diagonal, unity along the diagonal immediately above, and zero elsewhere.

JORDAN METHOD. A method of **matrix inversion** in which by a succession of row operations one reduces the given matrix to diagonal form.

JORDAN NORMAL FORM. See **Jordan matrix**.

JOST-LEHMANN REPRESENTATION. See **Dyson representation**.

JOUKOWSKI AIRFOILS. Two-dimensional **airfoil theory** is based mainly on the use of conformal mapping to transform the known solution for flow past a circular cylinder into flow past an airfoil. If z and ζ are the complex variables in the planes of the circle and the airfoil, the shape of the airfoil is defined by the mapping function $\zeta = f(z)$ and by the radius and position of the center of the circle in the z -plane.

Joukowski airfoils are those which are given by the simple mapping function

$$\zeta = z + \frac{c^2}{z} \quad (1)$$

The conditions of the transformation are chosen so that the airfoil has a sharp trailing edge, this being a singular point. The circulation round the airfoil is then determined by the **Joukowski condition**.

The family of Joukowski airfoils was the first to be studied theoretically. Because the airfoils have a cusp at the trailing edge, they are not really suitable for practical use, and are now mainly of historical interest.

Karman and Trefftz introduced a generalized Joukowski transformation, giving airfoils with a finite angle at the trailing edge. This is

$$\frac{\zeta + nc}{\zeta - nc} = \left(\frac{z + c}{z - c} \right)^n \quad (2)$$

The trailing-edge angle is then equal to $\pi(2 - n)$. The simple Joukowski transformation of Equation (1) is a special case of Equation (2), obtained by putting $n = 2$. (See H. Glauert, *The Elements of Aerofoil and Air-screw Theory* (2nd Edition), Cambridge, 1947.)

JOUKOWSKI CONDITION. In calculating the flow past a two-dimensional airfoil, results may be obtained for any arbitrarily chosen value of the circulation. For an airfoil with the usual sharp trailing edge, however, there is only one value of the circulation for which the theoretical velocity at the trailing edge is not infinite. Joukowski suggested that the circulation should be chosen to have this value; the circulation is then said to satisfy the Joukowski condition.

Experiments show that the circulation round an airfoil is slightly less than that given by the Joukowski condition, because of the effects of the boundary layers. The boundary layer near

the trailing edge of a lifting airfoil is usually thicker on the upper surface than on the lower, so that the circulation is that given by the Joukowski condition for an incidence slightly lower than the actual incidence. At high Reynolds numbers, when the boundary layers are very thin relative to the airfoil chord, the discrepancy is small and the Joukowski condition gives a good approximation to the circulation found in experiments.

JOULE. See **mechanical units**.

JOULE CYCLE. A quantity of ideal gas is taken through the following reversible processes: (a) from a pressure P_2 and volume V , compressed adiabatically to pressure P_1 ; (b) heated at constant pressure P_1 ; (c) expanded adiabatically to pressure P_2 ; (d) cooled at constant pressure P_2 to initial volume V .

The efficiency of a Joule engine is

$$1 - \left(\frac{P_2}{P_1}\right)^{\frac{\gamma-1}{\gamma}},$$

where γ is the ratio of the specific heats.

JOULE LAW. See **perfect gas**.

JOULE-THOMSON COEFFICIENT. The ratio of the change in temperature to the change in pressure when a gas expands at constant **enthalpy** to a lower pressure through a small aperture or porous plug. Its mathematical form is therefore

$$\left(\frac{\partial T}{\partial p}\right)_H.$$

JOULE-THOMSON INVERSION TEMPERATURE. The temperature, or one of the two possible temperatures, at which the **Joule-Thomson coefficient** changes its sign for a given gas.

J-SHAPED DISTRIBUTION. A frequency function $f(x)$ which, when graphed with $f(x)$

as ordinate against x as abscissa, has the shape roughly of part of the letter J or its mirror image.

JULIAN DAY. A system of chronological reckoning by days has many advantages in the simplification of calculations which involve long periods of time with the resulting confusion in calendar dates. The "Julian Era" is arbitrarily set to begin at Greenwich Mean Noon January 1, 4713 B.C. Julian days are reckoned consecutively from that era. Fractions of a day are recorded on the decimal system from Greenwich Mean Noon. January 1, 1960, is JD 2,436,934.00000 at GMT noon. Julian Day numbers are tabulated in the *American Ephemeris and Nautical Almanac*, together with tables to facilitate the determination of the Julian Day Number for any date.

JUMP. To (conditionally or unconditionally) cause the next **instruction** to be selected from a specified storage location.

JUMP, CONDITIONAL. An **instruction** which will cause the proper one of two (or more) **addresses** to be used in obtaining the next instruction, depending upon some property of one or more numerical expressions or other conditions.

JUMP DISCONTINUITY. See **discontinuity**.

JUMP, UNCONDITIONAL. An **instruction** which interrupts the normal process of obtaining instructions in an ordered sequence, and specifies the **address** from which the next instruction must be taken.

JURY PROBLEM. A differential equation solved numerically by a **method of successive approximations** which fits the solution to given **boundary conditions**.

Elliptic equations, such as the Poisson equation, lead to jury problems. A partial differential equation, such as the barotropic vorticity equation, may combine a jury problem and a **marching problem**.

K

KÁRMÁN CONSTANT. An absolute numerical constant, k , relating the mean velocity U and distance z from a plane wall to the shear stress τ_o and density ρ in rectilinear steady turbulent flow parallel to it, according to

$$(\tau_o/\rho)^{1/2} = kz \frac{\partial U}{\partial z}.$$

It is required that the shear stress be independent of distance from the wall. The **velocity profile** is logarithmic.

To demonstrate the existence of this constant it is necessary to assume that the motion is similar at all distances from the wall (or, in **mixing length** terminology that the mixing length, or eddy size, is proportional to distance from the wall), and that the level of turbulence is in equilibrium with the pressure field producing the motion and that it is at large Reynolds number (viscous stresses negligible in the mean motion). $k = 0.4$ approximately, according to experiments.

KÁRMÁN-FRIEDRICH EQUATIONS. In the analysis of two-spar wings, a spar may be considered as a beam on elastic supports provided by the ribs. The ribs are assumed to have infinite bending stiffness but finite torsional stiffness. The resulting equations are of the **three-moment** type.

KÁRMÁN-TSIEN RELATION. A theoretical relationship of the Mach 1 pressure coefficient to the corresponding pressure coefficient at low speed. The relationship takes into account the compressibility effects of high speeds. It gives a better correlation with experimental findings of actual pressure coefficient than the Glauert theory. The pressure coefficient according to the Kármán-Tsien relation is:

$$C_p = \frac{C_{p0}}{\sqrt{1 - M_1^2} + \frac{1}{2}C_{p0}[1 - \sqrt{1 - M_1^2}]}$$

where C_p is the pressure coefficient at Mach 1, and C_{p0} is the low speed pressure coefficient. The above relation refers to two-dimensional flow.

KÁRMÁN VORTEX STREET. See **vortex street**.

KATABATIC WIND. A down-slope wind, usually a shallow layer (2–3 meters deep) of air, cooled by contact with the ground, draining down a hillside.

KATOPTICS. Variant spelling of **catoptics**.

KEESOM ENERGY. The average interaction energy of two dipoles at a distance r . For two dipoles in line, the interaction energy is given by $\pm 2\mu^2/r^3$ where μ is the dipole moment. The \pm sign depends on whether the dipoles are oriented in opposite or parallel directions on the line. For two dipoles in a three-dimensional space, the interaction energy is $(\mu^2/r^3)f$, where f is a factor depending on the mutual orientation. For a **Boltzmann distribution**, if $\mu^2/r^3 \ll kT$, the average interaction energy of the two dipoles is

$$\epsilon_K = -\frac{2}{3} \frac{1}{r^6} \frac{\mu^4}{kT}.$$

ϵ_K is the Keesom energy.

At very high temperatures, the orientation becomes completely disordered, and ϵ_K becomes 0.

KEESOM POTENTIAL. This intermolecular potential applies to **rigid spheres** containing a **point dipole** (or a symmetrical quadrupole). Its analytical expression is

$$\phi(r, \theta_a, \theta_b, \phi_b - \phi_a) = \infty \quad r < \sigma \quad (1)$$

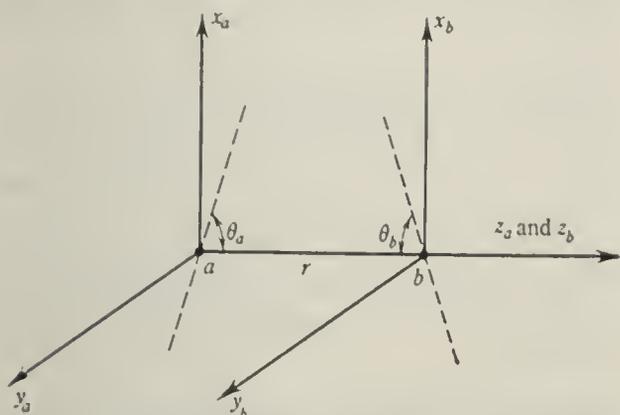

$$= -\frac{\mu_a \mu_b}{r^3} g(\theta_a, \theta_b, \phi_b - \phi_a) \quad r > \sigma \quad (2)$$

where

$$\begin{aligned} g(\theta_a, \theta_b, \phi_b - \phi_a) \\ = 2 \cos \theta_a \cos \theta_b - \sin \theta_a \sin \theta_b \cos(\phi_b - \phi_a). \end{aligned} \quad (3)$$

The figure represents two rigid spheres (e.g., molecules) having the centers at a and b . The axes of their components of moment, μ_a and μ_b ,

are indicated by the dashed lines shown at angles to the z -axis of θ_a and θ_b , respectively. The other two coordinates in the derivation,

Keesom potential.

ϕ_a and ϕ_b , define the corresponding axis orientations about the z -axis. The distance r between a and b is the distance between the centers of the molecules, or effectively the internuclear distance.

KEKULÉ STRUCTURE. See benzene, structures of.

KELLOGG EQUATION. An equation of state, relating the pressure, absolute temperature, and density of a gas. It is of the form:

$$p = RT\rho + \left(B_0RT - A_0 - \frac{C_0}{T^2} \right) \rho^2 + \left(bRT - a - \frac{c}{T^2} \right) \rho^3$$

in which p is the pressure, T the absolute temperature, ρ the density, R the gas constant, and A_0 , B_0 , C_0 , a , b , and c are constants.

KELVIN CIRCULATION THEOREM. See circulation theorem.

KELVIN EQUATION FOR SURFACE TENSION.

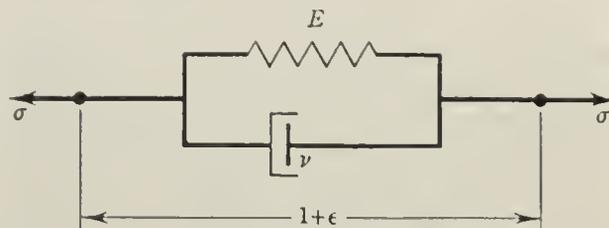

$$U_s = \gamma - T \frac{d\gamma}{dT}$$

where U_s is the surface energy per unit area, γ is the surface tension, T is absolute temperature.

KELVIN FORMULA FOR THE VAPOR PRESSURE OF SMALL DROPS. See influence of curvature on vapor pressure.

KELVIN FORMULATION OF THE SECOND LAW OF THERMODYNAMICS. See Planck-Kelvin formulation of the second law of thermodynamics.

KELVIN MATERIAL. Material whose mechanical behavior exhibits delay elasticity only. It is represented by the Kelvin model:

In the linear case the constitutive equation takes the form:

$$\sigma = E\epsilon + \nu\dot{\epsilon}.$$

(See viscoelasticity models.)

KELVIN MODEL. See Kelvin material for the basic Kelvin or Voigt model. More general viscoelastic materials can be represented by a sequence of Kelvin models in series with a spring and a dashpot, and this is sometimes referred to as the general Kelvin model. (See delay time for properties of this model.)

KELVIN TEMPERATURE SCALE. See temperature; thermodynamics, second law in closed systems.

KEPLER EQUATION. See anomaly, true and eccentric.

KEPLER LAWS. After much study of available data, Kepler drew three conclusions about the motion of the planets: (1) The orbit of each planet is an ellipse with the sun at one focus. (2) The radius vector drawn from the sun to the planet sweeps out equal areas in equal times. (3) The square of the period of a planet is proportional to the cube of the major axis of the elliptical orbit. Newton deduced the law of gravitation from Kepler's laws. (For further details see planetary motions.)

KERN (OR KERNEL OR CORE). A straight bar loaded by an eccentric force P parallel to its axis will bend as well as stretch or compress. The distribution of strain over the cross section is linear. In the elastic range the stress, too, is linearly distributed

$$\sigma = \frac{P}{A} + \frac{Pe_x y}{I_x} + \frac{Pe_y x}{I_y}$$

where x and y are principal axes and e_x and e_y are the eccentricities of P about the x and y -axes, respectively. The limits of the combination of e_x, e_y for the stress to have the same sign at each point of the cross section defines the kern. A compressive force within the kern produces no tension.

KERNEL. A known function, also called a **nucleus**, $K(x,z)$ which occurs in an **integral equation**. It is **symmetric** if $K(x,z) = K(z,x)$; **Hermitian** if $K(x,z) = K^*(z,x)$; **skew Hermitian** if $K(x,z) = -K^*(z,x)$, where the asterisk indicates the **complex conjugate**. A **polar kernel** has the form $K(x,z) = u(z)G(x,z)$, where $G(x,z)$ is symmetric. It may be transformed into a symmetric kernel by a change of the dependent variable. A **definite kernel**, positive or negative, satisfies the requirement

$$\int f(x)dx \int K(x,z)f(z)dz \geq 0,$$

where $f(x)$ is any finite function defined over the range for which the kernel is defined. A **singular kernel** has one or more **singular** points within its limits of integration. A kernel of the form

$$K(x,z) = \sum_{i=1}^k f_i(x)g_i(z)$$

is called degenerate. A solving kernel or resolvent is an infinite series of iterated kernels which appears in the **Liouville-Neumann series**. (See also **integral transform**.) (For use of the term kernel in structural engineering, see **kern**.)

KERNEL, DIFFUSION. In the diffusion of neutrons, these kernels may refer to point, line, plane, etc., sources. As an example, the point kernel

$$K_p(\mathbf{r},\mathbf{r}') = \frac{\exp\{-\kappa|\mathbf{r}-\mathbf{r}'|\}}{4\pi D|\mathbf{r}-\mathbf{r}'|}$$

with D being the diffusion constant and κ , the reciprocal of diffusion length, gives the monoenergetic neutron flux at \mathbf{r} due to unit source at \mathbf{r}' .

KERNEL, GAUSSIAN. In reactor theory, the Gaussian kernel,

$$K(\mathbf{r},\mathbf{r}') = (4\pi\tau)^{-3/2} \exp\left\{-\frac{|\mathbf{r}-\mathbf{r}'|^2}{4\tau}\right\}$$

with τ the age-to-thermal characteristic of the slowing-down medium being often used for a slowing-down kernel. It may be derived directly from Fermi age theory. (See **age equation, Fermi**.)

KERNEL, MULTIGROUP. In the multigroup formulation of the slowing-down of neutrons, in which neutrons, distributed continuously with respect to energy are assigned to a finite number of energy groups, the group kernel $K_j(\mathbf{r},\mathbf{r}')$ denotes the slowing-down kernel from point \mathbf{r}' in energy group $j-1$ to point \mathbf{r} in group j .

KERNEL, POINT. Of particular interest in the study of the penetration of radiation through matter (shields) this kernel, denoted $G(R)$ gives the total flux of radiation at a point separated by a distance R from a point source which emits one particle per second.

KERNEL, SCATTERING. In scattering theory, the microscopic cross-section describing the scattering of neutrons from energy E to E' through an angle θ . Often denoted by $\sigma_s(E \rightarrow E', \theta)$, the quantity, or its average over angle, acts as kernel in the transport equation describing the slowing down of neutrons.

KERNEL, SLOWING DOWN. In reactor theory, $K(\mathbf{r},E; \mathbf{r}',E')$, the flux of neutrons of energy E at point \mathbf{r} due to a unit point source of neutrons of energy E' at \mathbf{r}' is a quite general slowing-down kernel. Its average, $\bar{K}(\mathbf{r},\mathbf{r}')$, representing the probability that a fission neutron born at \mathbf{r}' , becomes thermal at \mathbf{r} , is often called the slowing-down kernel.

KERNEL, SYNTHETIC. An *ad-hoc* slowing-down kernel for neutrons, constructed to agree with experimental results. It is often expressed as the convolution of a number of multigroup kernels. (See **kernel, multigroup**.)

KERNEL, TRANSPORT. In the transport theory of monoenergetic neutrons, the transport kernel,

$$K(\mathbf{r},\mathbf{r}') = \sum_s \frac{\exp\{-\Sigma|\mathbf{r}-\mathbf{r}'|\}}{4\pi|\mathbf{r}-\mathbf{r}'|^2}$$

gives the flux of neutrons at \mathbf{r} which have suffered n collisions due to unit flux at \mathbf{r}' of neutrons which have suffered $n-1$ collisions.

KERR ELECTRO-OPTICAL EFFECT AND LAW. This effect occurs when an isotropic substance (e.g., nitrobenzene) becomes anisotropic in the presence of an electric field. Kerr's electro-optical law then applies: if n_p and n_s are the refractive radius for light polarized in planes parallel and perpendicular, respectively, to the electric vector of intensity E , then

$$n_p - n_s = B\lambda E^2$$

where B is the Kerr electro-optical constant for the given substance, wavelength and temperature.

KERR MAGNETO-OPTICAL EFFECT. See magneto-optical effect.

KET VECTOR. Vector in Hilbert space describing the state of a dynamical system in quantum mechanics. Denoted by the symbol $|A\rangle$. (See also bra vector.)

KEV. Symbol for one thousand electron volts, a unit of energy equal to 1.602×10^{-9} erg.

KEYES EQUATION. An equation of state for a gas, deduced from the concept of the nuclear atom. This equation is designed to correct the van der Waals equation for the effect upon the term b of the surrounding molecules. The equation is written as

$$P = \frac{RT}{V - Be^{-\alpha_l V}} - \frac{A}{(V + l)^2}$$

in which P is pressure, T is absolute temperature, V is volume, R is the gas constant, e is the base of natural logarithms, 2.718..., and A , α , B , and l are constants for each gas.

KEYES-SMITH-GERRY EQUATION. An empirical (thermal) equation of state for steam. It is given below in a dimensionally correct form, after E. Schmidt:

$$v = \frac{RT}{p} + B \left[1 + \left(\frac{Bp}{RT} \right) f_1(T) + \left(\frac{Bp}{RT} \right)^3 f_2(T) - \left(\frac{Bp}{RT} \right)^{12} f_3(T) \right]$$

where

$$R = 47.063 \frac{\text{kp m}}{\text{kg C}} = 85.78 \frac{\text{ft lbf}}{\text{lbm F}}$$

$$B = \left[1.890 - \frac{2641.6 \text{ C}}{T} \times 10^{(284.38 \text{ C}/T)} \right] \times 10^{-3} \frac{\text{m}^3}{\text{kg}}$$

$$= \left[3.0274 - \frac{7616.4 \text{ F}}{T} \times 10^{(511.88 \text{ F}/T)} \right] \times 10^{-2} \frac{\text{ft}^3}{\text{lbm}}$$

$$f_1(T) = \frac{367.00 \text{ C}}{T} - 0.7400 \left(\frac{1000 \text{ C}}{T} \right)^2$$

$$= \frac{676.80 \text{ F}}{T} - 0.7400 \left(\frac{1800 \text{ F}}{T} \right)^2$$

$$f_2(T) = 20.630 - 12.000 \left(\frac{1000 \text{ C}}{T} \right)^2$$

$$= 20.630 - 12.000 \left(\frac{1800 \text{ F}}{T} \right)^2$$

$$f_3(T) = 28994 - 5.398 \left(\frac{1000 \text{ C}}{T} \right)^{24}$$

$$= 28994 - 5.398 \left(\frac{1800 \text{ F}}{T} \right)^{24}$$

(See also steam tables.)

KILOMOLE. That quantity of substance whose mass expressed in kilograms is numerically equal to the molecular weight (mass) of the substance.

KILOPOUND. See kip.

KIND OF TENSOR. See tensors, type of.

KINEMATICALLY ADMISSIBLE. A term applied to pattern of deformation or rate of deformation which is geometrically permissible. In plastic limit analysis the deformations are taken as plastic only and may be discontinuous. In elastic analysis, kinematically admissible fields of displacement and corresponding strains are required for the theorem of minimum potential energy.

KINEMATIC BOUNDARY CONDITION. The condition that the fluid velocity directed perpendicular to a solid boundary must vanish on the boundary itself. This may be stated mathematically by the expression

$$\mathbf{n} \cdot \mathbf{V} = 0,$$

where \mathbf{n} is a unit vector normal to a solid surface, and \mathbf{V} is the fluid velocity vector. In meteorology, this **boundary condition** is often employed in considering flow near the earth's surface.

When the boundary is a fluid surface or **interface**, this condition applies to the vector difference of velocities across the interface and requires that the interface, although in motion, will at all times consist of the same fluid parcels. In meteorology, such a condition must be applied at fronts and other surfaces of discontinuity.

(See also **dynamic boundary condition**.)

KINEMATICS. The geometry of motion, without regard to forces or bodies of matter. Two of the aspects given special consideration are: the motion of points and the motion of rigid figures. Whatever system of space coordinates is found simplest may be used, and may be transformed from one system to another as desired.

The motion of a point may be completely specified by giving each of its three rectangular coordinates (for example) as a function of the time; that is, by writing its "equations of motion":

$$\left. \begin{aligned} x &= f_1(t), \\ y &= f_2(t), \\ z &= f_3(t). \end{aligned} \right\} \quad (1)$$

KINEMATIC VISCOSITY. See **absolute viscosity**.

KINETIC ENERGY. See **energy, kinetic**.

KINETIC ENERGY FLUX VECTOR. See **flux vector**.

KINETIC ENERGY, NEGATIVE. See **energy, negative kinetic**.

KINETIC ENERGY, OF IRROTATIONAL MOTION. If ϕ is the velocity potential then the kinetic energy, T , of the fluid contained within a bounding surface S is

$$T = \frac{1}{2}\rho \int \phi \operatorname{grad} \phi \cdot dS = \frac{1}{2}\rho \int \phi \frac{\partial \phi}{\partial n} dS.$$

In two dimensional motion with complex potential $\phi + i\psi$,

$$T = \frac{1}{2}\rho \int \phi d\psi$$

per unit length, the integral being taken round the boundary.

The *minimal theorem* of Kelvin states that for an incompressible fluid of uniform density the kinetic energy of the actual (irrotational) motion (satisfying $\operatorname{div} \mathbf{v} = 0$ and $\operatorname{curl} \mathbf{v} = 0$) is less than that of any other motion (not irrotational) satisfying the same boundary conditions.

KINETIC ENERGY OF RIGID BODY. The kinetic energy T of rigid body consists of two parts T' and T'' , i.e., $T = T' + T''$ where T' is the translational energy and T'' , the rotational energy.

$$T' = \frac{1}{2}m\mathbf{v}_o^2$$

where \mathbf{v}_o is the velocity of the center of mass and

$$T'' = \frac{1}{2}(A\omega_1^2 + B\omega_2^2 + C\omega_3^2)$$

where A, B, C are the principal moments of inertia and $\omega_1, \omega_2, \omega_3$ the components of the angular velocity $\boldsymbol{\omega}_o$ along the directions of A, B, C .

KINETIC MOMENTUM. Kinetic momentum of a charged particle in an electromagnetic field \mathbf{A}, ϕ , the vector $\mathbf{p} - (e/c)\mathbf{A}$, where \mathbf{p} is the momentum. Name arises from analogy with the kinetic energy $W - e\phi$, where W is the total energy.

KINETIC POTENTIAL. See **Lagrangian function**.

KINETICS. The science dealing with the effects of forces and moments on the motion of material bodies.

KINETICS, REACTOR. In reactor theory, the study of the time behavior of a chain-reacting system. If the diffusion approximation to neutron transport theory be used, the relevant time-dependent differential equations are:

$$\begin{aligned} D\nabla^2\Phi + [(1 - \beta)k_\infty P_\infty(B^2) - 1] \Sigma_a \Phi \\ + pP_\infty(B^2) \sum_{i=1}^m \lambda_i C_i = \frac{1}{v} \frac{\partial \Phi}{\partial t} \\ \frac{\partial C_i}{\partial t} = -\lambda_i C_i + \frac{k_\infty}{p} \beta_i \Sigma_a \Phi, \quad i = 1, \dots, m. \end{aligned}$$

The first equation expresses the diffusion of thermal neutrons (one-group theory, speed = v) in a medium characterized by diffusion

constant D , absorption Σ_a , infinite multiplication k_∞ , non-leakage probability (during slowing down) $P_\infty(B^2)$ and resonance escape probability p . The second equation gives the time variation of concentration of the i^{th} type of excited nucleus which acts as a source (“precursor”) of delayed neutrons. $\beta = \sum_i^m \beta_i$

is the total fraction of fission neutrons which are delayed and λ_i is the decay constant for i^{th} type of precursor.

KINETIC THEORY. A theory which explains the phenomena in gases described macroscopically by thermodynamics as due to the kinetic motion and collisions of atoms and molecules.

First introduced by Krönig and Clausius to explain the **perfect gas law**, it can be extended to furnish expressions for the **viscosity, thermal conductivity, diffusion coefficient**, and other transport coefficients of gases. Its natural extension is **statistical mechanics** where the attempt to deduce properties of matter in bulk from atomic properties is brought to its logical conclusion and is made applicable to liquids and solids as well as gases.

To derive the perfect gas law in kinetic theory one defines the pressure in a gas as the force per unit area, and thus, by Newton’s second law, as the (net) transport of momentum through a unit area. In this way one obtains

$$p = \frac{1}{3}nmv^2,$$

where p is the pressure, n the number of particles per unit volume, m their mass, and v their **root mean square velocity**.

Similarly one can derive **van der Waals’ equation** for an **imperfect gas**. (See also **viscosity, kinetic theory of; diffusion, kinetic theory of; and thermal conductivity, kinetic theory of**.)

KINETIC THEORY OF LIQUIDS. For many purposes liquids can be treated as if they were dense gases, and **kinetic theory** can be applied for such problems as the (kinetic) viscosity of liquids, the thermal conductivity of liquids, and diffusion through liquids.

KINETIC THEORY OF VISCOSITY. See viscosity, kinetic theory of.

KINETIC THEORY TEMPERATURE. Temperatures defined by the ratio of the aver-

age (random) kinetic energy of a (point) particle to $\frac{3}{2}k$ (k is Boltzmann’s constant).

KIP (OR KILOPOUND). One thousand pounds.

KIRCHHOFF EQUATION FOR THE HEAT OF REACTION. See Clausius equations.

KIRCHHOFF FORMULATION OF HUYGENS PRINCIPLE. Two theorems, due to Kirchhoff, contain a formulation of **Huygens’ principle** that generalize **Helmholtz’s formulation** for monochromatic wave-functions to heterochromatic wave-functions.

(1) If $u(x, y, z, t)$ is a wave-function with continuous first and second partial derivatives inside and on a closed surface S and (x_1, y_1, z_1) is a point inside S , then

$$4\pi u(x_1, y_1, z_1, t) = \iint_S \left\{ [u] \frac{\partial}{\partial n} \left(\frac{1}{r} \right) - \frac{1}{cr} \frac{\partial r}{\partial n} \left[\frac{\partial u}{\partial t} \right] - \frac{1}{r} \left[\frac{\partial u}{\partial n} \right] \right\} dS$$

where r is the distance from (x_1, y_1, z_1) to a generic point on S , $\partial/\partial n$ denotes differentiation along the inward normal to S , and

$$[f(x, y, z, t)] = f \left(x, y, z, t - \frac{r}{c} \right).$$

If, however, (x_1, y_1, z_1) is outside S , then the integral is zero.

(2) If $u(x, y, z, t)$ is a wave function having no singularities outside a closed surface S for all t' , $-\infty < t' < t$, and if u behaves like $F(ct - R)/R$ at large distances R from the origin, where $F(ct)$ and $F'(ct)$ are bounded near $t = -\infty$, then the above integral formula holds for points (x_1, y_1, z_1) outside S provided that $\partial/\partial n$ means differentiation along the outward normal to S . If (x_1, y_1, z_1) is outside S , in this case, the integral is zero.

KIRCHHOFF GEOMETRIC OPTICS THEOREM. A theorem due to Kirchhoff stating that geometrical optics is a limiting form of physical optics. More precisely, the diffuse boundary of the shadow in diffraction phenomena becomes the sharp shadow of geometrical optics as the wavelength of light tends to zero.

KIRCHHOFF LAW OF RADIATION. The monochromatic **emissivity** of a surface at temperature T is equal to its monochromatic **ab-**

sorptivity. It is a consequence of the second law of thermodynamics.

KIRCHHOFF LAWS OF NETWORKS. Two laws relating to electric networks carrying steady currents. The general case is that of n points or junctions, each one of which is connected with each of the $n - 1$ remaining points by a conductor containing a source of electromotive force. Kirchhoff's two statements are as follows:

(1) If conductors forming part of a network carrying a steady current meet at one point, the sum of the currents flowing toward the point is equal to the sum of those flowing away from it; or the algebraic sum of all the currents in these conductors is zero.

(2) Starting at any one of the junctions of such a network and following any succession of the conductors which form a closed path, around either way to the starting point, the algebraic sum of the products formed by multiplying the resistance of each conductor by the current through it is equal to the algebraic sum of the electromotive forces encountered on the journey. (In this reckoning, we call all currents moving with us positive, and all electromotive forces tending to cause such currents positive.)

Maxwell has set forth a general method of calculating the currents and the relative potentials of the junctions when the resistances and electromotive forces in the several branches of a network are given. For a network of n points, this method involves the solution of $n - 1$ simultaneous, first-degree equations. The work is often simplified, however, by the circumstance that some of the conductors or some of the electromotive forces are absent. (3) The Kirchhoff laws also hold when alternating rather than direct currents are flowing in circuits if the instantaneous currents and voltages are used. They do not necessarily hold for the average currents and voltages, since for circuit elements other than resistances (i.e., capacitance and inductance) the current and voltage are not in phase. Formally, if complex voltages, complex currents and complex impedances are used, with $V = IZ$, the Kirchhoff laws are applicable to alternating current circuits.

KIRKWOOD APPROXIMATION. An approximation used in the kinetic theory of liquids. The force on one molecule of a set

of molecules is assumed to be the sum of the forces exerted, neglecting in turn all but one other molecule of the set. In this way an equation may be obtained for the radial distribution function.

KIRKWOOD EQUATION FOR THE DIELECTRIC CONSTANT. Kirkwood has shown that for quasi-spherical molecules of dipole moment μ , whose polarizability is isotropic, the static dielectric constant ϵ_s is given by:

$$\epsilon_s - n^2 = \frac{3\epsilon_s}{2\epsilon_s + n^2} \frac{4\pi N_o \mu \cdot \mu^*}{3kT}$$
